Mr. NASH said that in a recent paper by Mr. J. H. Coste and himself, the advisability of determining the flash-point of all samples of turpentine was pointed out, and the present case confirmed this, for it was only the flash-point that showed that there was anything abnormal about the sample. Whatever might be the impurity that caused the low flash-point, it was certainly some spirit soluble in water, for when the turpentine was washed the flash-point rose to the normal figure. He should like to add that, when first trying the Conradsen reaction with this Finnish turpentine, he had obtained a negative result, but was so certain that the result ought to be positive that he obtained a fresh supply of sulphurous acid, with which the expected result was obtained. It was therefore evident that the sulphurous acid used must be concentrated. This was mentioned in Conradsen's original paper, but he had never seen the point emphasised.

NOTE ON THE GRAVIMETRIC ESTIMATION OF PHOSPHORUS IN MILK.

BY E. HOLL MILLER.

(*Read at the Meeting, November* 1, 1911.)

ACCORDING to Söldner, milk contains both primary and secondary phosphates, and also a tertiary phosphate, which is present as tricalcic phosphate. The primary and secondary phosphates are present as mono- and di-potassium phosphate and di-magnesium and calcium phosphate. It would seem highly probable that the temperature at which milk (milk solids) is ignited to obtain the ash, both the primary and secondary phosphates would be converted into the meta and pyro varieties respectively; for when milk is ignited, however careful one is to keep the temperature down during incineration, the temperature actually obtained is considerably higher than that at which primary and secondary phosphates lose water and pass into the meta and pyro states; in fact, it would seem impossible for either a primary or secondary phosphate to exist in a freshly incinerated milk ash. A considerable number of milk ashes have been analysed qualitatively in order to ascertain whether meta- and pyro-phosphates are present, with the final view of determining, if present, their effect on the accuracy of the estimation of phosphorus in milk by any of the ordinary gravimetric methods.

The result of the examination of some four hundred samples of milk ash gave only three which showed the presence of a soluble meta salt; solutions of these three in dilute hydrochloric acid coagulated egg-albumin. A considerable number showed the presence of varying quantities of pyrophosphates; and it was observed that, if during the incineration of the milk the ash was allowed to attain a red heat, pyrophosphates could easily be detected. The presence of pyrophosphate was shown by the solutions giving a bluish-white precipitate with copper sulphate solution, which was insoluble in acetic acid. They also gave a white precipitate with zinc sulphate, soluble in ammonia, and insoluble in acetic acid. These two reactions have been recommended by Arnold and Werner (*Chem. Zeit.*, 1905, **29**, 1326-1327) for the detection of pyrophosphoric acid in the presence of the ortho and meta acids. I may incidentally mention that a sample of milk-powder on incineration gave an ash which contained a very considerable portion of the phosphorus in the meta state. The total quantity of phosphorus in the powder was estimated (by methods mentioned later), and was found to be quite normal. No phosphates of any kind had been used in the preparation of the milk-powder. Very dilute acid solutions of the ash easily coagulated solutions of egg-albumin.

Estimations of phosphorus in a number of milks have been made; the determinations have been carried out on the ash, and the results, when compared with those obtained by treating the ash (in some cases the milk solids) with oxidising agents—*i.e.*, nitric acid, etc.—and then determining the phosphorus in the same manner, have been found to be invariably lower.

The methods used for determinating the phosphorus were the following:

I. By precipitating as magnesium ammonium phosphate after removing the lime as oxalate, and weighing as magnesium pyrophosphate.

II. By precipitating as magnesium ammonium phosphate in the presence of lime, holding the same in solution with ammonium citrate, and weighing as magnesium pyrophosphate.

III. By precipitating as ammonium phosphomolybdate, dissolving and reprecipitating as magnesium ammonium phosphate, and weighing as magnesium pyrophosphate.

IV. By Carius's method.

The following are some of the results obtained:

TABLE I.

	Ash. Per Cent.	CaO. Per Cent.	P_2O_5. Per Cent.
By Method I.			
(*a*) Precipitating as magnesium ammonium phosphate after filtering off lime as oxalate ...	0·72	0·18	0·218
(*b*) Ditto, after heating ash for ninety minutes with strong sulphuric acid	0·72	0·18	0·232
(*c*) Ditto, after heating ash with boiling nitric acid for one hour	0·72	0·18	0·236
(*d*) Ditto, after heating ash with mixture of equal parts of sulphuric and nitric acids for two hours	0·72	—	0·234
By Method II.			
(*e*) Precipitating as magnesium ammonium phosphate in the presence of lime, and keeping the lime in solution with ammonium citrate	0·72	—	0·220
(*f*) Ditto, after heating ash for ninety minutes with strong sulphuric acid	0·72	—	0·230
(*g*) Ditto, after boiling ash with nitric acid for one hour	0·72	—	0·232
(*h*) Ditto, after heating ash with equal parts of sulphuric and nitric acids for two hours ...	0·72	—	0·230

A sample of sweetened condensed milk gave the following results:

	Method I. Per Cent.	Method I. (*c*). Per Cent.	Method II. Per Cent.	Method II. (*g*). Per Cent.
Ash ...	2·004	2·006	2·01	2·004
P_2O_5 ...	0·580	0·670	0·58	0·665

TABLE II.

By Method III.

	Ash. Per Cent.	P_2O_5. Per Cent.
As magnesium pyrophosphate by Method I.	0·71	0·210
By Method II.	0·70	0·207
Ditto, after first heating ash for ninety minutes with strong sulphuric acid	—	0·223
Ditto, after boiling for one hour with strong nitric acid ...	—	0·225
Ditto, after boiling for two hours with mixture of equal parts of sulphuric and nitric acids	—	0·220

A sample of sweetened condensed milk gave the following results by Method III:

	Method III. Per Cent.	Boiling, as above, with Sulphuric Acid. Per Cent.	Nitric Acid. Per Cent.	Sulphuric and Nitric Acids. Per Cent.
Ash ...	1·92	1·920	1·940	1·940
P_2O_5 ...	0·57	0·598	0·621	0·629

An examination of these results shows that there is a small quantity of phosphorus apparently not estimated by Methods I., II., and III., unless the ash is previously treated with some reagent to convert pyro- or meta-, etc., phosphates into the ortho variety. The difference between the results is not very great in the case of milk, but with the samples of sweetened condensed milk the difference is considerably greater. In the case of milk-powder this difference would be greater still. It seems probable that this difference is due to the presence of phosphates in the ash in some condition other than the ortho, which are not precipitated, and thus tend to make the results low. The evidence seems to be conflicting as to whether ordinary magnesia mixture will cause precipitation in solutions of pyro- and meta-phosphates; but even if phosphates in this state are partially precipitated, precipitates of inconstant composition would be obtained which would behave abnormally before the blowpipe, and vitiate results. For these reasons it was thought advisable to compare the results obtained by treating the milk solids by the method of Carius and Method I.:

TABLE III.

Sample.	Ash. Per Cent.	Estimation of P_2O_5 by Method I. in the Ash. P_2O_5. Per Cent.	Treating Milk Solids by Carius's Method, and estimating P_2O_5 as in Method I. P_2O_5. Per Cent.
1	0·75	0·202	0·216
2	0·75	0·218	0·227
3	0·71	0·210	0·223
4	0·74	0·217	0·231
5	0·76	0·211	0·226
6	0·76	0·207	0·222
7	0·75	0·221	0·239

Average difference: 0·014 per cent.

Two samples of sweetened condensed milk gave the following results:

	Ash. Per Cent.	P_2O_5 in Ash. Per Cent.	P_2O_5 by Carius's Method. Per Cent.
1	1·96	0·590	0·63
2	2·04	0·588	0·65

The conclusions drawn from the above results are that the usual methods of estimating phosphorus in milk—viz., Methods I., II., and III.—give results that differ from Carius's method only by about 0·01 per cent. In the case of concentrated and sweetened condensed milk and milk-powders it is evident, however, that it is preferable to treat the milk solids by Carius's method, and estimate the orthophosphoric acid in the solutions so obtained.* It might be mentioned that the close agreement between the results in Table III. seems to show that no appreciable quantity of phosphorus is volatilised during the incineration of the milk. This has also been pointed out by Bordas and Touplain (*Compt. rend.*, 1911, **152**, 899-900).

DISCUSSION.

The CHAIRMAN (Dr. DYER) remarked incidentally that it was not infrequently the case that superphosphate was artificially dried for the purpose of concentrating it, and that in consequence an appreciable proportion of the soluble phosphoric acid was converted into a form that was not orthophosphoric acid, so that low determinations of soluble phosphoric acid might easily be obtained if the precaution of boiling the solution with nitric acid were neglected.

Mr. C. REVIS said that ordinarily he had found very little loss of phosphoric acid to occur in the case of milk, but it was well to bear in mind that the quantity obtained was dependent upon the proportion of lime in the ash. In some experiments which he had recently been making with casein precipitated from milk, he had found the phosphoric acid results to depend upon the quantity of lime that was left in the casein. He could fully confirm the author's remarks as to the Carius method, which he considered to be the most accurate for this purpose. Much the same results were obtained by destroying the organic matter by means of a mixture of hydrochloric acid and nitric acid, but the Carius method was perhaps simpler, and no difficulty was caused by the phosphoric acid being present in different forms.

Dr. MONIER-WILLIAMS considered that Neumann's volumetric method, as modified by Plimmer and Bayliss (*J. of Physiology*, 1906, **33**, 439), was by far the most accurate and expeditious method for the determination of phosphoric acid in any form in food stuffs. He had found the following to be a convenient way of carrying out the determination: A weighed quantity of the substance, which should contain not more than 25 mgrms. of phosphoric acid (P_2O_5) is treated in a round-bottomed Jena glass flask of about 1 litre capacity with 5 c.c. concentrated sulphuric acid, and an excess of strong nitric acid (sp. gr. about 1·40). With some substances the action takes place at once with copious evolution of red fumes, and may be moderated by addition of water. The contents of the flask are strongly heated over a free flame, with constant shaking and repeated addition of small quantities of nitric acid, until a clear liquid is obtained which does not darken on further heating. This operation lasts about ten to fifteen minutes. The liquid is then treated with 70 c.c. of water and 25 c.c. of 50 per cent. ammonium nitrate solution, warmed to about 80° C., and the phosphoric acid precipitated with 25 to 30 c.c. of 10 per cent. ammonium molybdate solution. The mixture is thoroughly shaken and cooled, and the precipitate filtered off by suction through asbestos on a Gooch crucible. It is washed several times with cold distilled water until free from acid, and then transferred together with the asbestos to an Erlenmeyer flask, with a small quantity of distilled water. $\frac{N}{2}$ NaOH is added from a burette in quantity more than sufficient to dissolve the precipitate, the liquid is boiled until all the ammonia has been driven off, cooled, and titrated back with $\frac{N}{2}$ H_2SO_4 and phenolphthaleïn. One c.c. $\frac{N}{2}$ NaOH $= 0{\cdot}001268$ grm. P_2O_5. He had used this method for a great many determinations of phosphoric acid in flour, and had found it to be quicker and more accurate than the gravimetric methods, while there could be no formation of meta- or pyro-phosphate. It was also, in his opinion, much better than the Carius method, and, as far as he could see, could be used for the determination of phosphoric acid in any form, organic or inorganic.

---

* After washing out the contents of the Carius tube, it is advisable to take the liquid down to dryness on the water-bath in order to get rid of excess of HNO_3. The residue can then be taken up in water, with the addition of a small quantity of HCl if necessary.

Mr. Bevan said that the working of the Neumann method had been shown to him by Dr. Monier-Williams, whose observations with regard to it he could fully confirm. He did not, however, quite understand why it should be necessary to eliminate the sulphuric acid by the addition of ammonium nitrate, because in some molybdic solutions sulphuric acid was deliberately used.

Dr. Monier-Williams thought it probable that the composition of the precipitate was constant only in presence of a large excess of nitric acid, and that if nitric acid were not present the ratio of ammonia to phosphoric acid might be different. Of course, where the precipitate was redissolved and weighed as magnesium phosphate, this ratio was of no moment.

Mr. W. Bacon said that in those processes in which sulphuric acid was allowed to be present, the solution was not heated beyond 40° C. At the higher temperature in Neumann's method the sulphuric acid might cause the precipitation of molybdic acid, which was perhaps the reason for insisting on its removal.

Mr. Richmond said that it seemed to him that in normal milk (*i.e.*, milk which had not become sour), although monobasic and dibasic phosphates were present, there was practically always sufficient base in combination with organic acids, to form orthophosphates with all the phosphoric acid on ignition. If, however, the milk contained even sufficient acid to cause it to curdle on heating, there was a disturbance of the conditions. When casein was precipitated by means of acid, the quantity of base remaining was insufficient to form orthophosphates with the whole of the phosphorus, organic and inorganic, so that, when separation of the casein took place (which of course would be local), there would be an excess of phosphoric acid and a deficiency of base, and meta- and pyro-phosphates would be formed. The proportions of soluble and insoluble ash in milk before and after souring were distinctly different.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Detection of Benzoic Acid in Foods, Etc. E. Polenske. (*Arbeit. Kaiserl. Gesundheitsamte*, 1911, **38**, 149-154; through *Chem. Zentralbl.*, 1911, II., 1179-1180.)

I. *Estimation of the Total Benzoic Acid Occurring in Cranberries.*—The method proposed consists of the following operations: (1) Extraction of the cranberries with 96 per cent. alcohol for one hour at a temperature of 70° C.; (2) separation of the impure benzoic acid; (3) purification of the same by treatment with potassium permanganate as described by von der Heide and Jakob (ANALYST, 1910, **35**, 166); and (4) sublimation and titration of the pure benzoic acid. The alcoholic extract of the fruit is rendered strongly alkaline with sodium hydroxide, filtered, the residue washed with alcohol, and the filtrate evaporated until all alcohol has been removed. The residual solution is acidified with sulphuric acid, and extracted with a mixture of ether and petroleum spirit, the benzoic acid being then obtained in aqueous solution by shaking the ethereal extract with sodium hydroxide solution. This alkaline benzoate solution is now heated and oxidised with potassium permanganate as described (*loc. cit.*), and, after the excess of permanganate employed has been decomposed by the addition of sodium sulphite and sulphuric acid, the benzoic acid is extracted from the solution with ether. The ethereal solution is filtered, the ether is evaporated, the residue is dissolved in a small quantity of ether, and the solution is transferred to a test-tube. After evaporating the ether, the dry residue is mixed with a quantity of sand, and heated in an oil-bath at 180° to 190° C. until the benzoic acid has sublimed on to the upper part of the tube. The bottom of the tube is then cut off, the crystals of benzoic acid are dissolved in alcohol, and the solution is titrated, using phenolphthaleïn as indicator; 1 c.c. of $\frac{N}{10}$ alkali solution is equivalent to 0·0122 grm. of benzoic acid. The total quantity of benzoic acid occurring naturally in cranberries was found to vary from 0·089 to 0·206 per cent., according to the degree of ripeness of the fruit.

II. *Detection of Benzoic Acid in Wine.*—After the wine has been evaporated and acidified, as described by von der Heide and Jakob (*loc. cit.*), it should be filtered before the extraction with ether in order to prevent the formation of a troublesome emulsion. The separated benzoic acid must be treated with permanganate to destroy any salicylic acid, etc., which may be present, and the benzoic acid is then identified by converting it into salicylic acid by fusion with potassium hydroxide and applying the ferric chloride test.

W. P. S.

Estimation of Benzoic Acid. O. Folin and F. F. Flanders. (*J. Amer. Chem. Soc.*, 1911, **33**, 1622-1626.)—The authors have adapted the modified method of La Wall and Bradshaw, used by them in the estimation of benzoic acid in cranberries, to the case of ketchup, using the chloroform titration method proposed by Folin and Wentworth (*J. Biol. Chem.*, 1908, **7**, 423) as the final stage. Twenty-five grms.

of ketchup are well mixed with 2 c.c. of strong nitric acid, and several small portions of sodium nitrite (about 0·2 to 0·3 grm. in all) added. These additions serve to destroy colouring matters, and to prevent subsequent emulsification. The bleached mass is transferred, without previous filtration, to a separator by means of 200 c.c. of a saturated solution of ammonium sulphate, and then extracted with successive quantities of 50, 35, 25, 25, and 25 c.c. of chloroform, the shaking being done by means of a gentle rotary motion. The mixed chloroform extracts are shaken twice with 200 c.c. each time of a saturated solution of sodium chloride containing 3 c.c. of hydrochloric acid (10 per cent.) per litre. The washed chloroform is then titrated with standard sodium alcoholate solution, using 4 or 5 drops of alcoholic phenolphthaleïn as indicator, to the first persistent pink colour. The standard alcoholate is prepared by dissolving 2·3 grms. of cleaned metallic sodium in 1 litre of absolute alcohol, and is standardised against pure benzoic acid in 160 c.c. of chloroform. Any hydrochloric acid in the chloroform used for standardisation should be got rid of just before use. Washing of the chloroform extract by salt solution removes glycolic, lactic, and acetic acids, but cinnamic acid, if present, will be estimated with the benzoic acid. The method may be adapted for the qualitative detection of benzoic acid. A. R. T.

The Dimethyl Sulphate Test for Creosote Oil and Creosote Baths (Dips). R. M. Chapin. (*U.S. Dept. Agric. Circular*, No. 167; through *Chem. Zentralbl.*, 1911, II., 1386-1387.)—The purpose of the test is to detect the presence of paraffin hydrocarbons in tar oils. The oil to be tested is submitted to fractional distillation, and 5 c.c. of a high-boiling fraction are shaken in a narrow tube with 8 c.c. of dimethyl sulphate; the lower layer will then consist of dimethyl sulphate containing the aromatic compounds, whilst the paraffins, if present, form the upper layer (*cf.* Valenta, ANALYST, 1906, **31**, 202). This test may be used in place of the sulphonation test, or, in important cases, employed in conjunction with the latter. In testing creosote baths (dips or washes), 50 grms. of the sample are treated with potassium hydroxide and extracted with ether; the ethereal extract is evaporated, dried, and tested with dimethyl sulphate. Should the result be negative, the sample contains neither creosote of doubtful origin, nor petroleum oils. If a positive result be obtained, a portion of the sample should be distilled, and the fraction boiling at 240° to 270° C., tested with dimethyl sulphate. (*Cf.* Harrison and Perkin, ANALYST, 1908, **33**, 2.) W. P. S.

Estimation of Gelatin. W. Greifenhagen, J. König, and A. Scholl. (*Biochem. Zeitsch.*, 1911, **35**, 217-227.)—As the results of an examination of various methods which have been proposed for the estimation of gelatin, the authors find that the precipitation method with formaldehyde described by Beckmann (ANALYST, 1895, **20**, 44) is useless. Precipitation with Nessler's reagent in the presence of a tartrate yields quantitative results, but when proteoses (albumoses) are present, these are also precipitated. Trichloracetic acid in large excess yields a turbidity with very dilute solutions of gelatin, and does not precipitate proteoses completely. Mercuric chloride precipitates proteoses from neutral solutions, but not gelatin; the proteoses are not, however, precipitated completely. If from a solution the gelatin and proteoses be precipitated together by means of zinc sulphate, the precipitate then dissolved, and treated with mercuric chloride, the nitrogen-content of the mercuric chloride precipitate affords evidence of the presence of gelatin; should it contain approximately the same amount of nitrogen as the zinc sulphate precipitate, gelatin is not present, but if there be a considerable difference between the two quantities of nitrogen, gelatin is probably present. In the latter case, a second portion of the solution under examination is treated with zinc sulphate, the precipitate formed is redissolved, and treated with a solution of mercuric iodide in either alcohol or acetone; if this precipitate contains much nitrogen, as compared with that present in the zinc sulphate precipitate, the presence of gelatin is confirmed. These methods, however, give only approximately quantitative results. W. P. S.

Detection of Invert Sugar in Honey. E. Feder. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 412-413.)—The test proposed depends upon the detection of α-hydroxyl-δ-methyl-furfural by means of aniline chloride, and is applied directly to the honey and not to the ethereal extract of the same as in Fiehe's test (ANALYST, 1908, **33**, 397; 1909, **34**, 399). Five grms. of the honey are mixed thoroughly in a porcelain basin with 2·5 c.c. of freshly prepared aniline chloride solution (100 c.c. of aniline and 30 c.c. of 25 per cent. hydrochloric acid). Should invert sugar be present, a bright red coloration develops almost immediately, its intensity being dependent on the quantity of α-hydroxyl-δ-methyl-furfural contained in the invert sugar. Pure honey yields a yellowish coloration with the test. W. P. S.

Estimation of Water in Honey. U. Fabris. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 353-358.)—The author has investigated various methods which have been proposed for the estimation of water in honey—namely: (1) Drying on sand *in vacuo* at 100° C.; (2) drying on sand *in vacuo* at 60° C.; (3) distillation with turpentine and measuring the volume of water distilling over with the turpentine; (4) drying at 95° C. on strips of paper for two and a half hours, the strips of paper being contained in a specially constructed tube through which a current of dry air is passed during the operation. The results obtained by the four methods are shown in the following table:

	Five Hours *in vacuo* at 100° C.	Twenty-eight Hours *in vacuo* at 60° C.	Distillation Method.	Drying in a Current of Air.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Sample 1	13·05	12·60	12·68	12·65
„ 2	18·72	18·25	18·30	18·32
„ 3	23·75	23·43	23·52	23·47

The first method always yields higher results than the others, whilst in the case of the distillation method it is somewhat difficult to obtain concordant results in duplicate estimations. W. P. S.

Valuation of Hops by Analysis. E. Moufang and A. Scheer. (*Wochsch. Brau.*, 1911, **28**, 449-452; through *J. Soc. Chem. Ind.*, 1911, **30**, 1226.)—The authors give the results of investigations on the determination of the extract of hops. A special straining vessel for holding the finely ground hops during mashing was used. This vessel, holding 20 to 25 grms. of material, is made of perforated sheet nickel, and is fitted with a vertical rod, the lower end of which is fixed to the bottom of the vessel. A perforated cover fits the interior of the vessel, and is provided with a collar which slides on the rod. The cover thus serves to press the hops after extraction, and the vessel serves to stir the mashing water. It is found that the best results (*i.e.*, the maximum yields of extract) are obtained by mashing 20 grms. of the finely divided hops with 265 c.c. of water at a temperature of 90° C. for fifty-five to sixty minutes; to allow for loss by evaporation, about 40 c.c. of water should be added during mashing. The amount of water required to make up the weight of the cooled mash must not exceed 3 to 5 grms., and instead of this, it seems advantageous to add only enough water to complete the weight to the next gram. Prior to analysis, the hops should be freed from stalks and foreign impurities, and thoroughly divided. The limit of error in the determination is about 0·2 to 0·3 per cent. Analyses of a number of hops from various sources showed that the extract contents ranged from 28·76 to 36·25 per cent., and corresponded closely with the price of the hops. In conjunction with the determination of extract, the aroma and colour of the hops may also be judged by the above method.

Estimation of Morphine by Extraction with Phenyl-ethyl Carbinol. A. D. Thorburn. (*J. Ind. Eng. Chem.*, 1911, **3**, 754-756.)—A quantity of the sample representing less than 0·175 grm. of anhydrous alkaloid is dissolved in a few c.c. of acidulated water; three-sevenths of its volume of ethyl alcohol are added to the solution, which is then filtered and transferred to a separating funnel with sufficient 30 per cent. alcohol to make a total volume of 10 to 15 c.c. The liquid is made alkaline with ammonia and a mixture of 3 c.c. of phenyl-ethyl carbinol with 1 c.c. of benzene is added. The contents of the funnel are shaken hard for several minutes, allowed to separate, and again shaken for several minutes, after which the two liquids are separated. The aqueous liquid is returned and extracted again with half the above quantity of mixed solvents. The alkaloidal extract should be heated in a bath of boiling water for an hour, and the residue poured into a separating funnel, washing with ether, a little at a time, until 30 c.c. have been added. A known volume (10 c.c.) of $\frac{N}{10}$ sulphuric acid is added, the liquid being shaken at intervals during half an hour. The aqueous layer is drawn off, the liquid in the funnel being washed with 3 c.c. of water three times. The morphine is finally estimated by titrating back the excess of sulphuric acid in presence of hæmatoxylin. J. F. B.

Estimation of Nitrates in Milk by Means of the Diphenylamine-Sulphuric Acid Test. J. Tillmans and A. Splittgerber. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 401-405.)—Certain modifications are recommended for the purpose of rendering more trustworthy the method described previously by one of the authors (ANALYST, 1911, 67). The protein and fat-free serum of the milk is best prepared by treating the milk with mercuric chloride and hydrochloric as described in the process for estimating sulphates in milk (ANALYST, 1910, **35**, 434); 1 c.c. of the serum thus obtained is mixed with 4 c.c. of the diphenylamine reagent and any blue coloration which develops is compared with that produced by solutions containing known amounts of nitrates. As the milk serum still contains substances which diminish the intensity of the coloration produced by the reaction, these standard solutions should be prepared by placing quantities of 0·45, 0·8, 1·2, 1·5 and 2·0 c.c. of potassium nitrate solution, containing 0·1871 grm. of the salt per litre, in separate 100 c.c. flasks, adding 2 c.c. of saturated sodium chloride solution to each, and diluting the mixtures with water to the mark. The solutions then contain quantities of nitric acid (N_2O_5) corresponding with 1, 2, 3, 4, and 5 mgrms. of N_2O_5 per litre of milk, respectively. W. P. S.

Estimation of Starch. W. Greifenhagen, J. König, and A. Scholl. (*Biochem. Zeitsch.*, 1911, **35**, 194-216.)—The polarimetric methods for the estimation of starch proposed by Lintner (ANALYST, 1907, **32**, 179) and Ewers (ANALYST, 1908, **33**, 101, 481) may be used for all kinds of starch; in Lintner's method the different starches have practically the same specific rotation, namely, +202°. This value varies slightly for different starches in Ewer's method, but for maize, rice, wheat, rye, barley, and oats, an average value of $[\alpha]_D$ +183·4° may be taken. Feeding stuffs and other products containing starch should be washed with cold water, alcohol, and ether before the estimation is commenced, in order to remove optically active substances other than starch; cellulose, hemi-cellulose, and pentosans are without influence on the results obtained by either method. Ewer's method is the more applicable to the estimation of starch in pepper, whilst Lintner's method may be used in the case of cocoa and cinnamon; the latter substance should be washed with hot alcohol previous to the estimation of the starch. W. P. S.

Estimation of Sucrose and the Detection of Dextrin in Foods. F. Vollant. (*Ann. Falsific.*, 1911, **4**, 504-509.)—The author has made a number of estimations of sucrose in such substances as commercial sugars, syrups, confectionery, sweetened milks, honey, etc., using the process described by Lemeland (ANALYST, 1910, **35**, 539), the results obtained showing that the process is trustworthy. After the sugar solution has been treated with manganese dioxide and alkaline hydrogen peroxide solution as prescribed, it is cooled and neutralised by the addition of acetic acid (*not* nitric acid as stated in the original paper), basic lead acetate is added, the mixture is diluted to a definite volume (100 c.c.), and filtered. Fifty c.c. of the filtrate are acidified with acetic acid, diluted to a volume of 55 c.c., and examined by the polarimeter. A sample of commercial sugar was found to contain 91·14 per cent. of sucrose, whilst the ordinary inversion method yielded 91·28 per cent. In the case of sweetened dry milk, 5 grms. of the sample are extracted with three successive quantities of 25 c.c. of 0·1 per cent. acetic acid, the insoluble matter being separated each time by centrifugal action; the united extracts are treated with 3 c.c. of a 25 per cent. sodium metaphosphate solution, and 3 c.c. of hydrochloric acid, diluted to a volume of 100 c.c., and filtered. An aliquot portion of the filtrate is then acidified with acetic acid, diluted to a definite volume, and polarised. A sample of this product yielded 14·0 per cent. of sucrose against 13·92 per cent. found by the inversion method. For the detection of dextrin in food materials, proteins and gums are removed by the usual methods, the sucrose which may be present is inverted, and the resulting solution is treated as described; any optical property it now exhibits is due solely to the presence of dextrin. W. P. S.

Essential Oil of Santolina Chamæcyparissus. L. Francesconi and Scarafia. (*Gazz. Chim. Ital.*, 1911, **41**, 185-203.)—The medicinal plant, *Santolina chamæcyparissus*, which is found in dry places in the Mediterranean provinces of Italy, contains a yellow essential oil, the yield of which was found to vary from 0·19 to 1·15 per cent., according to the season of distillation. Oil distilled in June had the following characteristics: Sp. gr. at 15° C., 0·8704; $[\alpha]_D = -11·66°$; saponification value, 11·78; and saponification value of acetylated oil, 11·74. On fractional distillation it yielded two main fractions at 94° to 97° C., and 98° to 101° C., respectively, a third smaller fraction at 102° to 113° C.; and a smaller fraction at 114° to 135° C. The oil contained neither free alcohols nor phenols, and only a small quantity of compound esters. It contained a terpene which was abundant in the first fraction, together with a phenolic ester; in the middle fractions there were one or more oxyterpenes and carbonylic compounds; whilst the last fraction contained other carbonylic compounds and the ester of an alicyclic alcohol. C. A. M.

Spanish Oil of Turpentine. O. Fernandez. (*Chem. Zeit.*, 1911, **34**, 1152.)—The principal constituent of Andalusian pine oil (*Pinus Halepensis*) is a terpene which is not quite identical with ordinary pinene. From Spanish pinene no nitrosite could be obtained. By the action of nitrogen peroxide at 0° C. in presence of acetic acid, a brownish-black substance was separated, which had an odour resembling that of cymene, amounting to about 55 per cent. of the original hydrocarbon. This is probably a form of oxime, becoming crystalline in course of time. The corresponding pinenenitrolpiperide forms a spongy, non-crystalline mass. With toluidine a viscous liquid boiling at 130° to 141° C. under 14 mm. pressure is obtained; α- and β-naphthylamine and sulphanilic acid yield no nitrolamines. Only about 10 per cent. of a crystalline terpene could be obtained from the Spanish pinene.

J. F. B.

Cider Vinegar. F. E. Mott. (*J. Ind. and Eng. Chem.*, 1911, **3**, 747-750.)—The author summarises the results of his investigations as under: Assuming that the sugars naturally present in pure cider vinegar are essentially lævulose and dextrose, a relation exists between the percentages of these two sugars in a pure cider vinegar. If the reducing sugars be determined with elimination of the error due to aldehyde, it is believed that in all pure cider vinegars the percentage of dextrose in the total solids is less than 0·6 times the percentage of lævulose. Whenever a cider vinegar is dextro-rotatory at 87° C., sucrose being absent, it may be inferred that it has been adulterated with foreign dextro-rotatory materials, usually dextrose; but a vinegar may be adulterated with such material and yet show a lævo-rotation at 87° C. Whenever a value for dextrose per cent. of solids is found in excess of 0·6 times the lævulose value, the sample is not exclusively the fermented product of pure apple-juice, but, sucrose being absent, has been adulterated with some foreign dextro-rotatory material. The method ultimately adopted for the determination of the analytical data is as follows:

Total Solids.—Ten c.c. of the vinegar are evaporated to dryness on the boiling water bath in a flat-bottomed platinum dish about 60 mm. in diameter. Five c.c. of water are added and again evaporated to dryness; again 5 c.c. of water are added and evaporated, and the dish is allowed to remain for one hour on the water-bath after the final evaporation. The dish is removed, wiped, and placed in an oven at 100° C. for five minutes, cooled in the desiccator, and weighed.

Reducing Sugars.—Twenty-five c.c. of water are added to the dry solids in the dish and heated till the latter are dissolved. The contents of the dish are rinsed into a 100 c.c. flask, cooled, neutralised, and made up to the mark. The reducing sugars are then determined by Munson and Walker's method on 50 c.c. of the solution, and calculated as dextrose.

Polarisation.—To 50 c.c. of the vinegar 5 c.c. of basic lead acetate, sp. gr. 1·25, are added, and two teaspoonfuls of animal charcoal which has previously been tested as to its suitability for polarisation purposes. The liquid is filtered and polarised in a 200 mm. tube, the result being expressed in Ventzke degrees corrected. The percentage of lævulose is then calculated by the formula $L = \frac{0{\cdot}793R - P}{2{\cdot}08}$, where R = per cent. of reducing sugars, as dextrose, in the total solids, and $P = \frac{p \times 26{\cdot}048}{\text{total solids}}$, where p is the polarisation observed as above.

The percentage of dextrose, $D = R - 0{\cdot}915L$. J. F. B.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Comparative Values of the Biological Reactions with Serum-Precipitin and the So-called Erythro-Precipitin for the Detection of Blood. D. Mirto. (*Arch. Farmacol. sperim.*, 1911, **12**, 145-158; through *Chem. Zentralbl.*, 1911, II., 1272.)—The results of an investigation regarding the sensitiveness and specific properties of these two reactions are recorded. The serum-precipitin method yields a positive reaction with the serum and hæmoglobin portion of blood, whilst the erythro-precipitin test (preparation of a precipitin-serum for human blood by the intraperitoneal injection of human blood-corpuscles into rabbits) only reacts with the hæmoglobin of the blood and not with the proteins of serum, semen, milk, or saliva; it is less sensitive than the serum-precipitin test, and does not give a reaction in the absence of oxyhæmoglobin. The serum-precipitin test is considered to be the more reliable test. W. P. S.

Use of Elastin in the Detection of Proteolytic Enzymes. E. Abderhalden and K. Kiesewetter. (*Zeitsch. physiol. Chem.*, 1911, **74**, 411-426.)—The use of elastin for the detection of active pepsin in the contents of the intestines has been described previously (ANALYST, 1911, 551) by Abderhalden and Meyer, and the authors now give the results of further experiments, showing the suitability, etc., of elastin for the purpose in question. They have also examined human, dogs' and horses' fæces as to the presence of proteolytic ferments; whilst small quantities of the latter sometimes appeared to be present, in many cases negative results were obtained. Further experiments proved the presence of peptolytic ferments in the plasma obtained from horses' livers and kidneys, and from yeast. W. P. S.

Occurrence, Detection, and Estimation of Nitrous Oxide in the Gases produced by Denitrifying Organisms. S. Suzuki. (*Zentralbl. Bakter. Parasitenk Zweite Abth.*, 1911, **31**, 27-49; through *Chem. Zentralbl.*, 1911, II., 1267-1268.) —It is known that bacteria are capable of producing nitrous oxide by the reduction of nitrates, and the author gives the following method of identifying this gas in the presence of the other gases produced at the same time : The gaseous mixture is collected in an ordinary explosion pipette over dry mercury, diluted with its own volume of air, and subjected to the action of a small electric spark. If the gases be then passed over potassium iodide-starch solution, a blue coloration will be obtained. The presence of 1 per cent. of nitrous oxide in the gases may thus be detected. The quantity of the nitrous oxide may be estimated by diluting the gases with pure nitrogen (if less than 10 per cent. of nitrous oxide be present this dilution is unnecessary), the carbon dioxide is removed by treatment with potassium hydroxide, the oxygen with pyrogallol, and the gaseous residue is heated in a platinum capillary tube after being mixed with carbon monoxide free from carbon dioxide and oxygen. The volume of the resulting carbon dioxide corresponds with the volume of the nitrous oxide. W. P. S.

Colorimetric Estimation of Sugar, Creatine, and Creatinine in Urine. W. Autenrieth and G. Müller. (*Münch. med. Wochenschr.*, 1911, **58**, No. 17; through *Chem. Zentralbl.*, 1911, II., 1380-1381.)—Whilst the process described by Autenrieth and Tesdorpf (ANALYST, 1910, **35**, 528) yields accurate results when applied to colourless urine, certain modifications are necessary in the case of dark-coloured urine. The use of blood-charcoal free from iron is recommended in place of lead acetate for removing the colouring matters, and this treatment is carried out after the diluted urine has been boiled with Bang's copper solution (ANALYST, 1907, **32**, 180); the blood-charcoal when free from iron does not retain any of the copper. Fifty c.c. of Bang's solution and 10 c.c. of the diluted urine (1 volume of urine to 4 volumes of water, or 10 volumes of water if much sugar be present) are boiled for three minutes, cooled, and diluted with potassium thiocyanate to a definite volume. To the mixture is now added 0·5 grm. of blood-charcoal, and, after shaking for ten minutes, the mixture is filtered, the amount of unreduced copper being then estimated by comparing the filtrate in a colorimeter with standard copper solutions, or other standards. The creatinine and creatine may be estimated by means of Folin's colorimetric process. W. P. S.

Colorimetric Estimation of Lactose in Urine and in Milk. W. Autenrieth and A. Funk. (*Münch. med. Wochenschr.*, 1911, **58**, No. 17; through *Chem. Zentralbl.*, 1911, II., 1382.)—In the case of urine, the actual presence of lactose should be ascertained by heating 5 c.c. of the urine with 4 c.c. of 10 per cent. ammonia and 4 drops of potassium hydroxide solution; should lactose be present, a red coloration is produced. Dextrose yields a brown coloration with the test when present in larger quantity than 1 per cent.; smaller quantities do not yield a coloration, nor do they interfere with the lactose reaction. For the estimation of lactose 10 c.c. of urine (containing not more than 0·04 grm. of lactose) are boiled with 50 c.c. of Bang's copper solution (ANALYST, 1907, **32**, 180), cooled, diluted with potassium thiocyanate solution to a definite volume, 0·5 grm. of blood-charcoal free from iron is added, and the mixture is filtered. The quantity of unreduced copper in the filtrate is then estimated by comparison with standard solutions in a colorimeter. Lactose may be estimated in milk by diluting 25 c.c. of the sample with about 400 c.c. of water, adding acetic acid, boiling the mixture, and diluting it, when cold, to a volume of 500 c.c. After filtration 10 c.c. of the filtrate are boiled with 50 c.c. of Bang's solution, the estimation being then carried out as described above. W. P. S.

Method of Destroying Organic Matter by Means of Bromine, particularly applicable to Toxicological Analysis. G. Magnin. (*J. Pharm. Chim.*, 1911, **4**, 302-306.)—It is recommended that the substance under examination, such as portions of animal organs, etc., be heated together with bromine on a water-bath. The organic matter is thus destroyed rapidly, and a clear solution obtained, which may then be tested for the presence of metallic poisons. W. P. S.

ORGANIC ANALYSIS.

Colorimetric Test for Alcohol in the Presence of Acetone. H. Agulhon. (*Bull. Soc. Chim.*, 1911, [iv.], **9**, 881-885.)—A solution of 0·5 grm. of potassium bichromate in 100 c.c. of pure nitric acid gives an immediate violet-blue coloration in the cold with organic compounds containing certain readily oxidisable groupings, whilst on heating there is a green coloration which changes to blue on cooling. These reactions, which are due to the formation of a chromium nitrate, are given in the cold by aldehydes, alcohols, and compounds containing an alcoholic group, such as sugars, hydroxy fatty acids, etc. Formaldehyde and alcohol react within one or two minutes when treated with 3 c.c. of the reagent to 1 c.c. of a solution of 0·5 per cent. strength and upwards. The test may be used for a quantitative colorimetric estimation of alcohol in the presence of acetone. An analogous but more restricted reaction is obtained by the use of a hot solution of 0·5 grm. of potassium bichromate and 50 grms. of potassium bisulphate in 50 c.c. of water. Green colorations are produced by alcohol, ether, and bodies containing alcoholic or aldehydic groups, but not by unsaturated fatty acids, such as oleic and linoleic acids. On the other hand, ricinoleic acid gives the reaction, and the test may be used for the detection of castor oil in the presence of other fatty oils. It may also be used for the detection of the ketones of cyclohexane. C. A. M.

Differentiation between Amino-Acids and Peptones or Peptides. P. A. Kober. (*J. Biol. Chem.*, 1911, **10**, 9-14; through *Chem. Zentralbl.*, 1911, II., 1063-1064.)—The fact that the copper salts of amino-acids separate copper hydroxide on boiling with alkali, whilst the copper compounds of peptones and peptides are not decomposed on such treatment, may be made to serve for the detection of amino-acids among the products of protein hydrolysis, and for the study of the quantitative relationships which exist between the nitrogenous substances of greater or less complexity at successive stages in an experiment with proteolytic enzymes. The neutral or very faintly alkaline solution is boiled for fifteen minutes with an excess of copper carbonate or of freshly precipitated copper hydroxide, and then filtered. If cuprous oxide separates during the boiling with copper hydroxide, the solution is filtered, neutralised, and reboiled with more copper hydroxide, and again filtered. The filtrate is rendered distinctly alkaline by addition of 5 to 10 c.c. of $\frac{N}{10}$ alkali, and again boiled when, if amino-acids are present, copper hydroxide separates.

G. C. J.

Estimation of Camphor. H. C. Fuller. (*J. Ind. and Eng. Chem.*, 1911, **3**, 791.)—The following adaptation of the hydroxylamine method for the estimation of ketones is described as applied to the determination of camphor in spirits of camphor: Twenty-five c.c. of the sample are measured out into an Erlenmeyer flask, 2 grms. of sodium bicarbonate are added, and then 35 c.c. of a solution of hydroxylamine (20 grms. of the hydrochloride, 30 c.c. of water, and 125 c.c. of absolute alcohol free from aldehyde). The flask is connected with a reflux condenser, and the liquid heated to boiling for two hours. It is then cooled, treated with a mixture of 6 c.c. of hydrochloric acid (1·12 sp. gr.) and 6 c.c. of water, transferred to a 500 c.c. graduated flask, and diluted to the mark; 50 c.c. are measured out, neutralised in presence of methyl orange, phenolphthaleïn is then added, and the excess of hydroxylamine is titrated with $\frac{N}{10}$ alkali. A blank experiment is made, using the same quantity of hydroxylamine solution and 25 c.c. of alcohol to correspond with the spirits of camphor, and the difference between the two titrations represents the hydroxylamine combined with the camphor; 1 c.c. of $\frac{N}{10}$ sodium hydroxide is equivalent to 0·01509 grm. of camphor. J. F. B.

Estimation of Carbon and Nitrogen in Organic Compounds. E. P. Frankland. (*J. Chem. Soc.*, 1911, **99**, 1783-1785.)—The Frankland-Armstrong vacuum-combustion process can be adapted to the estimation of carbon and nitrogen in organic compounds, the carbon dioxide and nitrogen produced in the combustion being measured together, and the latter found by absorption of the carbon dioxide with caustic alkali. The presence of halogens does not affect the results, and only very small quantities of substance are necessary (0·1 grm., or less).

Besides the Sprengel pump, two glass measuring-tubes of 150 c.c. and 50 c.c. capacity, graduated in $\frac{1}{10}$ c.c., are required, and glass cylinders in which the tubes may be levelled over mercury and water respectively. The substance is first mixed with fine copper oxide, and placed in a combustion-tube closed at one end, and the tube then nearly filled with coarse copper oxide. A reduced copper spiral is fitted in, and the tube then drawn out by the blowpipe, attached to the pump and exhausted, and towards the end of the exhaustion some burners below the copper spiral are lighted. The usual method is followed, and the gases evolved collected over mercury in a tube with a tap at one end. When the evolution of gas has ceased, the combustion-tube is exhausted, and the measuring-tube transferred to a cylinder of mercury, where the volume of moist gas (carbon dioxide and nitrogen) is measured. The results are accurate. A. R. T.

Determination of Acids in Sugar-Cane Juice. P. A. Yoder. (*J. Ind. Eng. Chem.*, 1911, 3, 640-647.)—A critical review of the methods available for the separate estimation of citric, aconitic, succinic, malic, tartaric, and oxalic acids in presence of each other and of large quantities of sugar and cane-juice. An apparatus for the continuous extraction of an aqueous solution by an immiscible solvent of greater or less density is figured, and its application to the ethereal extraction of succinic and aconitic acids described. It is shown that aconitic acid shares with citric acid the property of forming a calcium salt less soluble in hot than in cold water, and, further, that the properties of barium aconitate are such that, when Jörgensen's method for the differentiation of organic plant acids (*Zeitsch. Unters. Nahr. Genussm.*, 1907, 13, 241) is applied, aconitic acid is estimated partly as citric and partly as malic acid. Experiments are described which make it doubtful whether tartaric, succinic, or citric acid are present in cane-juice: Aconitic acid is certainly the preponderant acid, and malic and oxalic acids are certainly present, though in very small amount, their sum bearing the ratio of about 1 : 100 to the amount of aconitic acid. The absence of citric acid is by no means certain, owing to the difficulty of differentiating between it and aconitic acid, and the author's work did not take account of tricarballylic acid, found by von Lipmann in sugar beets, nor of lactic acid.

G. C. J.

Detection of Small Quantities of Disaccharides. C. Neuberg and S. Saneyoshi. (*Biochem. Zeitsch.*, 1911, 35, 44-55.)—The process described depends on the different behaviour of the osazones of maltose, isomaltose, lactose, and melibiose, towards hydrolytic agents, and may be applied to as small a quantity as 0·01 grm. of the osazones. The osazones are first prepared in the usual way ; the presence of maltosazone is detected by treating a solution or emulsion of the osazones with yeast-maltase; dextrose is formed, should the mixture contain this osazone, and the resulting solution reduces Fehling's solution. Isomaltosazone is not attacked by yeast-maltase, but by boiling with 1·5 per cent. sulphuric acid it is converted into dextrose, which may be identified from its rotation, reducing power, etc. Whilst lactosazone and melibiosazone are not acted on by yeasts, they are converted into *d*-galactose when heated with 1·5 per cent. sulphuric acid, and the *d*-galactose may be identified by its characteristic behaviour towards yeasts or enzymes, and by its rotation. It is not possible to distinguish between these two osazones, but it is unlikely that they will be found together in any liquid under examination, as lactose is obtained from the milk of animals, whilst melibiose is of vegetable origin.

W. P. S.

Estimation of Free Fatty Acids in the Presence of Soaps of the Alkalis and Alkaline Earths. D. Holde and J. Marcusson. (*Zeitsch. angew. Chem.*, 1911, **24**, 1945-1948.)—Of recent years fats containing considerable amounts of soaps of the alkalis and alkaline earths have been sold under the name of "Calypso fats," and the presence of these substances has an influence upon the quantities of solvent required to dissolve the free fatty acids. Experiments, which are described in detail, have shown that the acid values of such fats may be accurately estimated as follows: In the case of ordinary greases, 10 grms. of the sample are heated beneath a reflux condenser with 50 c.c. of a mixture of 9 parts by volume of petroleum spirit and 1 part of absolute alcohol, the solution filtered while hot, and the filtrate and washings shaken in a separating funnel with 30 c.c. of 50 per cent. (by volume) alcohol, and titrated with standard alkali until the lower layer appears red to phenolphthaleïn. For "Calypso fats" 100 c.c. of a mixture of petroleum spirit and alcohol (8 : 2) are used, a further addition of 10 c.c. of alcohol being made if required to dissolve the fat, and the solution is treated as described above. C. A. M.

Estimation of Formaldehyde. E. Elvove. (*Amer. J. Pharm.*, 1911, **83**, 455-471.)—The potassium cyanide method of estimating formaldehyde is commonly accepted as being only applicable to very dilute solutions. It is here shown, however, that it is more reliable than the hydrogen peroxide method for concentrated solutions, and that it allows of the estimation of formaldehyde in the presence of other aldehydes. Variations in the temperature do not affect the results provided that an excess of potassium cyanide of as much as half an equivalent is added. In using the method for the analysis of the ordinary 40 per cent. formalin solution, 0·5 grm. of the sample is weighed into a stoppered Erlenmeyer flask of about 150 c.c. capacity, and immediately treated with 100 c.c. of a standardised solution of potassium cyanide (about 6·5 grms. per litre). After thorough mixing, the contents of the flask are added to a mixture of 40 c.c. of $\frac{N}{10}$ silver nitrate solution and 10 c.c. of dilute (10 per cent.) nitric acid, the washings added, and the whole made up to 200 c.c., thoroughly shaken, and filtered. The excess of silver in 100 c.c. of the filtrate is then titrated with $\frac{N}{10}$ ammonium or potassium thiocyanate, with ferrous ammonium sulphate as indicator. The amount of potassium cyanide, in terms of $\frac{N}{10}$ silver nitrate solution, which has entered into combination with the formaldehyde, multiplied by 0·3 and divided by the weight of the sample, gives the percentage by weight of absolute formaldehyde. C. A. M.

Analysis of Fulminate Cap-Compositions. Utescher. (*Zeitsch. Schiess- und Sprengstoffwesen*, 1911, **6**, 402.)—Simple mixtures may be separated by treatment with different solvents in succession. A more complicated one, containing, for example, fulminate, potassium chlorate, antimony sulphide, and powdered glass, is dealt with as follows: To 1 grm. of the composition in a 250 c.c. beaker is added 100 c.c. water and 5 c.c. 1 in 5 sulphuric acid, and hydrogen sulphide passed for thirty to forty minutes through the liquid, previously heated to boiling. After cooling, filtering, and washing with hydrogen-sulphide water, the potassium chlorate is estimated in the filtrate by evaporating it in a porcelain basin until all chlorine is driven off, washing into a tared platinum basin, evaporating, igniting until the potassium sulphate begins to fuse, and weighing. To determine the glass, the precipitate, consisting of glass, antimony sulphide, and mercury sulphide, is warmed on the water-bath in the original precipitating vessel with 5 c.c. concentrated hydrochloric acid and 2 c.c. of 50 per cent. tartaric acid, until, with frequent stirring, the fibres of the filter are separated. From a pipette, 1 c.c. concentrated nitric acid (1·4) is added, the liquid heated, stirred, diluted with a small quantity of water, filtered, the filter washed with hot water, dried, ashed in a porcelain crucible, and the glass ignited and weighed. The mercury fulminate is estimated by electrolysis of the filtrate from the glass in a Frary apparatus. A current of 1·5 ampères at 3 volts is passed for two hours, roughened platinum gauze electrodes being used. Good arc-lamp carbons may be employed (two or three times) if preferred, but the platinum is not attacked by the dilute chlorine solution. The electrodes are washed with distilled water into the electrolyte. The cathode is washed with absolute alcohol and ether, and weighed (factor for mercury fulminate, 1·465). The antimony sulphide is determined in the mercury-free electrolyte by neutralising with caustic soda solution (sp. gr. 1·5), adding 5 c.c. more of this solution and 20 c.c. of 10 per cent. sodium sulphide solution (made by decolorising a solution of commercial crystallised sodium sulphide with ammoniacal hydrogen peroxide and filtering), and electrolysing as before, but with a current of 1 ampère, and keeping at 80° to 90° C., washing the cathode in water, moving it about frequently for five minutes in water at 100° C., but not boiling, washing it with distilled water, absolute alcohol, and ether, drying and weighing. To clean the electrodes, mercury may be removed by ignition, and antimony by immersion in 10 parts concentrated nitric acid and 1 part 50 per cent. tartaric acid. In the absence of electrolytic apparatus the filtrate from the glass is boiled, hydrogen sulphide passed through it for thirty to forty minutes, cooled, and the precipitate collected on a tared filter and washed with hydrogen sulphide water. A crucible of 80 c.c. content is placed beneath the funnel, and the antimony sulphide simultaneously dissolved out and washed into it with hot ammonium sulphide solution from a fine jet, followed by hot water. The mercury sulphide left on the filter is washed with hot water, alcohol, ether, and carbon disulphide, dried at 110° C., and weighed. The antimony solution is concentrated on the water-bath, oxidised by evaporation to dryness with nitric acid (1·4) three or four times, and strongly ignited.

If the cap-composition contains organic nitro-compounds, these are extracted first of all with solvents such as benzene. Black powder, the composition of which must be known or found in a separate sample, is estimated by extracting its sulphur with carbon disulphide. If potassium chlorate is simultaneously present, it is estimated with the nitre, or separately in the filtrate from the sulphides of antimony and mercury by driving off hydrogen sulphide, boiling with ferrous sulphate to complete the reduction of the chlorate, acidulating with nitric acid, and precipitating with silver nitrate. O. E. M.

Detection of Small Quantities of Glycuronic Acid. C. Neuberg and S. Saneyoshi. (*Biochem. Zeitsch.*, 1911, 35, 56-59.)—Glycuronic osazone yields a violet coloration soluble in benzene when it is heated with hydrochloric acid and naphtho-resorcinol; the osazones of pentoses, hexoses, and disaccharides, give a similar coloration, but the latter is not extracted from the mixture by benzene. A mixture of the osazones (about 0·008 grm.) is dissolved in 4 c.c. of concentrated hydrochloric acid, an equal volume of water is then added, and the solution is boiled. A quantity of about 0·1 grm. of naphthol-resorcinol is now added, the mixture is heated for thirty seconds, then cooled to a temperature of 50° C., and shaken with benzene. In the presence of glycuronic osazone, a red-violet colour is extracted by the benzene, and the solution exhibits an absorption band in the green-yellow portion of the spectrum. W. P. S.

Estimating Humus in Soils. J. B. Rather. (*J. Ind. Eng. Chem.*, 1911, **3**, 660-662.)—The method of Mooers and Hampton (ANALYST, 1908, **33**, 290) is a great improvement on the American official method, but it does not eliminate as much of the clay as is desirable. In some cases the residue before the final ignition may consist of more than 50 per cent. of clay. Better results are obtained by repeating the extraction with ammonia and evaporation several times; but this occupies much time, and, if acid fumes are present in the laboratory, may introduce appreciable errors. The author recommends the following method, in which the clay is coagulated and thrown out of suspension by means of ammonium carbonate, which can be subsequently eliminated below 100° C. (at about 85° C.). The soil is washed with 1 per cent. hydrochloric acid and water, digested with 4 per cent. ammonia, and filtered as in the official method. In 130 c.c. of the filtrate, 0·65 grm. ammonium carbonate is dissolved, and the solution allowed to stand in a glass-stoppered cylinder overnight. The clear supernatant liquid is then decanted through a dry filter into a dry flask, and 100 c.c. of the filtrate are evaporated in a tared platinum dish, dried for three hours at 100° C., weighed, ignited, and reweighed. The humus (final loss on ignition) is on the average nine-tenths that found by the method of Mooers and Hampton, but with some soils it is less than half as much. Judged by the criterion of Alway, Files and Pinckney (ANALYST, 1910, **35**, 495), the results yielded by the new method are the more trustworthy, as the final ash is always less than that yielded by the method of Mooers and Hampton, and is usually only one-third as great. G. C. J.

Testing of Imitation Parchment Papers for Resistance to Grease. G. Schacht. (*Wochenbl. Papierfab.*, 1911, **42**, 3632-3634; through *J. Soc. Chem. Ind.*, 1911, **30**, 1206.)—For testing "grease-proof" pergamyn or imitation parchment papers, two methods are in use: (1) the paper is required to show blisters when held just above the flame of a burning match; (2) when a little oil of turpentine is rubbed on the surface of the paper it should not penetrate sufficiently to leave a greasy mark on a sheet of white paper spread underneath. A certain amount of controversy has arisen between the advocates of these two methods, each suggesting that the other test is not quite reliable. There appears, however, to be little doubt that certain of these greaseproof papers fail to blister when heated, and yet are perfectly resistant to grease in ordinary use. Whether papers exist which show blisters but are not completely greaseproof is not so certain, but in any case the author considers that the turpentine test should be adopted and the blister test should be discarded. It is a principle in all industrial testing that the test should stand as far as possible in direct relationship to the property to be tested, and for this reason alone the blister test is to be regarded with suspicion. The blister test, if confirmed by the turpentine test, may be useful in the paper machine room as a rapid approximate test for the guidance of the machine foreman, who can if necessary make the adjustments which will increase the blistering properties of the paper when these are deficient. But the turpentine test is the ultimate test for grease resistance, and logically should form the only basis on which this quality is judged.

Candelilla Wax. Niederstadt. (*Chem. Zeit.*, 1911, **35**, 1190.)—Candelilla or canutilla wax is obtained from *Pedilanthus pavonis*, a plant belonging to the *Euphorbiaceæ*, and during the last four years has become a commercial product. Two sorts of Mexican wax are sold, one of which is of lighter colour than the other, and has a hardness similar to that of carnauba wax. Commercial samples of brown and yellow wax gave the following results respectively: Sp. gr. at 15° C., 0·9930 and 0·9360; melting-point, 68·4° C.; solidification-point, 63·8° C.; acid value, 21·13 and 19·16; saponification value, 54·95 and 55·23; and ratio value,* 1·60 and 1·88. This wax is readily soluble in turpentine oil, and is being extensively used for varnishes and for telephone cables. C. A. M.

INORGANIC ANALYSIS.

Modified Cobalt Reaction for the Detection of Very Small Quantities of Hydrogen Peroxide. M. Leuchter. (*Chem. Zeit.*, 1911, **35**, 1111.)—The reagent consists of a mixture in equal proportions of a 1 per cent. solution of crystallised cobalt chloride and of a solution of 1·6 parts borax in 20 parts glycerol (sp. gr. 1·229) and 100 parts water. The test depends on the formation of a dark-coloured ring at the surface of contact of the reagent and the solution to be tested, and the glycerol serves the double purpose of giving the reagent a fairly high density and of preventing the formation of a precipitate when the cobalt and borax solutions are mixed. When 1 to 2 c.c. of a dilute solution of hydrogen peroxide is poured carefully on to an equal bulk of the reagent in a test-tube, a brown zone appears at the surface of contact of the liquids, giving place in time to a finely divided precipitate which at first rises into the upper layer, colouring it brown, but which finally settles. If much hydrogen peroxide be present, there will be a visible evolution of gas. The test serves to detect as little as 0·015 mgrm. of hydrogen peroxide or 0·5 mgrm. of sodium perborate in 1 c.c. Persulphates give no reaction unless either caustic soda is added or the solution is warmed, and the test therefore serves to differentiate between perborates and persulphates (*cf.* Lenz and Richter, Analyst, 1911, 470). G. C. J.

Gravimetric Estimation of Nickel and Cobalt. L. Dede. (*Chem. Zeit.*, 1911, **35**, 1077.)—The precipitation of nickel or cobalt by boiling with alkali and bromine-water is attended with difficulties, the greatest of which is the tendency of the precipitate to retain alkali. This difficulty may be overcome entirely by using potassium (not ammonium) persulphate in place of bromine, and precipitating in the cold. The advantage of persulphate over bromine depends on the fact that, in presence of persulphate, the slightest excess of caustic alkali causes complete precipitation, whereas with bromine a considerable excess of alkali is necessary. The amount of alkali must, of course, be sufficient to neutralise the acid set free on decomposition of the persulphate, and, if ammonium salts are present, they must be first decomposed by boiling with excess of alkali. In absence of ammonium salts, rather more caustic alkali is added to the cold solution than is theoretically required by the nickel or cobalt which may be present, and by the equivalent amount of persulphate. The latter is then added, when, in tolerably concentrated solutions, precipitation is immediate and complete. With very little nickel or cobalt present, a brown solution may result. Except when the nickel and cobalt are mere traces, these brown solutions clear, with complete precipitation of the oxide, if left for an hour or two and shaken from time to time. By allowing to stand overnight, the most dilute solutions deposit their oxide. Precipitation in the cold and the use of cold water for washing secure a precipitate of such a character that any occluded alkali is easily removed by washing. The author reduces the ignited precipitate in a current of hydrogen, and weighs as metal. The extreme error of the method for nickel is ± 0·2 mgrm. on weighings up to 0·3 grm., for cobalt only half as much. G. C. J.

---

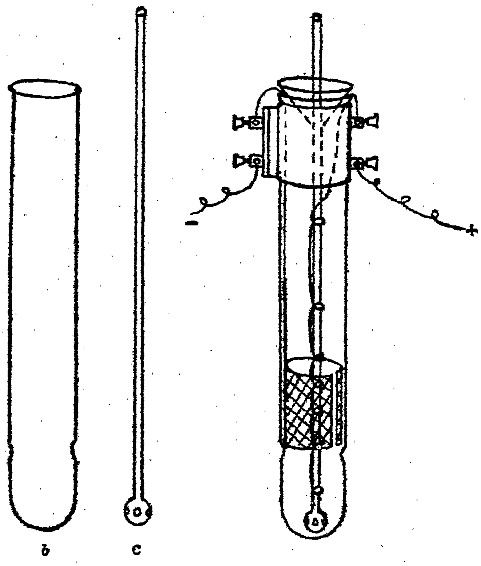
* The ratio between the amounts of alkali required by the free acids and that required to saponify the esters.

Precipitation of Zinc, Manganese, Cobalt, Nickel, Copper, and Cadmium from Ammoniacal Solutions by Means of Sodium Carbonate and Trimethylphenylammonium Carbonate. E. Schirm. (*Chem. Zeit.*, 1911, 35, 1177, 1193-1194.)—The above metals may be precipitated quantitatively from solutions of their complex ammonium salts by boiling with sodium carbonate until the escaping steam no longer smells of ammonia. The method is useful for the separation of zinc as a preliminary to an estimation of sulphuric acid. The zinc is first precipitated in the cold by the addition, drop by drop, of sodium carbonate. The precipitate of zinc carbonate and basic sulphate is next dissolved by addition of just sufficient ammonium carbonate solution and the mixture is heated to boiling. The solution, now cloudy, is cleared by addition of more ammonium carbonate and then boiled until ammonia can no longer be detected in the escaping steam. The precipitate is easily filtered and washed, and no trace of sulphuric acid remains with it. It is, however, never free from sodium, and if it be required to estimate the zinc, must be redissolved and the zinc precipitated as sulphide, or the following modified method may be used :—

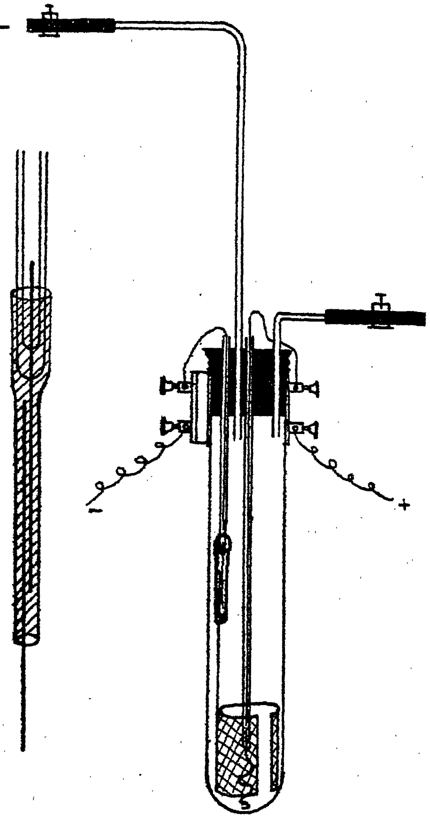
In place of sodium carbonate, trimethylphenylammonium carbonate is used. This is prepared by the interaction of dimethylaniline and methyl iodide and decomposition of the resulting trimethylphenylammonium iodide by rather less than the theoretical amount of moist silver oxide, as the presence of some iodide does not interfere, whilst that of silver would. With this reagent, an accurate estimation of zinc is possible. The precipitate is contaminated by the trimethylphenylammonium carbonate as by sodium carbonate, but this is eliminated on ignition. The precipitate is easily filtered and washed, but, like the precipitate obtained in the sodium carbonate method, sticks to the precipitating beaker. When washing is completed, the beaker is rinsed with hot dilute nitric acid, which is then poured through the filter, the latter washed with hot water, the solution evaporated to dryness, and the residue ignited for ten minutes in a covered crucible over a Bunsen burner and weighed as ZnO. The extreme error of the method is ±0·3 mgrm. with 0·13 grm. zinc oxide present.

When trimethylphenylammonium carbonate is used to separate zinc, any subsequent precipitation of sulphuric acid in the filtrate must be made by the addition of barium chloride drop by drop; the addition at one time of a large quantity of barium chloride gives rise to the formation of a scum, to trouble in washing, and to results which may be 10 per cent. too high. G. C. J.

Rapid Electro-Analysis with Agitation by Means of a Current of Gas. F. Fischer, C. Thiele, and E. Stecher. (*Zeitsch. Electrochem.*, 1911, **17**, 905-906.) —The complete apparatus is shown on the right. The tube *b* is supported by a holder, separately figured in the original paper to show that it consists of a felt-lined collar of non-conducting material, to which are attached two pairs of binding screws and a rod which can be held by the boss of a retort stand. The tube *b* is about 30 cm. × 4·5 cm., and 5 cm. from the bottom it has three indentations which serve to support the cathode. The gas-leading tube *c* is 35 cm. × 5 mm., and has blown on its end a 2·5 cm. bulb, which is pierced by a number of holes, including one at its lowest point. The anode consists of a platinum wire wound round the tube *c*, the windings being comparatively close at the elevation of the cathode. The cathode is a platinum gauze cylinder, open so that it can be dropped into place after the anode wire has been attached to its terminal, and with some 20 cm. of platinum wire welded to the end of the usual stem, so as to connect, as shown, with the binding screw on the left. A stemless funnel dropped over the tube *c*, after the electrical connections are made, serves to keep *c* central. The apparatus has so far been used only with hydrogen as agitating gas. The speed of gas is so regulated that the electrolyte, which normally just covers the cathode, is thrown up some 5 cm. higher. Working at 60° C., there is sufficient condensation of water to wash the walls of the apparatus. From 0·15 to 0·2 grm. of copper or nickel can be deposited in ten minutes with a current of 1·2 amps. (8 volts). The results are exact G. C. J.



Rapid Electro-Analysis under Reduced Pressure. F. Fischer, C. Thiele and E. Stecher. (*Zeitsch. Electrochem.*, 1911, **17**, 906-908.)—Agitation is effected by means of the gas liberated in the course of electrolysis, the volume of this gas being increased a hundredfold by working under diminished pressure. The apparatus is somewhat similar to that described in the preceding abstract, but the tubular container for the electrolyte has no constrictions to support the cathode, and is provided with a rubber stopper. Through this rubber stopper pass four tubes. The long bend is connected to a water-pump throughout the experiment, and at its end is pushed down into the tubular container so that the electrolyte and wash water can be removed by suction. The short bend admits water for washing. A third tube carries the wire anode which is sealed into it at the bottom, the tube being filled with mercury. The fourth tube, also filled with mercury, has a long platinum wire fused through its closed lower end. Over this wire and the end of the tube a piece of capillary rubber tube is passed, and into the rubber tube the stem of the cylindrical gauze anode is passed, thus forming a contact which is easily made and broken. The inset illustration shows this on a larger scale. The apparatus has been used for the estimation of copper in solutions containing 0·1317 grm. in 100 c.c., acidified with 1·5 c.c. sulphuric acid. At a temperature of 70° C., and with 2 to 3 amps. (8 volts), deposition is complete in less than ten minutes. The least accurate of three results given is 0·1314 grm. found with 0·1317 grm. present. G. C. J.



Determination of Dust in Blast Furnace Gas. W. Brady and L. A. Touzalin. (*J. Ind. Eng. Chem.*, 1911, **3**, 662-670.)—Apparatus is figured, and a full description given of the precautions necessary to estimate accurately the suspended matter in a rapidly moving current of gas. The principal conditions which must be observed are as follows: The sample must be withdrawn from that region of the main in which experiment shows that the velocity of the gas is the mean velocity. In withdrawing the sample means must be employed to change the direction of flow gradually (sampling-tube curved with radius of 12 inches), and to cause the flow in the entrance end of the sampling tube to be at the same velocity as the passing stream of gas. When a retardation occurs in the sampling-tube, the distortion of flow round its entrance causes an undue proportion of dust to lodge in the sampling-tube and be carried over into the filter. Giving the gas too high a speed in the sampling-tube, by means of too powerful suction, leads to errors of a contrary kind. These precautions are of the utmost importance where the suspended matter exceeds 1½ grains per cubic foot, and means are described for controlling the speed of gas in the sampling-tube within 2 or 3 per cent. Where possible, samples should be taken from a vertical main, and at least 15 feet from any bend or obstruction. The gas must be filtered above 100° C., and cooled below its dew-point (about 50° C.) before being delivered to the wet test meter. G. C. J.

Determination of Ferrous Iron in Silicate Rocks. M. Dittrich. (*Chem. Zeit.*, 1911, **35**, 1093.)—It is shown that the uncertain end-point in the titration of ferrous iron after decomposition of the rock by means of hydrofluoric and sulphuric acids is unconnected with the presence of manganese, and that the usual precautions fail to make the end-point even reasonably sharp with some rocks. These rocks were in every case found to contain notable proportions of titanium, but titanium dioxide, even in large amount, has no disturbing effect on the titration. Addition of titanous acid, however, to a ferrous solution before titration with permanganate, leads, as might be expected, to exactly the same indefinite end-points which are occasionally observed in the course of rock analysis. It is suggested that rocks may contain titanium as Ti_2O_3, as well as in one or other of the crystalline modifications of the dioxide. This view is confirmed by the fact that sharp end reactions may be obtained by the addition to the titration liquid of excess of finely divided silica and a considerable amount of potassium sulphate. Ferric salts are but slowly reduced by titanous acid in hydrofluosilicic acid solution, and high saline concentrations also tend to retard the reduction. G. C. J.

Volumetric Determination of Lead as Chromate. J. Waddell. (*J. Ind. Eng. Chem.*, 1911, **3**, 638-640.)—The following modification of the method of Guess (*Trans. Amer. Inst. Min. Eng.*, 1905, **35**, 359) is recommended for use with nearly all ores, but is said to be most satisfactory in just those cases where the molybdate method is least trustworthy—namely, with ores poor in lead, and containing much calcium carbonate. The ore (1 to 5 grms.), contained in a 250 c.c. flask, is dissolved in about 15 c.c. of hydrochloric acid, to which 3 to 5 c.c. of nitric acid is subsequently added, and the whole digested on the hot plate until solution is complete and the liquid is reduced to about 8 c.c. At the conclusion of this operation, which requires about fifteen minutes, the flask is removed from the hot plate, and its contents, when cool, are rendered slightly alkaline by addition of ammonia (1 : 1). Acetic acid is then added slowly with vigorous shaking until the liquid smells distinctly of acetic acid. Finally, some 5 c.c. of strong ammonium acetate solution is added to insure complete solution of the lead. If the ore contains no antimony, and no gelatinous silica has separated, any slight silicious residue in the bottom of the flask is disregarded, and the lead is precipitated in the hot, undiluted solution by addition of 10 c.c. of a 10 per cent. solution of potassium chromate. After shaking and allowing to settle for five minutes, the supernatant liquid is decanted off through a filter, and the precipitate in the flask and on the filter is washed with 0·5 per cent. acetic acid containing 0·2 to 0·3 grm. per litre of potassium chromate, and finally with water until free from soluble chromate. The filter is then set over the original flask, and the lead chromate is dissolved by the alternate application to the filter of cold dilute hydrochloric acid (1:3) and cold water, with the occasional use of 5 to 10 c.c. of hot water, following the cold water, the purpose of this procedure being the complete solution of the lead chromate without risk of evolution of chlorine. At least 100 c.c. of the dilute (1:3) acid should be used, as the accuracy of the final titration depends on the presence of a sufficient quantity of acid. To the hydrochloric acid solution of the lead chromate, about 1 grm. of potassium iodide is added, and then standard thiosulphate is run in from a burette at the rate of about 3 drops a second, using starch towards the end of the titration. The amount of potassium iodide used should not much exceed that stated, nor should the solution be specially cooled before titration, since low temperatures and excess of iodide give rise to the formation of yellow scales of lead iodide, which tend to obscure the end-point. The extreme error of the method is ± 0·1 c.c. of standard solution which, with the quantities taken for analysis by the author, corresponds to ± 0·3 per cent. of the lead present. Antimony, bismuth, silver, and gelatinous silica interfere, and, with large quantities (say, 20 per cent.) of iron in the ore, the tendency to form basic acetate causes difficulty in dissolving the lead. G. C. J.

Use of Logwood in Qualitative Analysis. Estimation of Bismuth. E. Vassallo. (*Gazz. Chim. Ital.*, 1911, **41**, 204-212.)—Logwood paper, prepared by saturating filter paper with an extract of 50 grms. of powdered logwood in 100 grms. of alcohol, gives characteristic reactions with solutions of different metals. Salts of bismuth give an intense violet coloration, which is stable even in an acid solution. Arsenic, antimony, and tin also give a violet colour in a neutral solution, but when sufficient acid is present only a red colour, due to the acid, is obtained; whilst molybdic solutions give an intense blue coloration. In applying the test it is best to allow the drop of liquid under examination to fall upon the test-paper, which is floated upon water slightly acidified. For the rapid detection of tin or bismuth in a mineral or alloy, the powdered sample is treated with nitric acid and a few crystals of sodium sulphate (to prevent the formation of insoluble bismuth arsenate), and heated until nitrous fumes appear. The residue is taken up with water, and the liquid filtered from the insoluble hydroxides of antimony and tin, whilst any bismuth arsenic, and molybdenum will be in the filtrate. The contents of the filter are washed with water acidified with nitric acid, and boiled with a saturated solution of tartaric acid, which will dissolve the antimony and leave the tin hydroxide. The latter, when boiled with a little sodium hydroxide and water, will give a solution, which will colour the logwood paper blue on account of the alkali present; but when the paper is floated on water acidified with nitric acid, the alkali is neutralised, and a violet coloration due to the tin will appear. The filtrate from the tin and antimony must be freed from molybdic acid by treatment with ammonia and sodium phosphate before testing for bismuth with the logwood paper. The test may be used in the volumetric estimation of bismuth, a standardised solution of disodium phosphate being added little by little to a dilute solution of bismuth nitrate which has been neutralised with ammonia, and then rendered acid again with 1 drop of dilute nitric acid. It is essential that the drops for spotting the test-paper should not be taken until the successive precipitates formed in the titration have completely subsided. The tabulated results thus obtained vary from + 0·11 to + 0·34 per cent. from the theoretical amounts of bismuth. C. A. M.

Estimation of Magnesium as Oxide. O. Kallauner. (*Chem. Zeit.*, 1911, **35**, 1165-1166.)—Whether ignited alone or in presence of mercuric oxide, the conversion of magnesium chloride to oxide is never quantitative. The proposal of Pfeifer (*Zeitsch. angew. Chem.*, 1909, **22**, 435), to heat to 450° C. only, leads to grave errors. By the use of a much higher temperature—namely, the highest attainable by means of a Teclu burner, or by double treatment with mercuric oxide, an hour suffices to give results sufficiently accurate for some technical purposes. By this the author means with an error not exceeding 1 in 400. G. C. J.

Estimation of Manganese in Vanadium and Chrome-Vanadium Steels. J. R. Cain. (*J. Ind. Eng. Chem.*, 1911, **3**, 630-631.)—Watters (*Met. Chem. Eng.*, 1911, **9**, 244) has described a method for the estimation of manganese in steels containing chromium and tungsten which eliminates the errors introduced by the use of the unmodified bismuthate method in the analysis of such steels. The steel is dissolved in sulphuric acid and oxidised by means of nitric acid, the solution is nearly neutralised, and the chromium and iron are precipitated by addition of an emulsion of zinc oxide. The mixture is made up to known bulk and filtered and in an aliquot portion of the filtrate manganese is estimated by the bismuthate method. The author has found the method satisfactory even with steels containing 0·2 per cent. of vanadium, but he suggests that for high vanadium products his cadmium carbonate method of precipitating chromium and vanadium (ANALYST, 1911, 476) is to be preferred. As a preliminary to a manganese determination, this method is carried out as follows: The steel (1 to 2 grms.) is dissolved in sulphuric acid (1 : 10), observing the precautions given in the paper quoted, and, without oxidising the iron, cadmium carbonate is used in the manner already described to precipitate the chromium and vanadium. Provided the iron is kept mainly in the ferrous state, no manganese will be co-precipitated. The solution is filtered, boiled with 25 c.c. of nitric acid until free from fumes, cooled and used for the estimation of manganese by the bismuthate method. G. C. J.

New Method of Separating Iron from Manganese. J. A. Sanchez. (*Bull. Soc. Chim.*, 1911, [iv.], **9**, 880-881.)—The hot solution of ferric and manganese salts is treated with pyridine, which precipitates the iron quantitatively as hydroxide, leaving the manganese in solution. In this way it is possible to separate 0·005 grm. of manganese from 1 grm. of iron. For the analysis of manganese ores 1 grm. of the sample is decomposed with hydrochloric acid, the silica separated in the usual way, and the bulk of the acid in the filtrate and washings neutralised with sodium hydroxide solution. The liquid is now made up to 200 c.c., treated with pyridine, and boiled for ten minutes, after which the precipitated iron hydroxide is separated and washed first with hot water saturated with pyridine and then with boiling water. When much manganese is present, the iron should be redissolved in hydrochloric acid and the precipitation repeated. In the case of minerals containing metals of the first group, the solution is treated with hydrogen sulphide, and the filtrate oxidised, nearly neutralised, and treated with pyridine as described. Zinc, if present, is also partially precipitated. In that case the precipitate should be redissolved in hydrochloric acid, and the iron reprecipitated by ammonium chloride and ammonia. C. A. M.

Analysis of Calcium Hypophosphite. E. Rupp and Kroll. (*Arch. Pharm.*, 1911, **249**, 493-497.)—A method of analysing calcium hypophosphite is based upon its quantitative oxidation to phosphate by means of bromine. The reagent contains 3·35 grms. of potassium bromate and 15 grms. of potassium bromide per litre, and 28 c.c. of it should liberate from acidified potassium iodide solution an amount of iodine corresponding to about 30 c.c. of $\frac{N}{10}$ thiosulphate solution. In making an estimation, 1·5 grms. of the calcium hypophosphite are dissolved in 500 c.c. of water, and 10 c.c. of the solution shaken in a stoppered flask with 50 c.c. of the reagent, after which 10 c.c. of dilute sulphuric acid are introduced, and the flask left for an hour in a dark place. Potassium iodide (1 grm.) is now introduced, the flask shaken, and allowed to stand for one or two minutes, and the liberated iodine titrated with $\frac{N}{10}$ thiosulphate solution; 1 c.c. of thiosulphate is equivalent to 0·00212 grm. of calcium hypophosphite. C. A. M.

Improved Hollemann's Method for the Estimation of Reverted Phosphoric Acid. E. Vittoria. (*Chem. Zeit.*, 1911, **34**, 1152.)—When a superphosphate is boiled for a few hours in a cold-saturated solution of ammonium nitrate, almost the whole of the phosphoric acid goes into solution. About 2 grms. of the superphosphate, finely ground and dried at 115° to 120° C., are vigorously boiled for about ten hours with 100 to 150 c.c. of ammonium nitrate solution, 10 c.c. of sodium acetate solution, and 500 c.c. of water; the water lost by evaporation is replaced from time to time, and the liquid is finally made up to 1 litre. Forty c.c. of this solution are made slightly alkaline with sodium hydroxide and shaken with 20 c.c. of $\frac{N}{10}$ silver nitrate solution; the silver phosphate is filtered off rapidly, and the excess of silver in the filtrate is titrated according to Volhard's method. J. F. B.

Assay of Platinum. A. Steinmann. (*Schweiz. Wochsch. Chem. u. Pharm.*, 1911, **49**, 441-444, 453-457; through *Chem. Zentralbl.*, 1911, II., 1061-1062.)—The ordinary assay for platinum consists of cupellation of the metal with lead, and at least twice its weight of silver, followed by rolling out the button, and parting the silver by means of boiling concentrated sulphuric acid. It is usual to run a control assay on platinum of known fineness, but it is said that the amount of platinum dissolved by the concentrated acid is very variable. It averages 2 to 3 per cent. of the metal, but may reach 5 per cent. The dissolved platinum may be recovered by evaporation of the parting acid, treatment of the residue with *aqua regia* to separate silver, and separation of the platinum finally as ammonium platinichloride. But the following modified method of assay is preferred. It depends mainly on the fact that sulphuric acid of 85 per cent. strength does not dissolve any appreciable quantity of platinum from its alloys with silver, whilst dissolving the silver readily.

The platinum or alloy is cupelled with silver, copper, and lead, the copper being approximately equal to the platinum present, the silver at least five times as much, and the lead according to a scale given in the paper. The button is rolled out to a thickness not exceeding 0·2 mm., and parted by the use of slightly diluted sulphuric acid (5:1), taking care that the temperature does not exceed 250° C. At 240° C. parting is complete in fifteen minutes. G. C. J.

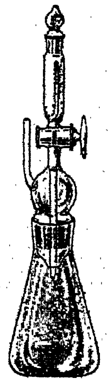
Detection of Small Quantities of Potassium as Cobalti-Nitrite. L. T. Bowser. (*J. Amer. Chem. Soc.*, 1911, **33**, 1566-1569.)—It has been found that by the method previously proposed (ANALYST, 1910, **35**, 141) the presence of alcohol with the mixture of potassium salt and cobalti-nitrite solution not only shortens the time of precipitation but increases the sensitiveness of the test some ten times. The omission of acetic acid, formerly employed, gives better results, the method being modified as follows: Five c.c. of the potassium solution in a tall beaker of narrow base and 50 or 100 c.c. capacity, and 5 c.c. of water in a similar beaker, are placed on a mirror, and 2·5 c.c. of sodium cobalti-nitrite reagent and 5 c.c. of alcohol (95 per cent.) added to each, rotating the solutions to mix the reagents. If upon looking downwards through the solutions into the mirror an equally sharp image of the observer can be seen in each beaker, potassium is absent; in the presence of two or more parts per million of this element the test solution yields a dimmer image than the blank test. It is necessary to avoid the presence of ammoniacal fumes and the presence of ammonium salts in the solution, and to have the solution neutral or slightly acid with acetic acid. Metallic salts do not interfere with the test. The solutions should be compared within a minute or two of mixing the reagents, as the first-formed precipitate gradually disappears. A. R. T.

Rapid and Accurate Method for the Analysis of White Metals. J. C. Beneker. (*J. Ind. Eng. Chem.*, 1911, **3**, 637-638.)—Tin and antimony are separated from other metals by a modification of Rössing's method (*Zeitsch. anal. Chem.*, 1902, **41**, 1), and their separate estimation depends on the fact that, in acid solution, both stannic and stannous sulphide yield stannic iodide on treatment with iodine, whilst both antimonious and antimonic sulphide yield antimonious iodide, the whole of the sulphur separating as such if iodine be present in excess. The antimonious iodide is subsequently titrated with iodine in presence of excess of sodium bicarbonate and the tin calculated from the volume of iodine solution required in this titration and that consumed by the mixed sulphides. The drillings (0·5 grm.) are dissolved in 25 c.c. of hydrochloric acid and 5 c.c. of nitric acid or in 25 c.c. of hydrochloric acid saturated with bromine. Tartaric acid (1 grm.) is added, and the mixture warmed on the steam bath. After diluting to about 400 c.c., the solution is made alkaline with caustic soda, and 20 c.c. of 10 per cent. sodium sulphide is then added. The sulphides of copper, lead, iron and zinc are washed twice by decantation, and subsequently on a filter with a hot dilute solution of sodium sulphide. The filtrate is rendered just distinctly acid with hydrochloric acid, and kept on the steam bath for an hour. The sulphides of tin and antimony (and arsenic if present) are then filtered off and washed with lukewarm water until free from hydrogen sulphide. They are next transferred with the filter-paper to a conical flask. A measured excess of $\frac{N}{10}$ iodine solution, 30 to 50 c.c. of hydrochloric acid and 2 grms. of tartaric acid are added to the contents of the flask, which is then fitted with a rubber bung carrying a swan-neck thistle tube containing a solution of potassium iodide. The contents of the flask are heated to boiling for a few minutes, then cooled and titrated with $\frac{N}{10}$ thiosulphate.

The titrated mixture is washed (or filtered if a sharper end point is desired) into a beaker, neutralised with sodium bicarbonate, after addition of powdered sodium bicarbonate, the antimonious iodide is titrated with $\frac{N}{10}$ iodine. One and a half times the volume of iodine required in this final titration is subtracted from that consumed by the mixed sulphides, and the remainder is calculated to tin (Sn = 4I). The results for antimony may be as much too low as corresponds to 0·1 c.c. of $\frac{N}{10}$ iodine, whilst those for tin may be as much too high as corresponds to 0·2 c.c. $\frac{N}{10}$ iodine, but are never below the truth. G. C. J.

Separation of Zinc and Sulphuric Acid. E. Schirm. (*Chem. Zeit.*, 1911, **35**, 1177, 1193-1194.)—*See* Precipitation of Zinc, etc., from Ammoniacal Solution by Means of Sodium Carbonate and Trimethylphenylammonium Carbonate (ANALYST, 1911, 599). G. C. J.

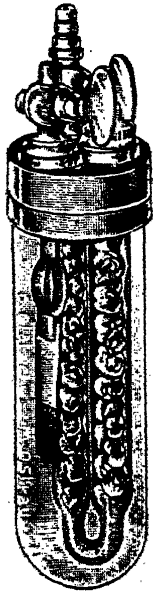
APPARATUS, ETC.



Apparatus for the Estimation of the Hexabromide Value of Oils. C. Niegermann. (*Chem. Zeit.*, 1911, **34**, 1131.)—The apparatus comprises a strong-walled Erlenmeyer flask of 200 c.c. capacity into which is ground a stoppered dropping funnel to contain the bromine; a side-tube is also provided in the stopper to allow the air to escape. For the estimation of the hexabromide value according to Hehner and Mitchell, which value stands in definite relationship to the iodine value of the oil, 1 to 2 grms. of the sample are weighed out into the flask and dissolved in about 40 c.c. of ether and 5 c.c. of concentrated acetic acid. The solution is thoroughly cooled, and bromine is admitted drop by drop, care being taken to keep the flask quite cold, until the brownish-red coloration is permanent. The liquid is allowed to remain for three hours, and the bromide is then collected on a tared filter dried at 100° C. The precipitate is washed with a few c.c. of cooled acetic acid, a little alcohol, and lastly with ether; it is then dried in the water-oven to constant weight. The resistance of the filter-paper to dilute bromine solution is controlled by a blank experiment. Swedish filter-paper is recommended in preference to asbestos. One dropping funnel and stopper may be made to fit several flasks. J. F. B.

Prevention of Bumping. H. Spurrier. (*J. Amer. Chem. Soc.*, 1911, **33**, 1632-1633.)—The author introduces into the flask containing the solution to be boiled a glass tube, open at both ends, and of such a length that the upper end rests, out of the liquid, against the side of the vessel. In the case of a liquid in a beaker, a cover should also be used to prevent loss. The device is particularly useful in the evaporation of the alcohol from aqueous liquids after saponification of an oil, where an oily layer remains on the surface of the liquid.

A. R. T.



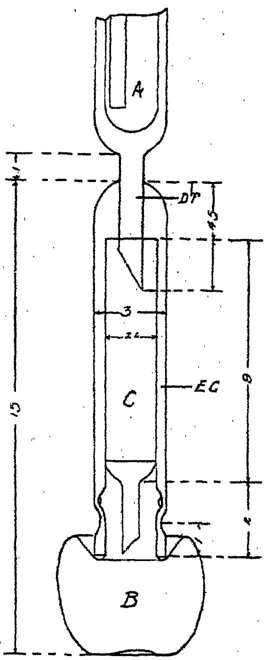
Carbon Monoxide Detector. R. Nowicki. (*Chem. Zeit.*, 1911, **34**, 1120.)—An apparatus by which even the smallest traces of carbon monoxide may be detected in the air is illustrated. It consists of a glass vessel strengthened by metal bands and fitted with a tap for the introduction of the air to be tested. A rubber bellows is attached to this tap, and is operated until the air passes through the vessel and out at a second tap. This second tap carries a clip, from which is suspended a strip of test-paper sensitive to carbon monoxide. The strip of paper is moistened with palladium chloride solution and becomes brown or black if any carbon monoxide be present. The time required for the appearance of the reaction is a measure of the proportion of carbon monoxide in the air, as ascertained by reference to a table. For instance, the presence of 0·01 per cent. by volume of carbon monoxide will give a visible change on the test-paper after eleven minutes, and total blackening after sixty minutes. The instrument is intended to be used for detecting escapes of gas from pipes or furnaces.

J. F. B.

New Accelerated Test for Paints. H. K. Benson and C. Pollock. (*J. Ind. Eng. Chem.*, 1911, **3**, 670-671.)—The bubbling test of Cushman (*Bull.* 35, *Office of Public Roads, U.S. Dept. of Agriculture*) for passivity of painted iron surfaces is useful, but is not sufficient alone to determine the efficiency of a paint. For example, its use alone places aluminium paint above all others in efficiency, which is not in accord with practical experience. The use of the following additional test is recommended: It depends on the measurement of the average electrical conductivity of a film of the paint during a six hours' test under standard conditions. Test pieces of steel, 1·4 × 1 × 0·3 inches, are prepared, and should preferably have rounded edges, as this facilitates rapid and uniform drying of the paint. Before painting, each test piece is put in good metallic connection with a stout copper wire. This is easily effected by bending of the wire at right angles half an inch from its end, and wedging the bent portion into a notch cut into the test piece with a hack saw. When these wires have been attached, the test pieces are given two coats of paint at intervals of a week, and when the second coat is apparently dry are kept for twelve hours in an oven at 45° C. Each test piece is then made the anode in a cell containing a normal salt solution, the cathode of platinum being placed at a distance of 4 inches. The copper conducting wire and the cathode are connected to a source of constant E.M.F.

(8 volts), a milliammeter being included in the circuit. Readings are taken immediately, and again at the expiration of ten, twenty, and thirty minutes, and one, two, and six hours, from the commencement of the experiment. The final readings are of the order of 100 milliampères. The reciprocal of the average current passing during the test is the measure of the resistant or insulating value of the paint. It is suggested that the product obtained by multiplying this value by the inhibitive value, as determined by Cushman's test (*loc. cit.*), is a better measure of the practical efficiency of a paint than either of these values alone. G. C. J.

Extraction Apparatus. C. K. Francis. (*J. Ind. Eng. Chem.*, 1911, 3, 673-674.)—Sealed on to a condenser, the lower end of which is shown in the illustration, is a tube, EC, 3 c.m. in diameter and constricted laterally to 2·7 c.m., at a point about 1 c.m. from its base which dips into the mercury contained in the re-entrant angle formed by the shoulder of the modified Knorr flask. The constriction runs nearly but not quite round the tube, so that in one position the points blown out on the neck of the flask can pass up into the tube EC. By giving the flask a quarter turn it is then supported by the points which rest on the constriction, thus dispensing with the necessity of any special support for the flask. The points on the neck of the flask are blown right out so as to provide two holes about 3 mm. in diameter for the upward escape of vapour to the condenser. The neck of the flask ends at the horizontal line below the letter C. The extraction tube C rests on the neck of the flask and is packed with cotton, asbestos, etc., before introducing the sample, or it may be replaced by a paper thimble supported on a very small funnel. G. C. J.



Rapid Filtering Funnel. H. Spurrier. (*J. Amer. Chem. Soc.*, 1911, **33**, 1584-1585.)—A funnel of the ordinary pattern filters far more rapidly if a series of etched lines (six or eight in number) be made from a point a little below the apex to a distance about halfway up the sides. A. R. T.

Consistency of Paints by the Stormer Viscosimeter. A. Rogers and A. H. Sabin. (*J. Ind. Eng. Chem.*, 1911, **3**, 737-738.)—The authors describe the use of the Stormer viscosimeter fitted with the cylindrical modification suggested by Forrest, as applied for the testing of paints. Glycerol of 95 per cent. strength is adopted as the standard, at a temperature of 20° C. The viscosimeter consists of a flat-bottomed cylindrical cup, $1\frac{7}{8}$ inches internal diameter by $2\frac{1}{2}$ inches deep, having two radial vertical wings or septa, $\frac{1}{4}$ inch wide, attached to its inner wall and extending from the bottom to within $\frac{5}{8}$ inch from the top, being obstructions to the rotary flow of the liquid. Within the cup is suspended a stirrer, the revolution of which is resisted by the viscosity of the liquid; this stirrer is a hollow metal cylinder $1\frac{3}{8}$ inches long and $1\frac{1}{4}$ inches in diameter, its lower end open, the upper end closed except for four holes, each $\frac{3}{16}$ inch in diameter, arranged symmetrically. The cylinder is supported from above by a vertical rod or shaft concentric with the cylinder, but external to it, being $\frac{3}{16}$ inch in diameter by $2\frac{1}{4}$ inches long. The end of the shaft is attached by a collar and screw to the bottom of a vertical shaft carrying a pinion $\frac{1}{2}$ inch in diameter with 25 teeth driven by a gear $5\frac{1}{4}$ inches in diameter with 275 teeth, to which is attached a drum around which is wound a small silk cord passing over a pulley and carrying a driving weight. The top of the shaft to which the small gear is attached also carries a worm, which engages and drives the serrated edge of a graduated disc, one revolution of which marks 100 revolutions of the stirrer. The stirrer is suspended so that its bottom is $\frac{3}{8}$ inch above the bottom of the cup, and its top is $\frac{3}{4}$ inch below the top of the cup; when in use the liquid stands $\frac{3}{8}$ inch above the top of the stirrer. To make 100 revolutions of the stirrer the weight descends about 39 inches. There is a clearance of $\frac{1}{16}$ inch between the stirrer and the two radial wings projecting from opposite sides of the cup.

The viscosity of any liquid placed in the cup is measured by the number of grms. required to cause the stirrer to make 100 revolutions in one minute; allowance must be made for the friction of the machine, which in a particular case was 5 grms. The instrument is used with a stop-watch, and is fitted with a friction clutch which, being opened, allows it to start. It is very important to make all observations at a standard temperature. J. F. B.

Substitute for Rubber Stoppers. (*Chem. Zeit.*, 1911, 35, 596.)—The device consists of a cap of rubber, with a hole bored in the crown for the reception of a leading tube. The cylindrical part of the cap, which is stretched over the neck of the flask, is of moderately thin rubber tube, but the crown is of sufficient thickness to give a reasonably long bearing to the tube which penetrates it, and thus to mainlain this approximately vertical. The caps are made by Bernard Tolmacz and Co., Berlin. G. C. J.

ERRATUM.—Page 526, lines 11 and 12, should read: "After washing free from sodium platinichloride and excess of hydrogen platinichloride, the potassium salt is dissolved. . . ."

REVIEW.

Analytical Chemistry. By F. P. Treadwell, Ph.D., Professor of Analytical Chemistry in the Polytechnic Institute of Zurich. English Edition, translated from the German by W. T. Hall, S.B., Instructor in Chemistry, Massachusetts Institute of Technology. Vol. II., Quantitative Analysis. Second Edition, thoroughly revised and enlarged. New York: John Wiley & Sons. London: Chapman & Hall. 1910. Pp. 787. Price $4.00.

This well-known work has already passed through four editions in German, which fact in itself constitutes a proof of its appreciation. The volume under review is the second English edition, and the text having been compared by the translator with the fourth German edition, certain additions have been made which are not to be found in the latter. Indeed, Mr. Hall, by reason of the numerous notes he has added, is rightly to be regarded as joint author.

Although there is no preface, it is plain that the work is intended as a students' textbook, and as such it fulfils its object, whilst it will also prove extremely valuable to the practising chemist, though obviously from its compass it cannot claim to be an exhaustive treatise. Such a work, in which the subject of quantitative analysis is dealt with on scientific lines, has long been needed for tutorial purposes, and the present volume certainly supplies this want.

The introductory chapter is concerned with generalities, and it contains some useful information on the principles of the balance, filtration and washing of precipitates, evaporation of liquids, drying of substances, etc. In regard to the washing of precipitates, the authors give the well-known formula for calculating the quantity of water required for this purpose; but although they point out that some precipitates require more water for their washing than others, and attribute this to adsorption, they omit to warn the student that it is not always advisable to drain a precipitate as dry as possible before the addition of washing water. That this is the case every practitioner is aware; nor, may it be added, is it invariably confined to amorphous, gelatinous precipitates. The ignition of wet precipitates is widely adopted by chemists, and there are cases where it is actually desirable; yet by most teachers it has hitherto been regarded as a rough-and-ready method. It is therefore interesting and satisfactory to observe that the present authors recommend it for those precipitates which do not suffer any permanent change by the combustion of the filter paper.

Following the introduction there are three main parts devoted to gravimetric analysis, volumetric analysis, and gas analysis, each part being subdivided. The exceptional order in which the gravimetric estimation of the metals is described appears difficult to justify. Thus, commencing with the alkali metals, the text deals *seriatim* with the alkali earths, the iron group and the sulphuretted hydrogen group. The last-mentioned group is further subdivided into "sulpho bases," comprising mercury, lead, bismuth, etc., and "sulpho acids," comprising arsenic, antimony, tin, gold, etc. This nomenclature will probably offend the susceptibilities of some of our purist colleagues. Non-metallic elements are classed together collectively as metalloids!

The methods both gravimetric and volumetric given throughout the book are for the most part well chosen, the descriptions are clear and concise, whilst the whole spirit of the teaching is based on scientific principles. The estimation of organic compounds in general does not enter into the text, although Kjeldahl's nitrogen method is described under ammonium. Here it is disappointing to find that potassium permanganate is still mentioned as one of the substances to be added to the sulphuric acid with which the substance being analysed is heated. Again the Jodlbauer modification is simply referred to, whereas a description of the latest modification should certainly have been included. The ninety pages of the text devoted to gas analysis contain some valuable matter for the student.

The text is well printed and the descriptions of the methods are rendered clearer by numerous illustrations. The book is distinctly to be regarded as a welcome addition to the literature of the subject. ARTHUR R. LING.

NEW BOOK.

THE MANUFACTURE OF CHEMICAL MANURES. By J. FRITSCH. Translated from the French, with numerous notes, by DONALD GRANT. Scott, Greenwood and Son, London, 1911. Price 10s. 6d. net.

This octavo volume contains 332 pages of subject-matter, with 69 illustrations, 108 tables, and an alphabetical index of subjects. The classification of the test is as follows: I. Phosphoric Acid. II. Principal Phosphate Deposits. III. Drying and Enrichment of Phosphates. IV. Historical Review of Superphosphate Manufacture. V. Theory of Manufacture of Soluble Phosphates. VI. Manufacture of Superphosphates. VII. Crushing, Sifting, Drying, and Storing of Superphosphate. Retrogradation. VIII. Compound Manures. IX. Manufacture of phosphoric acid, Double Superphosphates, and Various Products. Manufacture of Phosphorus in the Electric Furnace (Appendix). X. Manufacture of Bone-Dust and of Bone Superphosphate (Vitriolised Bones). XI. Basic Slag. XII. Nitrogenous Manures. XIII. Manure from Animal Waste. XIV. Recovery of Nitrogen from Distillery Spent Wash. Cyanamide and Nitrate of Lime. XV. Nitrogenised Phosphatic Manures. XVI. Potassic Manures. XVII. Transference and Handling of Raw Materials and Finished Products.

——, Monamino, Esterification of, by Means of Ethyl Iodide. Separation of Pyrrolidonecarboxylic Acid from Glutamic Acid, 360
——, Mono-Amino-, together with Polypeptides, Ester Method for the Detection of, 272
——, Nitric and Nitrous, in Acetic Acid Solution, the Determination of. The Stability of Nitric Acid in Acetic Acid Solution, 303
—— of the Oleic Series, the Iodine Value and the Structure of, Relationship between, 463
——, Succinic and Malic, in Wine, Estimation of, 453
——, the Higher Fatty, in Ether and in Petroleum Ether, Solubilities of the Lead Salts of, 399
Adiabatic Device for Bomb Calorimeter, 326
Adsorption, on the Application of, to the Detection and Separation of Certain Dyes, 339
Adulterants in Saffron, Detection of, 309
- in Vegetable Powders, Apparatus for the Estimation of, and Notes on Starch Granules, 529
-, Linseed Oil and its, Tests for, 192
Adulteration, Detection of, by Colloidal Chemical Methods, 557
———— of Cayenne Pepper, Detection of, 259
Aerated Water, the Bacteriology of, 395
Africa, British West, Kola Nuts from, 258
Agricultural Chemistry, Solubility Estimations in, 37
Air, Ether and Chloroform Vapours in, Gasometric Estimation of, 513
Alanin, Separation of Glycin from, and Composition and Properties of Glycin Picrate, 570
Albumin in Urine, the Detection of, Sensitive Test for, 505
———, the Coagulation of, by Heat, and its Precipitation by Mercuric-Potassium Iodide. Gravimetric and Volumetric Estimations, 458

Albumoses, Compounds of Ferric Salts with, 408
——— in Urine, Detection of, 24
Alcohol and a Neutral Salt, Simultaneous Effect of, on the Sensitiveness of Phenolphthaleïn, 321
——— and Sugars, the Iodimetric Titration of Sulphites in Presence of, 439
———, Estimation of Methyl Alcohol in Admixture with, and especially in Spirits, 514
———, Estimation of, New Method for, 565
———, Methyl, in a Current of Air, Separation of Arsenic from Antimony and Other Metals by Means of, 414
———, ———, in Admixture with Alcohol, and especially in Spirits, Estimation of, 514
———, ———, in Ethyl Alcohol, and Spirits, Detection of, 567
———, ———, Small Quantities of, Note on the Determination of, 16
the Detection and Estimation of, 364
-- Soluble Protein or Gliadin in Wheat-Flour, Determination of, 19
-- Test, the Reductase Test, and Acidity, in Milk, Relations between, 26
Alcohols and Alcoholic Hydroxyl Groups, Colour Reaction of, 407
———, Tertiary, Detection of, 197
Alcoholysis, Proximate Analysis of Complex Lipoids by, 463
Aldehyde Figure of Butter, 50
Aldehydes, Angeli's Reaction for, 359
———, Determination of, 568
———, Ehrlich's Reaction for, and Urobilinogen of Urine, 28
Aldoses and Ketoses, Method of Distinguishing between, 266
Aleurone Layer and Embryo of Hordeum, Amyloclastic Secretory Capacities of the, 97
Alkali and Hydrogen Peroxide, Behaviour of Invert Sugar in the Presence of, 28
——— Bicarbonate, Small Quantities of, Detection of, in Presence of Much Normal Carbonate, 372
——— Carbonates, Fusion of Certain Rare Earths with. Separation of Tungsten from Iron, Beryllium, and Aluminium, 591
Alkaline Permanganate Method, Activity of Organic Nitrogen as Measured by the, 365
Alkalinity and Peroxydase of Milk : are they Identical? 141
Alkalis in Silicates, Estimation of, by Fusion with Calcium Chloride, 146
———, Titration with, in the Presence of Phenolphthaleïn, Estimation of Free Carbon Dioxide in Water by, 582
Alkaloidal Assay of Calabar Beans, 142
Alkaloids, Certain, Micro-Chemical Detection of, 137
———, Extracting from Syrups, Process of, 138
———, Some of the, Micro-Chemical Tests for the Identification of, 400
Allo- and Neo-Chlorophyll in the Presence of One Another, Methods for Determining, 460
Alloys, High-Grade Tungsten, Analysis of, 424
———, Platinum, Analysis of, 420
Aluminium, Arsenic, Zinc, Tungsten, and Tin, Quantitative Separation of Copper from, by Means of Hydrogen Peroxide in Presence of Sodium Hydroxide and Sugar, 210
——— and Iron, Separation of Zirconium from, and a New Method for the Analysis of Ferro-Zircon, 36
———, Iron, and Beryllium, Separation of Tungsten from. Fusion of Certain Rare Earths with Alkali Carbonates, 591
———, Separation of Beryllium from, 373
Alundum Plates, Filtration with, 109
Amines, Tertiary, the Separation of, from Primary and Secondary Amines, New Method for, 201

Amino-Acids in Plants, Estimation of, by Means of the Formaldehyde Method, 312
————, Precipitant for, 359
————, Some, and Polypeptides, Hydrolytic Action of, on Certain Esters. Studies on Enzyme Action, 353
Amino-, Hydroxy-, and Imino-Derivatives of Organic Compounds, Quantitative Estimation of, by Means of the Grignard Reagent, and the Nature of the Changes Taking Place in Solution, 201
Ammonia and Ammonium Salts, Pyridine Bases in, Detection of, 413
Pyridine, Separation and Estimation of, 413
, Colour Reaction of, 468
in Carbonated Waters, the Estimation of, 173
Rapid Estimation of Pyridine in Gas-Water in the Presence of, 574
Ammonium Chloride, Inversion of Sucrose Solutions by Means of, 576
———— Citrate Solution, Neutral, 372
———— Molybdate Method of Lead Assay, on the Effect of Lime on the, 242
———— Salts and Ammonia, Pyridine Bases in, Detection of, 413
———— Sulphate, Behaviour of Milk when Treated with, and a New Method for the Estimation of Lactose, 350
Amyloclastic Secretory Capacities of the Embryo and Aleurone Layer of Hordeum, 97
Amylase, Pancreatic, a Further Investigation of the Properties of. Studies of Amylases, 454
Analysis, Crystallo-Chemical: a New Method of Chemical Analysis, 526
————, Electro-Chemical, Perchloric Acid in, 279
————, Elementary, 508
————, Food, New Sublimation Apparatus, and its Application in, 428
————, Gravimetric, Simplification of, 31
————, Luminescence, 526
————, Mechanical, of Arid Soils, 588
————, Organic Elementary, New Silver Spiral for Use in, 289
————, Potash (Potassium-Sodium Cobaltinitrite Method), 588
————, ————, without Hydrogen Sulphide, 377
————, Qualitative, System of, for the Common Elements. Part V.: Acidic Constituents, 322
————, Rational, of Nitrate of Soda, 523
————, Soil, Mechanical, Modification of the Method of, 589
————, Sugar, by Copper Reduction Methods, a Critical Study of, 414
————, Technical, of Spelter, 521
————, Volumetric, Arsenious Acid in, Use of. II.: Estimation of Mercury, 321
————, Water, Geochemical Interpretation of, 107
Analytical Chemistry, Certain Problems in, Application of Light Energy to the Study of, 479
————————, Study of Cobaltinitrites, and their Application to, 322
————————, Ultrafiltration in, Application of, 223
———— Constants of Some Vegetable Fats, 349
———— Work, Use of a Mixture of Nitric Acid and Hydrogen Peroxide in, 212
——, —— of Magnesia Rods instead of Platinum Wire in, 222
Angeli's Reaction for Aldehydes, 359
Aniline Dyes and Turmeric in Mustard, Detection of, 557
Animal Nutrition, the Value of Ordinary and Treated Sawdust for, Experiments on, 559
——— Substances, Fat in, Kumagawa-Suto Method of Estimating, 354
——— Tissues, the Drying of, Loss of Fat during, 355
Annual Address by the Retiring President, 81

Antimony and Arsenic, Detection, Separation, and Estimation of, 65
——————, Separation and Estimation of, 206
——————, Traces of, Detection of, 581
——— and Other Metals, Separation of Arsenic from, by Means of Methyl Alcohol in a Current of Air, 414
————————, the Separation of Arsenic from, with Some Applications to Toxicological Work, 229
——— and Tin, Bronzes containing, Estimation of Chromium in, 374
———, Copper, Bismuth, and Tin, Electro-Analysis of, with Acidified Chloride Electrolytes, 584
——— in Red Rubber Goods, Estimation of, 64, 65
Antiseptic Effect of Creosote Oil and Other Oils Used for Preserving Timber, 56
Apparatus, etc., Abstracts, 36, 68, 108, 153, 221, 286, 326, 382, 426, 478, 526, 592
———, Boiling-Point, the Landsberger, Modification of, 326
———, Constant-Temperature Heating, for Explosives, and Experiments on the Decomposition of Nitrocelluloses, 222
———, Convenient, for Obtaining an Average Sample of Gas, and for Regulating the Flow of a Gas into an Evacuated Vessel, 250
———, Electrolytic, for Use in Invert Sugar Determinations, 576
———, Extraction, 427
———, ———, New, 39
——— for Automatic Analysis of Liquids, 480
——— for Automatically Decanting and Washing Precipitates, 479
——— for Controlling the Evaporation or Distillation of Liquids, and for Cutting off the Supply of Gas to a Burner after any Desired Length of Time, 221
——— for Determination of Vapour Pressure Isothermals of Silicic Acid Gels, 328
——— for Extracting Liquids with Immiscible Solvents, and for Measurement of Evolved Gases, 69
——— for Measuring Liquids in an Atmosphere Free from Carbon Dioxide, 222
——— for Rapid Distillation of Mercury *in Vacuo*, 528
——— for Rapid Removal of Nitrogen from Gas Mixtures by Sparking, 224
——— for the Detection of Carbon Monoxide, 426
——— for Testing Water by Measurement of its Electrical Conductivity, 538
——— for the Estimation of Adulterants in Vegetable Powders, and Notes on Starch Granules, 529
———, Gas Analysis, New Forms of, 288
———, Laboratory, Two New Pieces of, 528
———, New, for the Coking Test of Coal, 383
———, ——, for Vacuum Sublimation, 290
———, —— Sublimation, and its Application in Food Analysis, 428
———, Shaking and Stirring, Thermostats, etc., Notes on, 70
———, Simple, for Sublimation in a Vacuum, 38
———, Soxhlet Extraction, Modified, with Distillation Arrangement, 596
———, the Beckmann, Modification of, 384
Apple, Insoluble Carbohydrates of the, 492
Arable Soils, Colloids in, Estimation of, 98
Arachis Oil, the Detection and Estimation of, 487, 537
Arid Soils, Mechanical Analysis of, 588
Arnold and Hardy, the Method of, for the Rapid Estimation of Sulphur in Siderurgical Products, Modification of, 283
Arsenates, Commercial Lead, Determination of Soluble Arsenic in, Short Method for, 206
Arsenic Acid, Titration of, 580

Arsenic, Aluminium, Zinc, Tungsten, and Tin, Quantitative Separation of Copper from, by Means of Hydrogen Peroxide in Presence of Sodium Hydroxide and Sugar, 210
——— and Antimony, Detection, Separation, and Estimation of, 65
———————, Separation and Estimation of, 206
———————, Traces of, Detection of, 581
———, Estimation of, 415
——— in Gelatin, Occurrence of, 94
——— in Organic Compounds, Detection and Estimation of, 66, 360
———————, Estimation of, 579
——— in Vegetable Foods, Amounts of, 254
———, Separation of, from Antimony and Other Metals by Means of Methyl Alcohol in a Current of Air, 414
———, Small Quantities of, Determination of, by the Gutzeit Test, 579
———, Soluble, in Commercial Lead Arsenates, Short Method for Determination of, 206
———, the Separation of, from Antimony and Other Metals, with Some Applications to Toxicological Work, 229
——— Xanthogenate, and its Use in Analysis, 569
Arsenious Acid, Estimation of, with Permanganate in Presence of Hydrochloric Acid, 417
———, Use of, in Volumetric Analysis. II.: Estimation of Mercury, 321
——— Chloride, Volatility of, 580
Asphalt in Mineral Oils, Pitch, etc., Estimation of, 58
Asphalts, Natural and Petroleum-Residue, Differentiation between, 407
Aspirator, Constant Flow, 481
Atmosphere Free from Carbon Dioxide, Apparatus for Measuring Liquids in, 222
Atomic Weights, International, 1912, 1
Australian Sweetened Condensed Milk, Composition of, 49
——— (Victorian) Milk, Composition of, 47
Autolysis, Effect of, on Cholesterol; Errors in the Estimation of Cholesterol by the Ritter Method, 199
Automatic Analysis of Liquids, Apparatus for, 480
——— Pressure Pipette, 153
Automatically Decanting and Washing Precipitates, Apparatus for, 479
Azo Dyestuffs, Titration of, by Means of Hydrosulphite, 568

Bacteria in Water, Direct Enumeration of, by Means of the Ultra-Microscope, Value of, 317
———, the Power of, to Decompose Proteins, Determination of. Method of Testing Water, 264
BACTERIOLOGICAL, PHYSIOLOGICAL, ETC., ABSTRACTS, 24, 56, 97, 140, 195, 262, 312, 352, 403, 454, 503, 561
Bacteriology of Aerated Water, 395
Baking Qualities of Flour, 190
———————, Influence of the Concentration of Hydrogen Ions on, 257
Balsam, Peru, Cinnamein in, Estimation of, 93
Banana Starch, Polarimetric Estimation of, 560
Bases, Organic, New Reaction for, 319
———, Pyridine, in Ammonia and Ammonium Salts, Detection of, 413
Bassia Kernels and Fats, 54
Bath, the Waters of the Thermal Springs of, Analysis of, 478
Beans, Calabar, Alkaloidal Assay of, 142
———, ———, Chemical Examination of, 60

Beans, Edible, from Hong-Kong, 494
Beckmann Apparatus, Modification of, 384
———— Thermometer, with a Modified Arrangement for Setting the Mercury Thread, 429
Beer and Wort, Bitter Principles in, Estimation of, 92
————, Extract in, Estimation of, 502
Beers and Worts, Bitter Resins of Hops in, and their Volumetric Estimation, 139
Beeswax and Carnauba Wax, Hydrocarbons in, Estimation of, 348
————, Refractive Index of, 348
Benzaldehyde in Maraschino Cherries and Liqueur, Estimation of, 446
Benzene Hydrocarbons and Petroleum Spirit in Turpentine Oil, Estimation of, 274
Benzoic Acid as an Acidimetric Standard, 458
————, Hippuric Acid, and Phenaceturic Acid in Urine, Estimation of, 356
———— in Foods, Detection of, 349
———— in Margarine, Butter, and Other Fats, Estimation of, 92
———— in Milk, the Detection of, Note on, 346
Benzol, Commercial, Sulphur Compounds in, Estimation and Elimination of, 100
(Benzoyl Peroxide) Lucidol, Influence of, on Certain Qualitative Tests for Oils, 273
Bertrand's Method, Estimation of Dextrose in the Presence of Other Optically Active Substances by, 512
Beryllium, Gravimetric Estimation of, 581
————, Iron, and Aluminium, Separation of Tungsten from. Fusion of Certain Rare Earths with Alkali Carbonates, 591
Separation of, from Aluminium, 373
--, Volumetric Estimation of, 276
Beverages and Foods, Saponin in, Detection of, by Hæmolysis, 350
————, Fermented, Caramel in, Detection of, 18
————, Foods, and Drugs, Saccharin and Dulcin in, Separation and Identification of, 23
Bicarbonate, Alkali, Small Quantities of, Detection of, in Presence of much Normal Carbonate, 372
Bilirubin, Small Quantities of, Estimation of, 352
Biochemical Method, Application of, to the Analysis of Uva-Ursi Leaves, 24
———— for the Estimation of Small Quantities of Salicylic Acid in Presence of Excess of *p*-Hydroxybenzoic Acid, 316
Biological Analysis, the Petri Dish for Cultivating Fungi and for, Substitute for, 561
Birds and Mice, Use of, for Detecting Carbon Monoxide after Mine Fires and Explosions, 315
Bismuth, Copper, Antimony, and Tin, Electro-Analysis of, with Acidified Chloride Electrolytes, 584
Bismuthate Method, Determination of Manganese by, 522
———— for Manganese, 148
————, the Estimation of Manganese by, 554
Bitter Principles in Wort and Beer, Estimation of, 92
—— Resins of Hops in Worts and Beers and their Volumetric Estimation, 139
Bituminous Materials, Examination of, 266
Bleaching, Natural and Artificial, Processes of, Report to the Local Government Board on the Nature of the Colouring Matter of Flour, and its Relation to, 596
———— Purposes, Sodium Peroxide for, Assay of, 476
————, Quality of Sulphite Pulp, Determination of, 511
Blende, Roasted, Sulphur in, Rapid Method for Determination of, 150
Blood and Urine, Dextrose in, Estimation of, 140
————, *l*-β-Hydroxybutyric Acid in, Quantitative Estimation of, 314

Blood and Urine, Quinine in, Quantitative Estimation of, 455
————————, Sugar in, Estimation of, 356
——, Fat and Lipoids in, Estimation of, and Notes on the So-Called Lipolysis, 561
—— in Blood-Stains, Chemical Detection of, 454
—— in Urine and Other Physiological Fluids, Detection of, 506
—— Spectra, the Intensity Distribution in, Photographic Estimation of, 313
—— -Stains, Blood in, Chemical Detection of, 454
——, Sugar in, Estimation of, 141, 263
Blue Colour-Reaction of Phosphotungstic Acid with Uric Acid and Other Substances, 355
Boiling Liquids, the Bumping of, Device for Preventing, 153
—— -Point Apparatus, the Landsberger, Modification of, 326
—— Sulphuric Acid, Action of, on Platinum, 590
Bomb Calorimeter, Adiabatic Device for, 326
——, New Calorimeter, with Special Advantages as to Material of Construction and Method of Operation, 592
Books, New, 294, 601
Books, Reviews of:
  A Textbook of Practical Chemistry for Technical Institutes, 73
  Alcools. Alcool, Alcool Dénaturé, Dénaturants, 39
  Allen's Commercial Organic Analysis, 385

  The Technology of Bread-Making: Chemistry and Analysis of Materials Used in Bread-Making and Confectionery, 115
  Theorie und Praxis der Massanalyse, 534

BOOKS, REVIEWS OF—*continued*
Vins, 599
Volumetric Analysis for Students of Pharmaceutical and General Chemistry, 390
Water Analysis for Sanitary and Technical Purposes, 482
Boric Acid in Nickel Baths, Estimation of, 277
———, Minute Traces of, Detection of, by Means of Tincture of Mimosa Flowers, 558
British West Africa, Kola Nuts from, 258
Bromide Method, Hübener, for the Estimation of Caoutchouc, 509
———, Hübener's, for the Estimation of Caoutchouc, 202
———, Hübener, for the Estimation of Rubber, 465
Bromine Absorption of Certain Vegetable Oils and Fats, 403
——— and Iodine Methods for the Volumetric Estimation of Cresol, 408
———, Detection of, by Fluorescein, 145
———, Free, Sensitive Reaction of, 581
——— in Aqueous Solution, Estimation of Cinnamic Acid by Means of, 102
Bronzes Containing Tin and Antimony, Chromium in, Estimation of, 374
Bullion and Ores, Small Amounts of Platinum in, Direct Determination of, 281
———, Gold, Sampling, 517
Bumping of Boiling Liquids, Device for Preventing, 153
Bunsen Burners, Porcelain, 426
Butter and Lard, Cocoanut Oil in, Detection of, 93
——— Fat and Cocoanut Oil in Margarine, the Determination of, Notes on, 122
———, Cocoanut Oil in, the Detection of, and Crude Phytosterol of Cocoanut Oil and the Crude Cholesterol of Butter Fat, 497
———, Margarine, and Other Fats, Benzoic Acid in, Estimation of, 92
———, Shea-, and Shea-Nuts, 496
———, the Aldehyde Figure of, 50
———, the Keeping Properties and Composition of, Influence of Certain Preservatives on, 52
———, Water in, Estimation of, 51
Butyrometer Tube, Modified, for the Estimation of Fat in Cheese, 221

Cadmium Potassium Iodide, Determination of Ozone by Means of, 587
Caffeine, New Method of Estimating, 401
Cake and Oil, Tea-Seed, 500
Calabar Beans, Alkaloidal Assay of, 142
———, Chemical Examination of, 60
Calcium Carbide, Method for Estimation of Moisture, 475
——— Carbonate in Soils, a Method of Estimating, 128
——— Chloride, Estimation of Alkalis in, Silicates by Fusion with, 146
Calorimeter Bomb, Adiabatic Device for, 326
——— Bomb, New, with Special Advantages as to Material of Construction and Method of Operation, 592
Camphor, Estimation of, 93
Candied Lemon Peel, Analysis of, 20
Cane-Sugar, Detection of, 493
——— in Foods, etc., Estimation of, 493
——— in Urine, Estimation of, in the Presence of Other Sugars, 506
Caoutchouc, Estimation of, as Tetrabromide, 361
———, the Estimation of, Hübener Bromide Method for, 509
———, ———, Hübener's Bromide Method for, 202
Capsicum (Cayenne Pepper), Composition of, 56

Caramel in Fermented Beverages, Detection of, 18
Carbohydrates, Insoluble, of the Apple, 492
Carbon Bisulphide in Oils, Detection of, 101
——— Dioxide, an Atmosphere Free from, Measuring Liquids in, Apparatus for, 222
——————, Free, in Water, Estimation of, by Titration with Alkalis in the Presence of Phenolphthaleïn, 582
——————, the Reaction of Liquids Containing, Electrometric Determination of, 416
———, Estimation of, by Moist Combustion, 459
——— in Ferro-Alloys, Use of Oxygen under Pressure for Estimating, 379
——— in Steel, Determination of, by Direct Combustion in the Newest Form of Shimer Crucible, with the Aid of a Perforated Clay Disc, 521
——————, the Estimation of, 392
——— Monoxide after Mine Fires and Explosions, Use of Birds and Mice for Detecting, 315
——————, Rapid Estimation of, 106
Carbonate, Magnesium, Magnesia in Admixture with, Estimation of, 211
————, Much Normal, Detection of Small Quantities of Alkali Bicarbonate in Presence of, 372
Carbonated Waters, Ammonia in, the Estimation of, 173
Carbonates, Alkali, Fusion of Certain Rare Earths with, Separation of Tungsten from Iron, Beryllium, and Aluminium, 591
————, Metallic, Influence of, on the Estimation of the Volatile Substances in Coal, 360
Carbonic Acid, Volumetric Determination of, 207
Carnauba Wax and Beeswax, Hydrocarbons in, Estimation of, 348
Carotin, Detection of, 199
Casein, Commercial, Analysis of, 493
Castor-Bean Lipase, Experiments with, 316
Catalase, Reductase, and Leucocyte Tests, Comparative Value of, in Detecting Mastitis, 401
———, Separation of Peroxydase from, 315
Catalytic Action of Light on the Oxidation of Phenolphthalin to Phenolphthaleïn, 30
Cathode, Mercury, Use of, particularly in the Electro-Analytical Separation of Metals, 279
Cayenne Pepper, Adulteration of, Detection of, 259
(Cayenne Pepper) Capsicum, Composition of, 56
Cellular Membranes, Structural Elements of, 503
Cellulose in Woods and Textile Fibres, Estimation of, 268, 510
Cement and Cement Raw Materials, Analysis of, 208
———, Portland, Free Lime in, Use of Higher Phenols in Testing for, 582
——— Raw Materials and Cement, Analysis of, 208
Centrifuge, Laboratory, for Quantitative Separation and Estimation of Solids and Liquids, 286
Ceresin and Paraffin Wax, Mixtures of, Analysis of, 59
Ceylon Tobaccos, Analyses of, 500
Champaca Oils, 28
Changes taking place in Meats, Physico-Chemical Method for Determining, 455
Charcoal as a Clarifying Agent in the Estimation of Sugar in Urine, Use of, 57
Cheese, the Estimation of Fat in, Modified Butyrometer Tube for, 221
Chemical Analysis, a New Method of: Crystallo-Chemical Analysis, 526
Chemistry, Agricultural, Solubility Estimations in, 37
Cherries and Liqueur, Maraschino, Benzaldehyde in, Estimation of, 446

Chinese and Japanese Wood Oil, the Examination of, 543

——— Wood Oil, Heat Test for, 410

——————, Method of Examining, 410

——————, Refractive Index of, 410

Chloral, Small Quantities of, Detection of, in Presence of Chloroform, 254

Chlorates, and Chloric Acid, Volumetric Estimation of, 373

Chloride, Ammonium, Inversion of Sucrose Solutions by Means of, 576

———, Arsenious, Volatility of, 580

———, Calcium, Estimation of Alkalis in Silicates by Fusion with, 146

———, Electrolytes, Acidified, Electro-Analysis of Copper, Antimony, Bismuth, and Tin with, 584

———, Mercury-Ammonium, the Analysis of, Gravimetric and Volumetric Methods for, 33

———, Titanous, Titration of Copper Salts with, 516

(Chlorites), Chlorous Acid, Estimation of, 583

Chloroform, Small Quantities of Chloral in Presence of, Detection of, 254

———— Vapours and Ether in Air, Gasometric Estimation of, 513

Chlorophyll, Minute Quantities of, Delicate Method for Determining, 503

Chlorous Acid (Chlorites), Estimation of, 583

Cholesterol, Effect of Autolysis on; Errors in the Estimation of Cholesterol by the Ritter Method, 199

————, the Crude, of Butter Fat, and Crude Phylosterol of Cocoanut Oil, and the Detection of Cocoanut Oil in Butter Fat, 497

Chromium, Estimation of, and its Separation from Vanadium Steels, 146

———— in Bronzes Containing Tin and Antimony, Estimation of, 374

Cineol in Volatile Oils, Estimation of, 461

Cinnamein in Peru Balsam, Estimation of, 93

Cinnamic Acid, Estimation of, by Means of Bromine in Aqueous Solution, 102

Citric Acid, Estimation of, 199

Citronella Oil, Geraniol in, Direct Estimation of, 363

————, Oil of, Analysis of, 567

Clarifying Agent in the Estimation of Sugar in Urine, Use of Charcoal as, 57

Clavicepsin: A New Glucoside in Ergot of Rye, 19

Coagulation, Mechanism of, 353

———— of Albumin by Heat and its Precipitation by Mercuric-Potassium Iodide. Gravimetric and Volumetric Estimations, 458

Coal and Coke, Methods of Analysing, 317

—— -Mines, Explosives Used in, Investigations of, 290

—— -Tar Dyestuffs, the Seven, Allowed (U.S.A.) to be Employed for Colouring Foodstuffs, Mixtures of, Method for Separating, 19

——, the Coking Test of, New Apparatus for, 383

——, the Volatile Substances in, the Estimation of, Influence of Metallic Carbonates on, 360

(Cobaltinitrite Method, Potassium Sodium), Potash Analysis, 588

Cobaltinitrites, and their Application to Analytical Chemistry, Study of, 322

Cocoa, Cocoa-Husks in, Estimation of, 52

———, Fat in, Estimation of, by Means of Zeiss' Refractometer, 495

——— -Husks in Cocoa, Estimation of, 52

——— Powders, Husk in, Estimation of, 402

Cocoanut Oil and Butter Fat in Margarine, the Determination of, Notes on, 122

———— in Butter and Lard, Detection of, 93

———— ———— Fat, the Detection of, and Crude Phytosterol of Cocoanut Oil and the Crude Cholesterol of Butter Fat, 497

————, Shrewsbury and Knapp's Process for Estimating, Notes on, 3

Cocoanut Oil or Palm Kernel Oils, Margarines Containing, on the Relation between Kirschner and Polenske Values for, 183
Coin, a Counterfeit Gold, Note on, 7
Coke and Coal, Methods of Analysing, 317
Coking Test of Coal, New Apparatus for, 383
Cold Solvents, Estimation of Fat by Extraction with, 102
Colloidal Chemical Methods, Detection of Adulteration by, 557
———— Silicic Acid, Phosphoric Acid in Presence of, Estimation of, 214
———— Solutions, the Concentration of, Estimation of, with the New Interferometer for Liquids, 382
Colloids in Arable Soils, Estimation of, 98
Colorimeter for Rapid Work with Widely Varying Standards, 329
Colorimetric Determination of Iron in Lead, and its Oxides, 520
———— Estimation of Hydrogen Ion Concentrations, Application of Methyl-Red to, 142
———— ———— Phenols in Effluents, 30
Salicylic Acid and Copper, 104
———— Method for the Estimation of Tryptophane, and the Quantity of Tryptophane in Horny Tissue and Other Proteins, 565
———— Method for the Estimation of Uric Acid, 358
———— ————, New, for the Determination of Vanillin in Flavouring Extracts, 501
for Titanium, 590
Colour Reaction, Blue, of Phosphotungstic Acid with Uric Acid and Other Substances, 355
———— of Alcohols and Alcoholic Hydroxyl Groups, 407
———— of Ammonia, 468
Colouring Matter of Flour, the Nature of, and its Relation to Processes of Natural and Artificial Bleaching, Report to the Local Government Board on, 596
Combustion of Volatile Organic Liquids, 361
Commercial Benzol, Sulphur Compounds in, Estimation and Elimination of, 100
———— Casein, Analysis of, 493
———— Lead Arsenates, Determination of Soluble Arsenic in, Short Method for, 206
———— Rennet, the Activity of, Estimation of, 564
———— Starches for Use in Cotton Mills, Method for Determining the Value of, 368
———— Value of Wood Preservatives, Tests to Determine, 578
Compensation Method, New, for the Comparison of Quantities of Radium, and Some Applications of this Method, 473
Complex Lipoids, Proximate Analysis of, by Alcoholysis, 463
Condensed Milk, Sucrose in, Estimation of, 450
————, Sweetened, Australian, Composition of, 49
Conductivity, Electrical, an Apparatus for Testing Water by Measurement of its, 538
Congress of Applied Chemistry, Eighth International, 228
Conifers, Oxalic Acid in the Leaves of, Estimation of, 204
Constant Flow Aspirator, 481
————-Pressure Hydrogen Generator, 331
————-Temperature Heating Apparatus for Explosives and Experiments on the Decomposition of Nitrocelluloses, 222
Continuous Fractional Distillation of Water, 474
Copaiba Oil, Examination of, 347
Copper Analysis, the Iodide Method of, the Electrolytic Standardisation of the Conditions of, and Sources of Error, 277

Copper and Salicylic Acid, Colorimetric Estimation of, 104
———, Antimony, Bismuth, and Tin, Electro-Analysis of, with Acidified Chloride Electrolytes, 584
——— -Arsenic Group, Precipitation of, and Separation of its Divisions, 376
———, Determination of: A Modification of the Iodine Method, 66
——— Fungicides, 262
——— in Pyrites, Electro-Analytical Estimation of, 468
———, Iodimetric Estimation of, 375
———, Oxygen and Occluded Gases in, Estimation of, 375
———, Quantitative Separation and Estimation of, by Means of Hydroxylamine Hydrochloride, 583
———, Quantitative Separation of, from Arsenic, Aluminium, Zinc, Tungsten, and Tin, by Means of Hydrogen Peroxide in Presence of Sodium Hydroxide and Sugar, 210
——— -Reducing Power of Normal Urine, 264
——— Reduction Methods, Sugar Analysis by, a Critical Study of, 413
———, Small Quantities of, in Plants, Detection and Estimation of, 313
Cotton Mills, Commercial Starches for Use in, Method for Determining the Value of, 368
——— Wax, Characteristics of, 202
Cow's and Goat's Milk, the Serum of, Refractometer Value of, 317
Cream and Milk Regulations (Draft), Government Report, 109
———, Milk, etc., Certain Proprietary Substances Sold as Preservatives for, Analyses and Methods of Detection of, Report to the Local Government Board on, 155
———, ———, ———, New Preservative for, Note on, 178
Creosote Oil and Other Oils Used for Preserving Timber, Antiseptic Effect of, 56
———, the Sulphonation Test for, Modification of, 269
Cresol, the Volumetric Estimation of, Bromine and Iodine Methods for, 408
p-Cresol and Phenol in the Presence of Each Other, Estimation of, 62
Crucible, Shimer, the Newest form of Determination of Carbon in Steel by Direct Combustion in, with the Aid of a Perforated Clay Disc, 521
Crucibles, Porcelain, etc., Marking of, 289
Crude Fibre, Estimation of, 447
———, the Sweeney Method for, Modification of, 447
Crystallo-Chemical Analysis: A New Method of Chemical Analysis, 526
Cyanides, Detection and Estimation of Halides in the Presence of, by Means of Formaldehyde, 461
Cyanogen and Hydrogen Cyanide, Detection and Determination of, 511
Cypress, the Southern, Oil of, 364

Dairy Federation, the International, Study Committee of, 532
——— Materials and Water, Sterilisation of, by Ultra-Violet Rays, 196
Density of Minerals, Determination of, by Means of Rohrbach Solution of Standard Refractive Index, 148
Densivolumeter, New, for Determination of Density of Solids, 328
Device, Adiabatic, for Bomb Calorimeter, 326
——— for the Combustion of Volatile Substances, Estimation of Halogens in Organic Compounds, Including, 461
Dextrose, Detection of Lævulose in the Presence of, 507
——— in the Presence of Other Optically Active Substances, Estimation of, by Bertrand's Method, 512
——— in Urine and Blood, Estimation of, 140
Diabetic Urine, Glycuronic Acid in, Detection of, 507

Diastatic Power of Malt, 58
Digestive Enzymes, the Assay of, Observations on, 57
——— Value of Papain, Determination of, 405
Digitalis, Chemical Valuation of, 189
Dimethyl-Glyoxime, Action of, on Platinum Salts, 524
Dimethylglyoxime as a Reagent for Ferrous Salts, 102
———, Separation of Nickel and Palladium by Means of, 379
Diphenylamine Test for Gun-Cotton, 512
Direct Determination of Rubber, 574
Dirt in Milk, Estimation of, 450
Dish, the Petri, for Cultivating Fungi and for Biological Analysis, a Substitute for, 561
Distillation Arrangement, Modified Soxhlet Extraction Apparatus with, 592
———, Continuous, Fractional, of Water, 474
——— or Evaporation of Liquids, Apparatus for Controlling, and for Cutting off the Supply of Gas to a Burner after any Desired Length of Time, 221
———, Rapid, of Mercury in Vacuo, Apparatus for, 528
Distilled Vinegar when Stored in Wooden Casks, the Acid-Content of, Alteration of, 23
Drugs, Beverages, and Foods, Saccharin and Dulcin in, Separation and Identification of, 23
Dry Matter in Potatoes, Estimation of, and the Applicability of the Ordinary Tables, 259
Drying Oven, 385
Dulcin and Saccharin in Beverages, Foods, and Drugs, Separation and Identification of, 23
Dyes, Aniline, and Turmeric, in Mustard, Detection of, 557
———, Certain, the Detection and Separation of, on the Application of Adsorption to, 339
Dyestuffs, Azo, Titration of, by Means of Hydrosulphite, 568
———, Coal-Tar, the Seven, Allowed (U.S.A.) to be Employed for Colouring Foodstuffs, Mixtures of, Method for Separating, 19
Dynamite, Exudation of Nitroglycerine from, 572
——— Glycerol, Valuation of, 103

Earth Reactions, Rare, in Non-Aqueous Solvents, 524
Earths, Certain Rare, Fusion of, with Alkali Carbonates. Separation of Tungsten from Iron, Beryllium, and Aluminium, 591
———, the Rare, Separation of, 380
Eastern France, Wines from, Analyses of, 352
Ebullioscopic Determinations at Low Temperatures (−36° to −83° C.), 287
Edible Beans from Hong-Kong, 494
Effluents, Phenols in, Colorimetric Estimation of, 30
———, Sewage, Nitrates in, Estimation of, 149
Eggs, Hens', Composition of, 25
Ehrlich's Reaction for Aldehydes, and Urobilinogen of Urine, 28
Electric Current, Separation of Rennin and Pepsin by Means of the, 141
——— Vacuum Furnace, Determination of Oxygen in Iron and Steel by Reduction in an, 586
Electrical Conductivity, an Apparatus for Testing Water by Measurement of its, 538
——— Furnace for Studying the Course of Reactions under Great Pressure, 288
——— Method, Analysis of Organic Substances by, 331
Electrically-Heated Microscope Slide, 592

Electro-Analysis of Copper, Antimony, Bismuth, and Tin, with Acidified Chloride Constituents, 584
———-Analytical Estimation of Copper in Pyrites, 468
——————— Separation of Metals, Use of the Mercury Cathode, Particularly in, 279
Electrochemical Analysis, Perchloric Acid in, 279
Electrode, the Hydrogen, Rapid Determination of Magnesia in Limestone by Means of, 585
Electrolytes, Acidified Chloride, Electro-Analysis of Copper, Antimony, Bismuth, and Tin with, 584
Electrolytic Apparatus for Use in Invert Sugar Determinations, 576
————— Estimation of Manganese and its Separation from Iron, 419
————— ————— of Molybdenum. Part I., 420
Electrometric Determination of the Reaction of Liquids Containing Carbon Dioxide, 416
Elementary Analysis, 508
Elements, Structural, of Cellular Membranes, 503
————, the Common, System of Qualitative Analysis for. Part V.: Acidic Constituents, 322
Elm-Seed Fat, 201
Embryo and Aleurone Layer of Hordeum, Amyloclastic Secretory Capacities of the, 97
Emulsions, Lecithin, Method of Preparing, and the Subsequent Estimation of their Strength, 307
—————, Oil, Saponin and Saccharin in, Estimation of, 22
Engler's, Redwood's, and Saybolt's Viscosimeters, Comparative Examination of, 223
Enumeration, Direct, of Bacteria in Water by Means of the Ultra-Microscope, Value of, 317
Enzyme Action, Studies on. II. Hydrolytic Action of Some Amino-Acids and Polypeptides on Certain Esters, 353
————, Proteolytic, of Malt, 504
Enzymes, Digestive, the Assay of, Observations on, 57
———— of Honey, Inversion of Sucrose by the, 194
Ergot of Rye, a New Glucoside in: Clavicepsin, 19
Error, Source of, in the Kjeldahl-Gunning Method, 203
———, Sources of, and the Electrolytic Standardisation of the Conditions of the Iodide Method of Copper Analysis, 277
———————, in the Estimation of the Polenske Value of Fats, 256
Essential Oil in Mustard, Estimation of, 309
————— in Preparations of Mustard, Estimation of, 451
Essential Oils, in Spices, etc., Small Quantities of, the Estimation of. Part II., 88
—————, New Philippine, 61
Ester Method for the Detection of Mono-Animo-Acids together with Polypeptides, 272
Esterification of Monamino Acids by Means of Ethyl Iodide. Separation of Pyrrolidonecarboxylic Acid from Glutamic Acid, 360
Esters, Certain, Hydrolytic Action of Some Amino-Acids and Polypeptides on. Studies on Enzyme Action, 353
Ether and Chloroform Vapours in Air, Gasometric Estimation of, 513
———— Petroleum Ether, the Higher Fatty Acids in, Solubilities of the Lead Salts of, 399
——— in Normal Salt Solution, Solubility of, 448
Ethyl Alcohol and Spirits, Methyl Alcohol in, Detection of, 567
Eudiometer, Explosion, Modified, 38
Evacuated Vessel, the Flow of a Gas into, a Convenient Apparatus for Regulating, and for Obtaining an Average Sample of Gas, 250

Evaporation or Distillation of Liquids, Apparatus for Controlling, and for Cutting off the Supply of Gas to a Burner after any Desired Length of Time, 221
Explosion Eudiometer, Modified, 38
Explosions and Fires, Mine, Use of Mice and Birds for Detecting Carbon Monoxide after, 315
Explosives, Constant-Temperature Heating Apparatus for, and Experiments on the Decomposition of Nitrocelluloses, 222
——————, Used in Coal-Mines, Investigations of, 290
Extract in Wort and Beer, Estimation of, 502
Extraction Apparatus, 427
——————-, New, 39
——————-, Soxhlet, Modified, with Distillation Arrangement, 596
—— Thimble, New Form of, 288
—— with Cold Solvents, Estimation of Fat by, 102
Extracts, Flavouring, the Determination of Vanillin in, New Colorimetric Method for, 501
————, Meat, Some New Zealand, Chemical Composition of, 193
——————, the Nitrogenous Constituents of, Changes in the Composition of, 21
————, Tobacco, Nicotine in, Methods of Estimating, 452

Fabrics, Rubberised, Analysis and Testing of, 575
Fat and Lipoids in Blood, Estimation of, and Notes on the So-Called Lipolysis, 561
——, Butter, and Cocoanut Oil in Margarine, the Determination of, Notes on, 122
——————, the Crude Cholesterol of, and Crude Phytosterol of Cocoanut Oil, and the Detection of Cocoanut Oil in Butter Fat, 497
——, Elm-Seed, 201
——, Estimation of, by Extraction with Cold Solvents, 102
——, Hare, Composition of, 255
——, Hydnocarpus, 20
—— in Animal Substances, Kumagawa-Suto Method of Estimating, 354
—— in Cheese, the Estimation of, Modified Butyrometer Tube for, 221
—— in Cocoa, Estimation of, by Means of Zeiss' Refractometer, 495
——, Loss of, during the Drying of Animal Tissues, 355
Fats and Bassia Kernels, 54
—— and Oils, Certain Vegetable, Bromine Adsorption of, 403
——————, Glycerides Occurring in: Heptadecoic Acid and its Glyceride, 411
——, Fractional Saponification of, 558
——, Glycerol in, Estimation of, 571
——, Other, Margarine, and Butter, Benzoic Acid in, Estimation of, 92
——, Saponification of, by Sulphuric Acid, 256
the Polenske Value of, the Estimation of, Sources of Error in, 256
-, Vegetable, Some, Analytical Constants of, 349
Fatty Acid, Free, Effect of, on Specific Gravity of Some Fatty Oils, 410
—— Acids, Small Quantities of, Estimation of the Molecular Weight of, 203
——————, the Higher, in Ether and in Petroleum Ether, Solubilities of the Lead Salts of, 399
—— Oils Obtained from the Seeds of *Illicium Verum* Hook and *Illicium Religiosum* Sieb, Composition of, 495
-, Some, Specific Gravity of, Effect of Free Fatty Acid on, 410
Feeding Materials, Some, Acid-Soluble Phosphorus Compounds of, 193
Fehling's Solution, the Estimation of Furfural by Means of, 41

Fehling's Solution, the Estimation of Reducing Sugars by, Influence of Peptones on, 367
Fermented Beverages, Caramel in, Detection of, 18
Ferric Iron, Presence of Certain Organic Substances, the Estimation of, 179
——- Salts, Compounds of, with Albumoses, 408
Ferricyanides, Reaction of Hydrazine and Hydroxylamine with, and New Methods for Estimating Hydrazine and Ferricyanides, 417
Ferro-Alloys, Carbon in, Use of Oxygen under Pressure for Estimating, 379
Ferrocyanide Titration of Zinc, Influence of Lead on, 585
Ferrocyanides, Estimation of, 362
Ferro-Tungsten, Manganese in, Rapid Estimation of, 107
Ferrotungsten, Tungsten in, Rapid and Exact Estimation of, 220
Ferro-Zircon, Analysis of, 220
————, The Analysis of, a New Method for, and Separation of Zirconium from Iron and Aluminium, 36
Ferrous Ion, Estimation of the, by Means of Iodine, 32
——- Iron in Silicate Rocks, Estimation of, 146
——- Salts, Dimethylglyoxime as a Reagent for, 102
Ferruginous Minerals, Zinc in, Estimation of, 425
Fibre, Crude, Estimation of, 447
——, ——, the Sweeney Method for, Modification of, 447
Fibres, Hemp and Flax, Microscopic Differentiation of, 195
Fibres, Textile, and Woods, Cellulose in, Estimation of, 268, 510
Filter, Inorganic, for Laboratory Purposes, New Type of, 526
—— Pumps, Valve for, 480
Filtration with Alundum Plates, 109
Finishes, Textile, Analysis of, 200
Fires and Explosions, Mine, Use of Mice and Birds for Detecting Carbon Monoxide after, 315
Fish Oils, Viscosity of, 143
Flavouring Extracts, the Determination of Vanillin in, New Colorimetric Method for, 501
Flax and Hemp Fibres, Microscopic Differentiation of, 195
Flour, Baking Qualities of, 190
——, " Gasolene Colour Value " of, the Determination of, Method for, 255
——, Improver, 90
——, Mustard, Analysis of, 55
——, Studies on, 495
——, the Baking Qualities of, Influence of the Concentration of Hydrogen Ions on, 257
——, the Colouring Matter of, the Nature of, and its Relation to Processes of Natural and Artificial Bleaching, Report to the Local Government Board on, 596
Flours, Mustard, and Oil-Cakes, Mustard Oils in, Estimation of, 95
Flue Gases, the Technical Analysis of, Use of the Zeiss Interferometer in, 427
Fluid, Spermatic, Microchemical Reaction of, 358
Fluids, Other Physiological, and Urine, Blood in, Detection of, 506
Fluorescein, Detection of Bromine by, 145
Fluorescence Test for Mineral and Rosin Oils, 30
Fluorides, Detection of, 32
Fluorine in Foods, etc., Detection of, 191
———, Minute Quantities of, in Waters, Minerals, and Living Tissues, Detection and Estimation of, 517
Fluorspar, Valuation of, 210
Food Analysis, New Sublimation Apparatus, and its Application in, 428

Foods and Beverages, Saponin in, Detection of, by Hæmolysis, 350
—— and Drugs Acts, the Sale of, 1875 to 1907, Circular to Local Authorities for the Purposes of, 434
—— AND DRUGS ANALYSIS, ABSTACTS, 18, 51, 92, 137, 189, 254, 306, 347, 400, 446, 492, 557
——, Benzoic Acid in, Detection of, 349
——, Beverages, and Drugs, Saccharin and Dulcin in, Separation and Identification of, 23
——, etc., Cane-Sugar in, Estimation of, 493
——, ——, Fluorine in, Detection of, 191
——, Inspectors of, on the Work of, 71
——, Saccharin in, Estimation of, 194
——, Vegetable, Amounts of Arsenic in, 254
Food-Stuffs and Other Organic Substances, Incineration of, Prior to the Determination of their Phosphorus-Content, 257
————, Phosphorus in, Determination of, by Titration with Uranyl Solutions, 258
Foodstuffs, the Seven Coal-Tar Dyestuffs Allowed (U.S.A.) to be Employed for Colouring, Method for Separating Mixtures of, 19
Formaldehyde, Detection and Estimation of Halides in the Presence of Cyanides by Means of, 461
——, Estimation of, 269
——, Method, Estimation of the Amino-Acids in Plants by Means of the, 312
——, Solutions, the Strength of, Refractometric Estimation of, 202
——, Tetraformal-trisazine from, and Hydrazine Hydrate, a New Reducing Agent for Analytical Use, 369
Formic Acid in Fruit Products, Detection of, 403
—— in Honey, 258
—— in Syrups, Detection and Estimation of, 558
—— in the Presence of Other Acids, Estimation of, by Means of Potassium Permanganate, 270
Formolite Reaction, Application of, to the Analysis of Paraffin Wax, 274
Fractional Distillation of Water, Continuous, 474
—— Saponification of Fats, 558
France, Eastern, Wines from, Analyses of, 352
Free Bromine, Sensitive Reaction of, 581
—— Carbon Dioxide in Water, Estimation of, by Titration with Alkalis in the Presence of Phenolphthaleïn, 582
—— Fatty Acid, Effect of, on Specific Gravity of Some Fatty Oils, 410
—— Lime in Portland Cement, Use of Higher Phenols in Testing for, 582
—— Sulphur, Estimation of, Rapid Volumetric Method for, 151
Freezing-Point of Milk, 307
Frehse's and Vamvaka's Tests, Detection of Saponin and Glycyrrhizin in Lemonades by Means of, 22
Freshness of Milk, Tests for Ascertaining the, 25
Fruit Juice Statistics for the Year 1911, 94
—— Juices, Watered, Nitric Acid in, Detection of, 21
—— Products, Formic Acid in, Detection of, 403
Fulminate, Mercury, Investigations on, 318
Fungi, Cultivating, the Petri Dish for, and for Biological Analysis, a Substitute for, 561
Fungicides, Copper, 262
Furfural, the Estimation of, by Means of Fehling's Solution, 41
Furnace, Electric Vacuum, Determination of Oxygen in Iron and Steel by Reduction in, 586

Furnace, Electrical, for Studying the Course of Reactions under Great Pressure, 288
Fuse and Miners' Squibs, Investigations of, 291

Gas, an Average Sample of, a Convenient Apparatus for Obtaining, and for Regulating the Flow of a Gas into an Evacuated Vessel, 250
——, Analysis Apparatus, New Forms of, 288
——, Apparatus for Cutting off the Supply of, to a Burner after any Desired Length of Time, and for Controlling the Evaporation or Distillation of Liquids, 221
——, Flow of, Combined Governor and Gauge for Regulating, 330
——, Illuminating, Sulphur in, Estimation of, 152
—— Mixtures, Hydrogen and Methane in, Estimation of, 518
————, Rapid Removal of Nitrogen from, by Sparking, Apparatus for, 224
—— Producer, Tar in, Estimation of, 275
—— -Water, Pyridine in the Presence of Ammonia in, Rapid Estimation of, 574
Gases, Evolved, Measurement of, Apparatus for Extracting Liquids with Immiscible Solvents, and for, 69
———, Flue, the Technical Analysis of, Use of the Zeiss Interferometer in, 427
———, Occluded, and Oxygen in Copper, Estimation of, 375
———, Poisonous, from Oilfields, 486
"Gasolene Colour Value" of Flour, the Determination of, Method for, 255
Gasometric Estimation of Ether and Chloroform Vapours in Air, 513
Gauge and Governor, Combined, for Regulating Flow of Gas, 330
Gelatin, Arsenic in, Occurrence of, 94
Gels, Silicic Acid, Vapour Pressure Isothermals of, Apparatus for Determination of, 328
Generator, Hydrogen, Constant-Pressure, 331
Geochemical Interpretation of Water Analysis, 107
Geraniol in Citronella Oil, Direct Estimation of, 363
Gironde, the Department of, Analyses of Wines from, 352
Glands, Thyroid, Iodine Content of, 455
Glasses, Soda Lime, the Refractive Index of, Relation of, to their Chemical Composition, 278
Gliadin or Alcohol-Soluble Protein in Wheat-Flour, Determination of, 19
Glucosamine in Ovomucoid and Pseudomucin, Polarimetric Estimation of, 561
Glucose in Leather, Estimation of, 270
Glucoside, New, in Ergot of Rye: Clavicepsin, 19
Glutamic Acid, Separation of Pyrrolidonecarboxylic Acid from. Esterification of Monamino Acids by Means of Ethyl Iodide, 360
Glyceride, Heptadecoic Acid and its: Glycerides Occurring in Fats and Oils, 411
Glycerol, Dynamite, Valuation of, 103
——— in Fats, Estimation of, 571
——— in Wine, Estimation of, 260
——— in Wines, the Estimation of, New Method for, 351
Glycyrrhizic Acid in Liquorice Juice, Estimation of, 138
Glycyrrhizin and Saponin in Lemonades, Detection of, by Means of Vamvakas' and Frehse's Tests, 22
Glycin Picrate, Composition and Properties of, and Separation of Glycin from Alanin, 570
Glycuronic Acid in Diabetic Urine, Detection of, 507
Goat's and Cow's Milk, the Serum of, Refractometer Value of, 317
Gold Bullion, Sampling, 517
—— Coin, a Counterfeit, Note on, 7
—— Salts, Reaction of, with *m*-Phenylenediamine, 469
——, Silver, and Platinum, Estimation of, 281

Government Reports, 109, 155, 432
Governor and Gauge, Combined, for Regulating Flow of Gas, 330
Granules, Starch, Notes on, and Apparatus for the Estimation of Adulterants in Vegetable Powders, 529
Grass Oils, Aromatic, Part I., 61
———, ———, Part II., 197
———, ———, Part III., 265
Gravimetric Analysis, Simplification of, 31
——— and Volumetric Estimations. The Coagulation of Albumin by Heat and its Precipitation by Mercuric-Potassium Iodide, 458
——————— Methods for the Analysis of Mercury-Ammonium Chloride, 33
Grignard Reagent, Quantitative Estimation of Hydroxy-, Amino-, and Imino-Derivatives of Organic Compounds by Means of, and the Nature of the Changes Taking Place in Solution, 201
Group, the Copper-Arsenic, Precipitation of, and Separation of its Divisions, 376
Guadaloupe Rum, Composition of, 97
Gum in Syrups, Estimation of, 94
—— Resins, Notes on the, 270
—— Tragacanth, Volatile Acidity of, Compared with that of Indian Gum, 318
Gun-Cotton, Diphenylamine Test for, 512
Gutzeit Test, Determination of Small Quantities of Arsenic by the, 579

Hæmolysis, Detection of Saponin in Foods and Beverages by, 350
Hæmolytic Action, their: Toxicity of Mushrooms, 563
Hair of Persons who have Received Subcutaneous Doses of Mercury Compounds, Occurrence of Mercury in. Detection of Minute Quantities of Mercury, 562
Halides in the Presence of Cyanides, Detection and Estimation of, by Means of Formaldehyde, 461
Halogens and Sulphur in Small Quantities of Organic Substances, Estimation of, 216
——— in Organic Compounds, Estimation of, Including a Device for the Combustion of Volatile Substances, 461
———, Other, and Organic Matter, Iodine in the Presence of, Determination of, 418
Hand Photometer, New, 429
Hardy and Arnold, the Method of, for the Rapid Estimation of Sulphur in Siderurgical Products, Modification of, 283
Hare Fat, Composition of, 255
Hawaiian Soil, Humus in, Determination of, 513
Health, Public Act (Regulations as to Food), 1907, Regulations under the, 432
Heat, Alteration of Nitrocellulose and Nitrocellulose Powders by, 104
—— Test for Chinese Wood Oil, 410
Heating Apparatus, Constant-Temperature, for Explosives and Experiments on the Decomposition of Nitrocelluloses, 222
Heats, Latent, of Vaporisation of Mixed Liquids. Part III.: Mixtures of Associated with Non-Associated Liquids, and the Detection of Solvates in Mixtures of Liquids, 362
Heavy Petroleum in Paints and Vegetable Oils, the Detection of, 247
Hemp and Flax Fibres, Microscopic Differentiation of, 195
Hens' Eggs, Composition of, 25
Heptadecoic Acid and its Glyceride: Glycerides Occurring in Fats and Oils, 411
High-Grade Tungsten Alloys, Analysis of, 424
Higher Fatty Acids in Ether and in Petroleum Ether, Solubilities of the Lead Salts of, 399

Higher Oxides of Lead, Analysis of, 148
——— Phenols, Use of, in Testing for Free Lime in Portland Cement, 582
Hippuric Acid, Benzoic Acid, and Phenaceturic Acid in Urine, Estimation of, 356
————— in Urine, the Estimation of, Method for, 507
—————————, ——————, New Method for, 356
Honey Analysis, Application of the Quantitative Precipitin Reaction in, II., 404
———, Formic Acid in, 258
——— from Various Countries, Composition of, 53
———, the Analysis of, Examination of Methods Used in, 449
———, the Enzymes of, Inversion of Sucrose by, 194
———, the Mutarotation of, 95
Hong-Kong, Edible Beans from, 494
Hop, Determination of Hard and Total Soft Resins in the, Comparative study of the Methods for, 191
Hops in Worts and Beers, Bitter Resins of, and their Volumetric Estimation, 139
Hordeum, the Embryo and Aleurone Layer of, Amyloclastic Secretory Capacities of, 97
Horny Tissue and Other Proteins, the Quantity of Tryptophane in, and Colorimetric Method for the Estimation of Tryptophanes, 565
Hübener Bromide Method for the Estimation of Caoutchouc, 509
———————————————— Rubber, 465
Hübener's Bromide Method for the Estimation of Caoutchouc, 202
Humus in Hawaiian Soil, Determination of, 513
———, Soil, Studies on, 466
Husk in Cocoa Powders, Estimation of, 402
Hydnocarpus Fat, 20
Hydrazine and Hydroxylamine, Reaction of, with Ferricyanides, and New Methods for Estimating Hydrazine and Ferricyanides, 417
————, Estimation of, 364
———— Hydrate and Formaldehyde, a New Reducing Agent for Analytical Use, from Tetraformal-trisazine, 369
Hydrocarbon Mixtures, Analysis of, 462
Hydrocarbons, Benzene, and Petroleum Spirit in Turpentine Oil, Estimation of, 274
————— in Beeswax and Carnauba Wax, Estimation of, 348
—————, Other, in Turpentine, Detection of, 311
Hydrochloric Acid, Estimation of Arsenious Acid with Permanganate in Presence of, 417
Hydrochloride, Hydroxylamine, Quantitative Separation and Estimation of Copper by Means of, 583
Hydrocyanic Acid, Rate of Evolution of, from Linseed, under Digestive Conditions, 313
Hydrogen, Active, in Organic Compounds, Quantitative Estimation of, by Magnesium-Methyl Iodide, 571
———— and Methane in Gas Mixtures, Estimation of, 517
———— Cyanide and Cyanogen, Detection and Determination of, 511
———— Electrode, Rapid Determination of Magnesia in Limestone by Means of the, 585
———— Generator, Constant-Pressure, 331
———— Ion Concentrations, the Colorimetric Estimation of, Application of Methyl-Red to, 142
———— Ions in Sea-Water, Concentration of, Measurement of, 425
—————, Influence of the Concentration of, on the Baking Qualities of Flour, 257
———— Peroxide, and Alkali, Behaviour of Invert Sugar in the Presence of, 28

Hydrogen Peroxide and Nitric Acid, Use of a Mixture of, in Analytical Work, 212
—————— in Presence of Sodium Hydroxide and Sugar, Quantitative Separation of Copper from Arsenic, Aluminium, Zinc, Tungsten, and Tin by Means of, 210
———— Sulphide, Qualitative Analysis without, 377
(Hydrogenised) Solidified Oils, 452
Hydrolysis, Complete, of Proteins, Conditions for, 573
Hydrolytic Action of Some Amino-Acids and Polypeptides on Certain Esters. II.: Studies on Enzyme Action, 353
Hydrosulphite, Titration of Azo Dyestuffs by Means of, 568
Hydroxy-, Amino-, and Imino-Derivatives of Organic Compounds, Quantitative Estimation of, by Means of the Grignard Reagent, and the Nature of the Changes Taking Place in Solution, 201
p-Hydroxybenzoic Acid, the Estimation of Small Quantities of Salicylic Acid in Presence of Excess of, Biochemical Method for, 316
β-Hydroxybutyric Acid and Lactic Acid, Estimation of, in Mixtures of the Same, 409
l-*β*-Hydroxybutyric Acid in Urine and Blood, Quantitative Estimation of, 314
Hydroxyl Groups, Alcoholic, and Alcohols, Colour Reaction of, 407
Hydroxylamine and Hydrazine, Reaction of, with Ferricyanides, and New Methods for Estimating Hydrazine and Ferricyanides, 417
—————— Hydrochloride, Quantitative Separation and Estimation of Copper by Means of, 583

Ignition, Effect of, on the Solubility of Soil Phosphates, 523
Illicium Verum Hook and *Illicium Religiosum* Sieb, the Fatty Oils Obtained from the Seeds of, Composition of, 495
Illuminating Gas, Sulphur in, Estimation of, 152
Imino-, Hydroxy-, and Amino-Derivatives of Organic Compounds, Quantitative Estimation of, by Means of the Grignard Reagent, and the Nature of the Changes Taking Place in Solution, 201
Imitation Parchment Papers and "Pergamyn," 144
Immiscible Solvents, Extracting Liquids with, Apparatus for, and for Measurement of Evolved Gases, 69
Improvements in the Ludwig-Sipöcz Method for the Estimation of Water in Silicates, 380
Improver, a Flour, 90
Incineration of Food-Stuffs and Other Organic Substances Prior to the Determination of their Phosphorus-Content, 257
Index, Refractive, of Beeswax, 348
——————, of Chinese Wood Oil, 410
——————, of Soda Lime Glasses, Relation of, to their Chemical Composition, 278
Indian Gum, Volatile Acidity of Gum Tragacanth Compared with that of, 318
Indicator in Iodimetric Titrations, the Use of Methylene Blue as, 252
————, Use of Phenolphthaleïn as an, 320
Indigos Containing Starch, Analysis of, 319
Indole Reaction, the, 562
INORGANIC ANALYSIS, ABSTRACTS, 31, 64, 106, 145, 206, 276, 321, 372, 414, 468, 516, 579
———— Filter for Laboratory Purposes, New Type of, 526
———— Phosphorus in Plant Substances, Estimation of, 472
INSTITUTE OF CHEMISTRY, 76, 119, 162, 294, 438
Intensity Distribution in Blood Spectra, Photographic Estimation of, 313

Interferometer, New, for Liquids, Estimation of the Concentration of Colloidal Solutions with, 382
——————, the Zeiss, Use of, in the Technical Analysis of Flue Gases, 427
Invert Sugar Determinations, Electrolytic Apparatus for Use in, 576
——————, Expanded Meissl-Hiller Table for, 575
—————— in the Presence of Alkali and Hydrogen Peroxide, Behaviour of, 28
Iodide, Cadmium Potassium, Determination of Ozone by Means of, 587
———, Magnesium Methyl, Quantitative Estimation of Active Hydrogen in Organic Compounds by, 571
———, Method of Copper Analysis, the Electrolytic Standardisation of the Conditions of, and Sources of Error, 277
Iodides, Determination of, by Direct Titration, 378
———, etc., the Method of Precipitating Metals as, from Sulphuric Acid Solution, Applications of, 519
———, the Estimation of, Methods for, 519
Iodimetric Estimation of Copper, 375
————— Titrations, Methylene Blue as an Indicator in, the Use of, 252
Iodine and Bromine Methods for the Volumetric Estimation of Cresol, 408
——— Content of Thyroid Glands, 455
———, Estimation of the Ferrous Ion by Means of, 32
——— in the Presence of Other Halogens and Organic Matter, Determination of, 418
——— Method, a Modification of the: Determination of Copper, 66
——— Value and the Structure of Acids of the Oleic Series, Relationship between, 463
Ion, the Ferrous, Estimation of, by Means of Iodine, 32
Ions, Hydrogen, in Sea-Water, Concentration of, Measurement of, 425
——————, Influence of the Concentration of, on the Baking Qualities of Flour, 257
Iron and Aluminium, Separation of Zirconium from, and a New Method for the Analysis of Ferro-Zircon, 36
—— and Steel, Oxygen in, Determination of, by Reduction in an Electric Vacuum Furnace, 586
——————, Paint Films and Preservative Coatings for, New Method for Testing, 213
——————, Sulphur in Volumetric Estimation of, 67
——, Beryllium, and Aluminium, Separation of Tungsten from. Fusion of Certain Rare Earths with Alkali Carbonates, 591
——, Electrolytic Estimation of Manganese, and its Separation from, 419
——, Ferric, in Presence of Certain Organic Substances, the Estimation of, 179
——, Ferrous, in Silicate Rocks, Estimation of, 146
——, in Lead and its Oxides, Colorimetric Determination of, 520
——, in Milk, Estimation of, 308
—— in (Pharmaceutical) Scale Preparations, Determination of, 306
——, Separation of, from Titanium, 323, 469
——, Small Quantities of, in Organic Substances, Estimation of, 32
Isothermals, Vapour Pressure, of Silicic Acid Gels, Apparatus for Determination of, 328

Japanese and Chinese Wood Oil, the Examination of, 543
Juice, Liquorice, Glycyrrhizic Acid in, Estimation of, 138
Juices, Fruit, Watered, Detection of Nitric Acid in, 21
———, Plant, the Oxidase Content of, Measurement of, 261

Ketoses and Aldoses, Method of Distinguishing between, 266

Kirschner and Polenske Values for Margarines Containing Cocoanut or Palm Kernel Oils, on the Relation between, 183
Kjeldahl-Gunning Method, Source of Error in the, 203
Knapp and Shrewsbury's Process for Estimating Cocoanut Oil, Notes on, 3
Kola Nuts from British West Africa, 258
Kumagawa-Suto Method of Estimating Fat in Animal Substances, 354

Laboratory Apparatus, Two New Pieces of, 528
——— Centrifuge for Quantitative Separation and Estimation of Solids and Liquids, 286
———, Government, the Work of, for the Year Ending March 31, 1912, Report of the Government Chemist upon, with Appendices, 530
——— Purposes, Inorganic Filter for, New Type of, 526
Studies of Rennin, 405
Lactic Acid, Analysis of,29
———, and β-Hydroxybutyric Acid, Estimation of, in Mixtures of the Same, 409
——— in the Presence of Proteins, Estimation of, 403
(Lactose, a Correction for), Reducing Sugar Methods, Unification of, 145
———, the Estimation of, a New Method for, and Behaviour of Milk when Treated with Ammonium Sulphate, 350
Lævulose, Detection of, in the Presence of Dextrose, 507
——— Reaction, the Seliwanoff, Physico-Chemical Basis of, 367
Lamps, Sodium Flame, for Polarisation, 594
Landsberger Boiling-Point Apparatus, Modification of, 326
Lanthanum, Quantitative Separation of, from Yttrium, 469
Lard and Butter, Cocoanut Oil in, Detection of, 93
Latent Heats of Vaporisation of Mixed Liquids. Part III.: Mixtures of Associated with Non-Associated Liquids, and the Detection of Solvates in Mixtures of Liquids, 362
Lead and its Oxides, Iron in, Colorimetric Determination of, 520
——— Arsenates, Commercial, Determination of Soluble Arsenic in, Short Method for, 206
——— Assay, the Ammonium Molybdate Method of, on the Effect of Lime on, 242
———, Higher Oxides of, Analysis of, 148
———, Influence of, on the Ferrocyanide Titration of Zinc, 585
——— Salts of the Higher Fatty Acids in Ether and in Petroleum Ether, Solubilities of, 399
Leather, Glucose in, Estimation of, 270
Leaves of Conifers, Oxalic Acid in, Estimation of, 204
———, Uva-Ursi, the Analysis of, Application of the Biochemical Method for, 24
Lecithin Emulsions, Method of Preparing, and the Subsequent Estimation of their Strength, 307
——— in Medicinal Tablets, Estimation of, 449
Lemon Peel, Candied, Analysis of, 20
Lemonades, Saponin and Glycyrrhizin in, Detection of, by Means of Vamvakas' and Frehse's Tests, 22
Leucocyte, Catalase, and Reductase Tests, Comparative Value of, in Detecting Mastitis, 401
Light, Catalytic Action of, on the Oxidation of Phenolphthalin to Phenolphthaleïn, 30
——— Energy, Application of, to the Study of Certain Problems in Analytical Chemistry, 478
Lime, Free, in Portland Cement, Use of Higher Phenols in Testing for, 582
——— Liquors, Sulphides in, Estimation of, 325

Lime, On the Effect of, on the Ammonium Molybdate Method of Lead Assay, 242
Limestone, Rapid Determination of Magnesia in, by Means of the Hydrogen Electrode, 585
Linseed, Evolution of Hydrocyanic Acid from, under Digestive Conditions, Rate of, 313
——— Oil and its Adulterants, Tests for, 192
Lintner's Polarimetric Method for the Determination of Starch, 498
Lipase, Castor-Bean, Experiments with, 316
Lipoids, and Fat in Blood, Estimation of, and Notes on the So-Called Lipolysis, 561
———, Complex, Proximate Analysis of, by Alcoholysis, 463
Lipolysis, the So-Called, Notes on, and Estimation of Fat and Lipoids in Blood, 561
Liqueur, and Cherries, Maraschino, Benzaldehyde in, Estimation of, 446
Liquids and Solids, Quantitative Separation and Estimation of, Laboratory Centrifuge for, 286
———, Apparatus for Controlling the Evaporation or Distillation of, and for Cutting off the Supply of Gas to a Burner after any Desired Length of Time, 221
———, Automatic Analysis of, Apparatus for, 480
———, Boiling, the Bumping of, Device for Preventing, 153
———, Containing Carbon Dioxide, the Reaction of, Electrometric Determination of, 416
———, Extracting with Immiscible Solvents, Apparatus for, and for Measurement of Evolved Gases, 69
———, Mixed, Vaporisation of, Latent Heats of. Part III.: Mixtures of Associated with Non-Associated Liquids, and the Detection of Solvates in Mixtures of Liquids, 362
——— in an Atmosphere Free from Carbon Dioxide, Apparatus for Measuring, 222
———, the Boiling-Points of which Lie Close together, or which Form Mixtures of Minimum Boiling-Point, Separation of, 272
———, the New Interferometer for, Estimation of, the Concentration of Colloidal Solutions with, 382
———, Volatile, Molecular Weights of, Determination of, 595
-- Organic, Combustion of, 361
Liquorice Juice, Glycyrrhizic Acid in, Estimation of, 138
Liquors, Lime, Sulphides in, Estimation of, 325
Lithium, Determination of, 470
Lithopone, the Analysis of, 238
Living Tissues, Waters, and Minerals, Minute Quantities of Fluorine in, Detection and Estimation of, 517
Lucidol (Benzoyl Peroxide), Influence of, on Certain Qualitative Tests for Oils, 273
Ludwig-Sipöcz Method for the Estimation of Water in Silicates, Improvements in, 380
"Luminator" Treatment of Water, 154
Luminescence Analysis, 526

Magnesia, in Admixture with Magnesium Carbonate, Estimation of, 211
——— in Limestone, Rapid Determination of, by Means of the Hydrogen Electrode, 585
——— Rods, Use of, Instead of Platinum Wire, in Analytical Work, 222
Magnesium Carbonate, Magnesia in Admixture with, Estimation of, 211
———, Gravimetric Estimation of, 471
——— Methyl Iodide, Quantitative Estimation of Active Hydrogen, in Organic Compounds by, 571
Malic Acid, Determination of, 29
——— and Succinic Acids in Wine, Estimation of, 453
Malt, Proteolytic Enzyme of, 504

Malt, the Diastatic Power of, 58
—— Vinegar, Standards for, 123
Manganese, Bismuthate Method for, 148
————, Determination of, by the Bismuthate Method, 522
————, Electrolytic Estimation of, and its Separation from Iron, 419
————, in Ferro-Tungsten, Rapid Estimation of, 107
————, the Estimation of, by the Bismuthate Method, 554
————, Total, in Soils, Estimation of, 423
————, Volumetric Estimation of, 471
Maraschino Cherries and Liqueur, Benzaldehyde in, Estimation of, 446
Margarine, Butter, and Other Fats, Benzoic Acid in, Estimation of, 92
————, Butter Fat and Cocoanut Oil in, the Determination of, Notes on, 122
Margarines Containing Cocoanut or Palm Kernel Oils, the Kirschner and Polenske Values for, on the Relation between, 183
Mastitis, Comparative Value of the Catalase, Reductase, and Leucocyte Tests in Detecting, 401
Meal, Examination of, 139
Measurement of Concentration of Hydrogen Ions in Sea-Water, 425
———— of Evolved Gases, Apparatus for, and for Extracting Liquids with Immiscible Solvents, 69
———— of Relative Tryptic Activity, 457
Measuring Absolute Viscosity, Method of, 154
———— Liquids in an Atmosphere Free from Carbon Dioxide, Apparatus for, 222
Meat Extracts, Some New Zealand, Chemical Composition of, 193
————, the Nitrogenous Constituents of, Changes in the Composition of, 21
Meats, Potassium Nitrate in, Estimation of, 140
———, the Changes Taking Place in, Physico-Chemical Method for Determining, 455
Mechanical Analysis of Arid Soils, 588
———— Soil Analysis, Modification of the Method of, 589
Medicinal Tablets, Lecithin in, Estimation of, 449
Meissl-Hiller Table, Expanded, for Invert Sugar, 575
Melting-Point, Determination of, with the Aid of the Microscope, 428
———— of Pitch, New Nethod for Determining, 62
Membranes, Cellular, Structural Elements of, 503
Mercuric-Potassium Iodide, the Coagulation of Albumin by Heat and its Precipitation by, Gravimetric and Volumetric Estimations, 458
Mercurisalicylic Acid, and Oxyphenyldimercuric Acetate, Mercury in, Estimation of, 103
Mercurous Nitrate and Potassium Iodide as Sensitive Reagents for Tungsten and Molybdenum, 378
Mercury-Ammonium Chloride, the Analysis of, Gravimetric and Volumetric Methods for, 33
———— Cathode, Use of, Particularly in the Electro-Analytical Separation of Metals, 279
———— Compounds, Persons who have Received Subcutaneous Doses of, Occurrence of Mercury in the Hair of, Detection of Minute Quantities of Mercury, 562
————, Estimation of, Use of Arsenious Acid in Volumetric Analysis, 321
———— Fulminate, Investigations on, 318
———— in Oxyphenyldimercuric Acetate and Mercurisalicylic Acid, Estimation of, 103
———— in Smokeless Powder, Estimation of, 273
———— in Vacuo, Rapid Distillation of, Apparatus for, 528
———— Thread, Beckmann Thermometer with a Modified Arrangement for Setting the, 429

Metallic Carbonates, Influence of, on the Estimation of the Volatile Substances in Coal, 360
Metals, Other, and Antimony, Separation of Arsenic from, by Means of Methyl Alcohol in a Current of Air, 414
——, ——, ————, the Separation of Arsenic from, with Some Applications to Toxicological Work, 229
——, the Electro-Analytical Separation of, Use of the Mercury Cathode, particularly in, 279
——, the Method of Precipitating, as Iodides, etc., from Sulphuric Acid Solution, Applications of, 519
Methane and Hydrogen in Gas Mixtures, Estimation of, 518
Methyl Alcohol, Detection and Estimation of, 364
———— in a Current of Air, Separation of Arsenic from Antimony and Other Metals by Means of, 414
———— in Admixture with Alcohol, and Especially in Spirits, Estimation of, 514
———— in Ethyl Alcohol and Spirits, Detection of, 567
————, Small Quantities of, Note on the Determination of, 16
—— -Red, Application of, to the Colorimetric Estimation of Hydrogen Ion Concentrations, 142
Methylcyclopentenolon in Pyroligneous Acid, Occurrence of, 319
Methylene Blue as an Indicator in Iodimetric Titrations, The Use of, 252
Metropolitan Water Board, Research Work of, Seventh Report on, 195
Mice and Birds, Use of, for Detecting Carbon Monoxide after Mine Fires and Explosions, 315
Micro-Chemical Detection of Certain Alkaloids, 137
———— Reaction of Spermatic Fluid, 358
———— Tests for the Identification of Some of the Alkaloids, 400
Microscope, Determination of Melting-Point with the Aid of the, 428
——— Slide, Electrically-Heated, 592
Milk and Cream Regulations (Draft), Government Report, 109
——, Australian (Victorian), Composition of, 47
——, Benzoic Acid in, the Detection of, Note on, 346
——, Condensed, Sucrose in, Estimation of, 450
——, Cow's and Goat's, the Serum of, Refractometer Value of, 317
——, Cream, etc., Certain Proprietary Substances Sold as Preservatives for, Analyses and Methods of Detection of, Report to the Local Government Board on, 155
——, ——, ——, New Preservative for, Note on, 178
——, Dirt in, Estimation of, 450
——, Freezing-Point of, 307
——, Iron in, Estimation of, 308
——, Serums, Preparation of, and their Use in the Analysis of Milk, 450
——, Sweetened Condensed, Australian, Composition of, 49
——, the Alkalinity and Peroxydase of, are they Identical? 141
——, the Composition of, 298
——, the Freshness of, Tests for Ascertaining, 25
——, the Reductase Test, Acidity, and Alcohol Test in, Relations between, 26
——, the Souring of, 168
——, when Treated with Ammonium Sulphate, Behaviour of, and a New Method for the Estimation of Lactose, 350
Mills, Cotton, Commercial Starches for Use in, Method for determining the Value of, 368
Mimosa Flowers, Tincture of, Detection of Minute Traces of Boric Acid by Means of, 558

Mine Fires and Explosions, Use of Mice and Birds for Detecting Carbon Monoxide after, 315
Mineral and Rosin Oils, Fluorescence Test for, 30
——— Oils, Pitch, etc., Asphalt in, Estimation of, 58
Minerals and Rocks, Radium in, Estimation of, 323, 421
———, Ferruginous, Zinc in, Estimation of, 425
———, the Density of, Determination of, by Means of Rohrbach Solution of Standard Refractive Index, 148
———, Waters, and Living Tissues, Minute Quantities of Fluorine in, Detection and Estimation of, 517
Miners' Squibs and Fuse, Investigations of, 291
Mkonga Oil, 256
Modified Form of Stability Test, 573
Moist Combustion, Estimation of Carbon by, 459
Moisture, Estimation of, Calcium Carbide Method for, 475
Molasses, Water in, Determination of, 560
Molecular Weight of Small Quantities of Fatty Acids, Estimation of, 203
——— Weights of Volatile Liquids, Determination of, 595
Molybdenum and Tungsten, Sensitive Reagents for, Potassium Iodide and Mercurous Nitrate as, 378
———, Electrolytic Estimation of. Part I., 420
Monamino Acids, Esterification of, by Means of Ethyl Iodide. Separation of Pyrrolidonecarboxylic Acid from Glutamic Acid, 360
Monazite Sand, Thorium, Especially in, Quantitative Estimation of, by Means of Sodium Hypophosphate, 423
Mono-Amino-Acids, together with Polypeptides, the Detection of, Ester Method for, 272
Morphine in Opiates, Estimation of, 308
Mushrooms, Toxicity of: Their Hæmolytic Action, 563
Mustard, Aniline Dyes and Turmeric in, Detection of, 557
———, Essential Oil in, Estimation of, 309
——— Flour, Analysis of, 55
——— Flours and Oil-Cakes, Mustard Oils in, Estimation of, 95
———, Preparations of, Essential Oil in, Estimation of, 451
Mutarotation of Honey, 95

Natural and Petroleum-Residue Asphalts, Differentiation between, 407
Neo- and Allo-Chlorophyll, in the Presence of One Another, Methods for Determining, 460
Neutral Ammonium Citrate Solution, 372
——— Salt, and Alcohol, Simultaneous Effect of, on the Sensitiveness of Phenolphthalein, 321
New Zealand Meat Extracts, Some, Chemical Composition of, 193
Nickel and Palladium, Separation of, by Means of Dimethylglyoxime, 379
——— and Zinc, the Gravimetric Separation of, 443
——— Baths, Boric Acid in, Estimation of, 277
Nicotine in Tobacco, Estimation of, 311
——— Extracts, Methods of Estimating, 452
Nitrate, Mercurous, and Potassium Iodide, as Sensitive Reagents for Tungsten and Molybdenum, 378
——— of Soda, Rational Analysis of, 523
Nitrates and Nitrites in Water, Estimation of, by Schlœsing's Method, 212
——— in Presence of Nitrites, Detection of, 149
——— in Sewage Effluents, Estimation of, 149

Nitrating and Waste Acids, Sulphuric Acid, Nitric Acid, and Nitrous Acid in, Volumetric Estimation of, 381
Nitric Acid and Hydrogen Peroxide, Use of a Mixture of, in Analytical Work, 212
————, the Separation of Nitrous Acid from, and the Estimation of Nitrites, New Volumetric Method for, 586
———— in Acetic Acid Solution, the Stability of. The Determination of Nitric and Nitrous Acids in Acetic Acid Solution, 303
———— in Watered Fruit Juices, Detection of, 21
—— and Nitrous Acids in Acetic Acid Solution, the Determination of. The Stability of Nitric Acid in Acetic Acid Solution, 303
Nitrites and Nitrates in Water, Estimation of, by Schlœsing's Method, 212
———, Nitrates in Presence of, Detection of, 149
———, the Estimation of, and the Separation of Nitrous Acid from Nitric Acid, New Volumetric Method for, 586
Nitrocellulose and Nitrocellulose Powders, Alteration of, by Heat, 104
-, Sulphur in, Estimation of, 152, 273
—— Powders, New Stability Test for, 572
Nitrocelluloses, Experiments on the Decomposition of, and Constant-Temperature Heating Apparatus for Explosives, 222
Nitro-Compounds, Separation of Nitroglycerine from, 572
Nitrogen, Organic, Activity of, as Measured by the Alkaline Permanganate Method, 365
———, Rapid Removal of, from Gas Mixtures by Sparking, Apparatus for, 224
Nitrogenous Constituents of Meat-Extracts, the Composition of Changes in, 21
Nitroglycerine, Exudation of, from Dynamite, 572
—————, Separation of, from Nitro-Compounds, 572
—————, the Determination of, by Means of the Nitrometer, Effect of the Nitrotoluenes on, 572
Nitrous Acid, New Reaction of, 33
—————, Nitric Acid, and Sulphuric Acid, in Nitrating and Waste Acids, Volumetric Estimation of, 381
—————, Separation of, from Nitric Acid, and the Estimation of Nitrites, New Volumetric Method for, 586
—————, Small Quantities of, the Detection and Estimation of, a New Method for, 345
——— and Nitric Acids in Acetic Acid Solution, the Determination of, the Stability of Nitric Acid in Acetic Acid Solution, 303
Nitrotoluenes, Effect of, on the Determination of Nitroglycerine by Means of the Nitrometer, 572
Non-Aqueous Solvents, Rare Earth Reactions in, 524
Normal Carbonate, Much, Detection of Small Quantities of Alkali Bicarbonate in Presence of, 372
——— Salt Solution, Solubility of Ether in, 448
——— Urine, Combined Glycuronic Acid in, Detection of, 562
—————, Copper-Reducing Power of, 264
Nutrition, Animal, the Value of Ordinary and Treated Sawdust for, Experiments on, 559
Nuts, Kola, from British West Africa, 258
——, Shea-, and Shea-Butter, 496

OBITUARY NOTICES:

——, ——, ————, Part III., 265
——, (Hydrogenised), Solidified, 452
——, Mineral and Rosin, Fluorescence Test for, 30

Oils, Mineral, Pitch, etc., Asphalt in, Estimation of, 58
——, Mustard, in Oil-Cakes and Mustard Flours, Estimation of, 95
——, New Oxygen Absorption Method for, 412
——, Other, and Creosote Oil, Used for Preserving Timber, Antiseptic Effect of, 56
——, Other, Sesame Oil in, Reaction for Detecting, 62
——, Palm Kernel or Cocoanut, Margarines Containing, on the Relation between the Kirschner and Polenske Values for, 183
——, Rosin and Mineral, Fluorescence Test for, 30
——, Vegetable, and Paints, Heavy Petroleum in, the Detection of, 247
——, Vegetable, Serger's Reaction for, Notes on, 412
——, Volatile, Cineol in, Estimation of, 461
Oleic Series, Acids of the, Relationship between the Iodine Value and the Structure of, 463
Opiates, Morphine in, Estimation of, 308
Optical Method, New, for the Estimation of the Various Proteins in Ox Serum: The Proteins of Ox Serum. Refractive Indices of Solutions of Certain Proteins, 355
Ores and Bullion, Small Amounts of Platinum in, Direct Determination of, 281
——, Steels, etc., Determination of Vanadium in, Rapid Method for, Based on its Quantitative Inclusion by the Phosphomolybdate Precipitate, 284
ORGANIC ANALYSIS, ABSTRACTS: 28, 58, 100, 142, 197, 265, 317, 359, 407, 458, 508, 565
———— Bases, New Reaction for, 319
———— Compounds, Arsenic in, Detection and Estimation of, 66, 360
———— ————, ————, Estimation of, 579
———— ————, Estimation of Halogens in, Including a Device for the Combustion of Volatile Substances, 461
———— ————, Hydroxy-, Amino-, and Imino- Derivatives of, Quantitative Estimation of, by Means of the Grignard Reagent, and the Nature of the Changes Taking Place in Solution, 201
———— ————, Quantitative Estimation of Active Hydrogen in by Magnesium-Methyl Iodide, 571
———— ————, the Relative Reactivity of, Method for Determining, 204
———— Liquids, Volatile, Combustion of, 361
———— Matter, and Other Halogens, Iodine in the Presence of, Determination of, 418
———— Nitrogen, Activity of, as Measured by the Alkaline Permanganate Method, 365
———— Substances, Action of Permanganate on, 366
———— ————, Analysis of, by an Electrical Method, 331
———— ————, Certain, the Estimation of Ferric Iron in Presence of, 179
———— ————, Other, and Food-Stuffs, Incineration of, Prior to the Determination of their Phosphorus-Content, 257
———— ————, ——, ————, Phosphorus in, Determination of, by Titration with Uranyl Solutions, 258
———— ————, Small Quantities of, Estimation of Sulphur and of Halogens in, 216
———— ————, Small Quantities of Iron in, Estimation of, 32
Oven, Drying, 385
Ovomucoid and Pseudomucin, Glucosamine in, Polarimetric Estimation of, 561
Ox Serum, the Proteins of: A New Optical Method for the Estimation of the Various Proteins in Ox Serum. Refractive Indices of Solutions of Certain Proteins, 355
Oxalic Acid in the Leaves of Conifers, Estimation of, 204
———— Vegetable Substances, Estimation of, 564

Oxidase Content of Plant Juices, Measurement of, 261
Oxidation of Phenolphthalin to Phenolphthaleïn, Catalytic Action of Light on, 30
Oxides, Higher, of Lead, Analysis of, 148
———, Lead and its, Iron in, Colorimetric Determination of, 520
Oxygen Absorption Method, New, for Oils, 412
——— and Occluded Gases in Copper, Estimation of, 375
——— in Iron and Steel, Determination of, by Reduction in an Electric Vacuum Furnace, 586
——— under Pressure, Use of, for Estimating Carbon in Ferro-Alloys, 379
Oxyphenyldimercuric Acetate and Mercurisalicylic Acid, Mercury in, Estimation of, 103
Ozone, Absorption of Ultra-Violet Rays in, and its Application to the Estimation of Ozone in Small Concentrations, 472
———, Determination of, by Means of Cadmium Potassium Iodide, 587

Paint Films and Preservative Coatings for Iron and Steel, New Method for Testing, 213
Paints and Vegetable Oils, Heavy Petroleum in, the Detection of, 247
Palladium and Nickel, Separation of, by Means of Dimethylglyoxime, 379
Palm, Kernel or Cocoanut Oils, Margarines Containing, on the Relation between the Kirschner and Polenske Values for, 183
—— Oil from Different Varieties of Palm, Characteristics of, 55
Pancreas Function, the Quantitative Investigation of, Modification of Wohlgemuth's Method for, 315
Pancreatic Amylase, a Further Investigation of the Properties of Studies of Amylases, 454
Pancreatin, the Tryptic Value of, New Method for Determining, 26
Papain, the Digestive Value of, Determination of, 405
Paraffin Wax and Ceresin, Mixtures of, Analysis of, 59
————, the Analysis of, Application of the Formolite Reaction to, 274
Paraldehyde, Acetaldehyde in, Estimation of, 265
Parchment Paper, 465
———— Papers, Imitation, and "Pergamyn," 144
Peel, Candied Lemon, Analysis of, 20
Pepper, Cayenne, Adulteration of, Detection of, 259
Pepsin and Rennin, Separation of, by Means of the Electric Current, 141
Peptones, Influence of, on the Estimation of Reducing Sugars by Fehling's Solution, 367
Perchlorates, Certain, Perchloric Acid in, Estimation of, 33
————, Quantitative Determination of, 374
Perchloric Acid in Electrochemical Analysis, 279
"Pergamyn" and Imitation Parchment Papers, 144
Permanganate, Action of, on Organic Substances, 366
————, Estimation of Arsenious Acid with, in Presence of Hydrochloric Acid, 417
———— Method, the Alkaline, Activity of Organic Nitrogen as Measured by, 365
————, Potassium, Estimation of Formic Acid in the Presence of Other Acids by Means of, 270
———— Solution, Potassium, Standardisation of, by Sodium Oxalate, 280
Peroxide, Hydrogen, and Alkali, Behaviour of Invert Sugar in the Presence of, 28
Peroxydase and Alkalinity of Milk; Are they Identical? 141
————, Nature of, 504
————, Separation of, from Catalase, 315
Peru Balsam, Cinnamein in, Estimation of, 93

Pétri Dish for Cultivating Fungi and for Biological Analysis, a Substitute for the, 561
Petroleum and its Products, Water in, Determination of, 573
——— Ether and Ether, the Higher Fatty Acids in, Solubilities of the Lead Salts of, 399
———, Heavy, in Paints and Vegetable Oils, the Detection of, 247
——— in Turpentine, Estimation of, 371
———, Mixtures Containing, the Examination of, 8
——— -Residue and Natural Asphalts, Differentiation Between, 407
——— Residues, "Acid Resins" from, 515
——— Spirit and Benzene Hydrocarbons in Turpentine Oil, Estimation of, 274
———, Sulphur in, Estimation of, 217
Petroleums of the San Joaquin Valley of California, Physical and Chemical Properties of, 104
Phenaceturic Acid, Benzoic Acid, and Hippuric Acid in Urine, Estimation of, 356
Phenol and *p*-Cresol in the Presence of Each Other, Estimation of, 62
——— in Urine, Estimation of, 356
——— *p*-Sulphonic Acid, the Determination of, Volumetric Method for, 464
———, Rapid Methods for Determining, 515
Phenolphthaleïn, as an Indicator, Use of, 320
———, Estimation of Free Carbon Dioxide in Water by Titration with Alkalis in the Presence of, 582
———, the Oxidation of Phenolphthalin to, Catalytic Action of Light on, 30
———, the Sensitiveness of, Simultaneous Effect of Alcohol and a Neutral Salt on, 321
Phenols, Higher, Use of, in Testing for Free Lime in Portland Cement, 582
———, in Effluents, Colorimetric Estimation of, 30
m-Phenylenediamine, Reaction of Gold Salts with, 469
Philippine Essential Oils, New, 61
Phosphates, Soil, the Solubility of, Effect of Ignition on, 523
Phosphomolybdate Estimation of Phosphoric Acid in Soils, 130
——— Precipitate, Rapid Method for Determination of Vanadium in Steels, Ores, etc., Based on its Quantitative Inclusion by the, 284
Phosphomolybdates, Separation of, from Silicomolybdates, 107
Phosphoric Acid, Estimation of, by Von Lorenz's Method, 149
———, in Presence of Colloidal Silicic Acid, Estimation of, 214
——— in Soils, the Phosphomolybdate Estimation of, 130
——— in Wines, Estimation of, 453
Phosphorus Compounds, Acid-Soluble, of Some Feeding Materials, 193
——— in Food-Stuffs and Other Organic Substances, Determination of, by Titration, with Uranyl Solutions, 258
——— in Wine, Estimation of, 24
———, Inorganic, in Plant Substances, Estimation of, 472
Phosphotungstic Acid, Blue Colour-Reaction of, with Uric Acid and Other Substances, 355
Photographic Estimation of the Intensity Distribution in Blood Spectra, 313
Photometer, New Hand, 429
Physical Analysis of Soils, New Method for, 36
Physico-Chemical Basis of the Seliwanoff Lævulose Reaction, 367
——— Method for Determining the Changes taking Place in Meats, 455
——— Volumetric Method, Estimation of Sulphates in Solution by, 282
Physiological Fluids, Other, and Urine, Blood in, Detection of, 506
Phytosterol, Crude, of Cocoanut Oil, and the Crude Cholesterol of Butter Fat, and the Detection of Cocoanut Oil in Butter Fat, 497
Pine Oil, in Turpentine Oil, Detection of, 143

Pipette, Automatic Pressure, 153
Pitch, Mineral Oils, etc., Asphalt in, Estimation of, 58
——, the Melting-Point of, New Method for Determining, 62
——, the Viscosity of, Comparison of Methods for Determining, 413
Plant Juices, the Oxidase Content of, Measurement of, 261
—— Substances, Inorganic Phosphorus in, Estimation of, 472
Plants, Small Quantities of Copper in, Detection and Estimation of, 313
——, the Amino-Acids in, Estimation of, by Means of the Formaldehyde Method, 312
Plates, Alundum, Filtration with, 109
Platinum, Action of Boiling Sulphuric Acid on, 590
———— Alloys, Analysis of, 420
————, Gold and Silver, Estimation of, 281
———— Salts, Action of Dimethyl-Glyoxime on, 524
————, Small Amounts of, in Ores and Bullion, Direct Determination of, 281
Wire, Use of Magnesia Rods instead of, in Analytical Work, 222
Poisonous Gases from Oilfields, 486
Polarimetric Estimation of Banana Starch, 560
———— ———— of Glucosamine in Ovomucoid and Pseudomucin, 561
———— ———— of Starch, 351
of Starch in Sausages, 498
Method, Lintner's, for the Determination of Starch, 498
Polarisation, Sodium Flame Lamps for, 594
Polenske and Kirschner Values for Margarines Containing Cocoanut or Palm-Kernel Oils, on the Relation between, 183
———— Value of Fats, the Estimation of, Sources of Error in, 256
Polypeptides and Some Amino-Acids, Hydrolytic Action of, on Certain Esters. Studies on Enzyme Action, 353
————, Mono-Amino-Acids together with, the Detection of, Ester Method for, 272
Portland Cement, Free Lime in, Use of Higher Phenols in Testing for, 582
Potash Analysis (Potassium-Sodium Cobaltinitrite Method), 588
Potassium in Potassium Silicate, Estimation of, 588
———— Iodide and Mercurous Nitrate as Sensitive Reagents for Tungsten and Molybdenum, 378
————, Much, the Estimation of Small Quantities of Rubidium in Presence of, Spectroscopic Process for, 324
———— Nitrate in Meats, Estimation of, 140
———— Permanganate, Estimation of Formic Acid in the Presence of Other Acids by Means of, 270
———————— Solution, Standardisation of, by Sodium Oxalate, 280
———— Silicate, Potassium in, Estimation of, 588
————, Small Quantities of, Estimation of, 214
---, Volumetric Estimation of, 34
Potatoes, Dry Matter in, Estimation of, and the Applicability of the Ordinary Tables, 259
Powder, Smokeless, Mercury in, Estimation of, 273
Powders, Cocoa, Husk in, Estimation of, 402
————, Nitrocellulose, and Nitrocellulose, Alteration of, by Heat, 104
————, Vegetable, the Estimation of Adulterants in, Apparatus for, and Notes on Starch Granules, 529
Precipitant for Amino-Acids, 359
Precipitates, Apparatus for Automatically Decanting and Washing, 479
————, Small Quantities of, the Quantitative Manipulation of, 68
Precipitation of the Copper-Arsenic Group and Separation of its Divisions, 376

Precipitin Reaction, the Quantitative, Application of, in Honey Analysis, II., 404
Preservative Coatings and Paint Films for Iron and Steel, New Method for Testing, 213
————, New, for Milk, Cream, etc., Note on, 178
Preservatives, Certain, Influence of, on the Keeping Properties and Composition of Butter, 52
———— for Milk, Cream, etc., Detection of Certain Proprietary Substances Sold as, Report to the Local Government Board on Analyses and Methods of. 155
————, Wood, the Commercial Value of, Tests to Determine, 578
Pressure, Great, the Course of Reactions under, Electric Furnace for Studying, 288
Primary and Secondary Amines, the Separation of Tertiary from, New Method for, 201
Producer Gas, Tar in, Estimation of, 275
Products, Natural, Sugars in, Estimation of, 145
————, Petroleum and its, Water in, Determination of, 573
Protein, Alcohol-Soluble, or Gliadin, in Wheat-Flour, Determination of, 19
Proteins, Certain, Refractive Indices of Solutions of. VI. The Proteins of Ox Serum: A New Optical Method for the Estimation of the Various Proteins in Ox Serum, 355
Proteins, Determination of the Power of Bacteria to Decompose, Method of Testing Water, 264
————, Estimation of Lactic Acid in the Presence of, 403
————, Other, and Horny Tissue, the Quantity of Tryptophane in, and Colorimetric Method for the Estimation of Tryptophane, 565
————, the Complete Hydrolysis of, Conditions for, 573
Proteolytic Enzyme of Malt, 504
Proximate Analysis of Complex Lipoids by Alcoholysis, 463
Pseudomucin and Ovomucoid, Glucosamine in, Polarimetric Estimation of, 561
Public Health (Regulations as to Food) Act, 1907, Regulations under the, 432
Pulp, Sulphite, Bleaching Quality of, Determination of, 511
Pumps, Filter, Valve for, 480
Purification, Softening, and Sterilisation of Water Supplies, 334
Pyridine and Ammonia, Separation and Estimation of, 413
———— Bases in Ammonia and Ammonium Salts, Detection of, 413
———— in the Presence of Ammonia in Gas-Water, Rapid Estimation of, 574
Pyrites and Sulphur, Selenium in, Iodimetric Estimation of, 215
Method for the Estimation of, 67
————, Copper in, Electro-Analytical Estimation of, 468
————, Sulphur in, Estimation of, 34
————, ————, Exact Determination of, 524
Pyroligneous Acid, Methylcyclopentenolon in, Occurrence of, 319
Pyrrolidonecarboxylic Acid, Separation of, from Glutamic Acid. Esterification of Monamino Acids by Means of Ethyl Iodide, 360

Qualitative Analysis, System of, for the Common Elements, Part V. Acidic Constituents, 322
———— without Hydrogen Sulphide, 377
———— Tests, Certain, for Oils, Influence of Lucidol (Benzoyl Peroxide) on, 273
Quantitative Analysis of Solutions by Precise Thermometry, New Method for, 333
Quinine in Urine and in Blood, Quantitative Estimation of, 455

Radium in Minerals and Rocks, Estimation of, 323, 421
————, the Comparison of Quantities of, New Compensation Method for, and Some Applications of this Method, 473

Rare Earths, Certain, Fusion of, with Alkali Carbonates. Separation of Tungsten from Iron, Beryllium, and Aluminium, 591

————, Separation of the, 380

Raw Materials, Cement, and Cement, Analysis of, 208

—— Rubber, the Amount of Insoluble Particles in, a Method for Determining, 13

Rays, Ultra-Violet, in Ozone, Absorption of, and its Application to the Estimation of Ozone in Small Concentrations, 472

——————, Sterilisation of Water and Dairy Materials by, 196

Reagent for Ferrous Salts, Dimethylglyoxime as a, 102

———, the, "Tetramethyl Base," Use of, 105

———, the Grignard, Quantitative Estimation of Hydroxy-, Amino-, and Imino-Derivatives of Organic Compounds by Means of, and the Nature of the Changes Taking Place in Solution, 201

Reagents, Sensitive, for Tungsten and Molybdenum, Potassium Iodide and Mercurous Nitrate as, 378

Red Rubber Goods, Antimony in, Estimation of, 64, 65

Reducing Agent, a New, for Analytical Use, Hydrazine Hydrate, and Formaldehyde, Tetraformal-trisazine from, 369

———— Sugar Methods (A Correction for Lactose), Unification of, 145

———— Sugars, Direct Determination of Sucrose in the Presence of, 451

——————, the Determination of the, New Method for, 205

——————, the Estimation of, by Fehling's Solution, Influence of Peptones on, 367

Reductase, Catalase, and Leucocyte Tests, Comparative Value of, in Detecting Mastitis, 401

———— Test, Acidity, and Alcohol Test in Milk, Relations between, 26

Redwood's, Engler's, and Saybolt's Viscosimeters, Comparative, Examination of, 223

Refractive Index of Beeswax, 348

—————— of Chinese Wood Oil, 410

——————, Standard, Rohrbach Solution of, Determination of the Density of Minerals by Means of, 148

———— Indices of Solutions of Certain Proteins. VI. The Proteins of Ox Serum: A New Optical Method for the Estimation of the Various Proteins in Ox Serum, 355

Refractometer Value of the Serum of Cow's and Goat's Milk, 317

—————, Zeiss', Estimation of Fat in Cocoa by Means of, 495

Refractometric Estimation of the Strength of Formaldehyde Solutions, 202

Rennet, Commercial, the Activity of, the Estimation of, 564

Rennin and Pepsin, Separation of, by Means of the Electric Current, 141

———, Laboratory Studies of, 405

(Report, Eighth, on Research Work. Metropolitan Water Board.) The Softening, Purification, and Sterilisation of Water Supplies, 334

———, Investigations of Explosives Used in Coal-Mines, 290

———, ————— of Fuse and Miner's Squibs, 291

———, Milk and Cream Regulations (Draft), 109

——— of the Government Chemist upon the Work of the Government Laboratory for the Year Ending March 31, 1912, with Appendices, 530

——— on the Work of Inspectors of Foods, 71

———, Seventh, on Research Work of the Metropolitan Water Board, 195

———, Sixth Annual, Metropolitan Water Board, 597

———, Study Committee of the International Dairy Federation, 532

———, The Connecticut Agricultural Experiment Station. Thirty-third and Thirty-fourth Reports, 1909 and 1910, 72

Report to the Local Government Board on Analyses and Methods of Detection of Certain Proprietary Substances Sold as Preservatives for Milk, Cream, etc., 155
——— to the Local Government Board on the Nature of the Colouring Matter of Flour and its Relation to Processes of Natural and Artificial Bleaching, 596
Resin, Scammony, and Scammony Root, Composition of, 194
"Resins, Acid," from Petroleum Residues, 515
Resins, Bitter, of Hops in Worts and Beers and their Volumetric Estimation, 139
———, Gum, Notes on the, 270
———, the Amount of, and the Viscosity of Rubber Solutions, Relationship between, 575
———, Total Soft, and Hard, in the Hop, Determination of, Comparative Study of Methods for, 191
Riegler's Method, Estimation of Urea in Urine by. A Correction Factor, 357
——————— for the Estimation of Urea in Urine, Modification of, 100
Ritter Method, the Estimation of Cholesterol by the Errors in; Effect of Autolysis on Cholesterol, 199
Roasted Blende, Sulphur in, Rapid Method for Determination of, 150
Rocks and Minerals, Radium in, Estimation of, 323, 421
———, Silicate, Ferrous Iron in, Estimation of, 146
Rods, Magnesia, Use of, instead of Platinum Wire, in Analytical Work, 222
Rohrbach Solution of Standard Refractive Index, Determination of the Density of Minerals by Means of, 148
Rosin and Mineral Oils, Fluorescence Test for, 30
Rubber, Direct Determination of, 574
——— Goods, Red, Antimony in, Estimation of, 64, 65
———, Raw, the Amount of Insoluble Particles in, a Method for Determining, 13
——— Solutions, the Viscosity of, and the Amount of Resins, Relationship between, 575
———, the Estimation of, Hübener Bromide Method for, 465
Rubberised Fabrics, Analysis and Testing of, 575
Rubidium, Small Quantities of, the Estimation of, in Presence of Much Potassium, Spectroscopic Process for, 324
Rum, Guadaloupe, Composition of, 97
Rye, Ergot of, a New Glucoside in: Clavicepsin, 19

Saccharin and Dulcin in Beverages, Foods, and Drugs, Separation and Identification of, 23
———— and Saponin in Oil Emulsions, Estimation of, 22
———— in Foods, Estimation of, 194
Saffron, Adulterants in, Estimation of, 309
Sale of Food and Drugs Acts, 1875 to 1907, Circular to Local Authorities for the Purposes of, 434
Salicylates, Thymol, and Allied Compounds, Estimation of, 369
Salicylic Acid and Copper, Colorimetric Estimation of, 104
——————, Small Quantities of, in Presence of Excess of *p*-Hydroxybenzoic Acid, Biochemical Method for the Estimation of, 316
Salt, a Neutral, and Alcohol, Simultaneous Effect of, on the Sensitiveness of Phenolphthaleïn, 321
—— Solution, Normal, Solubility of Ether in, 448
Salts, Ammonium, and Ammonia, Pyridine Bases in, Detection of, 413
——, Copper, Titration of, with Titanous Chloride, 516
——, Ferric, Compounds of, with Albumoses, 408

Salts, Ferrous, Dimethylglyoxime as a Reagent for, 102
——, Gold, Reaction of, with *m*-Phenylenediamine, 469
——, Lead, of the Higher Fatty Acids of Ether and in Petroleum, Ether, Solubilities of, 399
——, Platinum, Action of Dimethylglyoxime on, 524
——, the Penetration of, in Treated Wood, Determination of, 150
Sand, Monazite, Thorium, Especially in, Quantitative Estimation of, by Means of Sodium Hypophosphates, 423
"Sapometer," 479
Saponification of Fats by Sulphuric Acid, 256
——————, Fractional, 558
Saponin and Glycyrrhizin in Lemonades, Detection of, by Means of Vamvakas' and Frehse's Tests, 22
——— and Saccharin in Oil Emulsions, Estimation of, 22
———, Detection of, 350
———, in Beverages and Foods, Detection of, by Hæmolysis, 350
Sausages, Starch in, Polarimetric Estimation of, 498
Savin Oil, Detection of, in Toxicological Cases, 357
——, Oil of, the Constituents of, 295
Sawdust, Ordinary and Treated, the Value of, for Animal Nutrition, Experiments on, 559
Saybolt's, Engler's, and Redwood's Viscosimeters, Comparative Examination of, 223
Scale Preparations (Pharmaceutical), Iron in Determination of, 306
Scammony Resin and Scammony Root, Composition of, 194
Schlœsing's Method, Estimation of Nitrates and Nitrites in Water by, 212
Sea-Water, Concentration of Hydrogen Ions in, Measurement of, 425
Secondary and Primary Amines, the Separation of Tertiary from, New Method for, 201
Secretory Capacities, Amyloclastic, of the Embryo and Aleurone Layer of Hordeum, 97
Seeds of *Illicium Verum* Hook and *Illicium Religiosum* Sieb, the Fatty Oils obtained from, Composition of, 495
Selenium in Sulphur and Pyrites, Iodimetric Estimation of, 215
——————————, the Estimation of, Method for, 67
Seliwanoff Lævulose Reaction, Physico-Chemical Basis of, 367
Sensitive Reaction of Free Bromine, 581
——— Reagents for Tungsten and Molybdenum, Potassium Iodide and Mercurous Nitrate as, 378
——— Test for the Detection of Albumin in Urine, 505
Sensitiveness of Phenolphthaleïn, Simultaneous Effect of Alcohol and a Neutral Salt on, 321
Serger's Reaction for Vegetable Oils, Notes on, 412
Serum of Cow's and Goat's Milk, Refractometer Value of, 317
——, Ox, the Proteins of: A New Optical Method for the Estimation of the Various Proteins in Ox Serum. Refractive Indices of Solutions of Certain Proteins, 355
Serums, Milk, Preparation of, and their Use in the Analysis of Milk, 450
Sesame Oil in Other Oils, Reaction for Detecting, 62
Sewage Effluents, Nitrates in, Estimation of, 149
Shea-Nuts and Shea-Butter, 496
Shellacs and Stick-Lacs, Various, the Examination of, Preliminary Notes on, 204
Shimer Crucible, the Newest Form of, Determination of Carbon in Steel by Direct Combustion in, with the Aid of a Perforated Clay Disc, 521
Shrewsbury and Knapp's Process for Estimating Cocoanut Oil, Notes on, 3
Siderurgical Products, the Rapid Estimation of Sulphur in, Modification of the Method of Arnold and Hardy for, 283

Silicate, Potassium, Estimation of Potassium in, 588
——— Rocks, Ferrous Iron in, Estimation of, 146
Silicates, Alkalis in, Estimation of, by Fusion with Calcium Chloride, 146
———, the Estimation of Water in, Improvements in the Ludwig-Sipöcz Method for, 380
Silicic Acid, Colloidal, Phosphoric Acid in Presence of, Estimation of, 214
——— Gels, Vapour Pressure Isothermals of, Apparatus for Determination of, 328
Silicomolybdates, Separation of Phosphomolybdates from, 107
Silver, Gold, and Platinum, Estimation of, 281
——— Spiral, New, for Use in Organic Elementary Analysis, 289
Slide, Electrically-Heated Microscope, 592
Smokeless Powder, Mercury in, Estimation of, 273
Soap, Water in, Estimation of, 31
SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS, PROCEEDINGS OF, 3, 41, 81, 121, 168, 229, 295, 339, 392, 439, 485, 537
Soda Lime Glasses, the Refractive Index of, Relation of, to their Chemical Composition, 278
——, Nitrate of, Rational Analysis of, 523
Sodium Flame Lamps for Polarisation, 594
——— Hydroxide and Sugar, Hydrogen Peroxide in Presence of, Quantitative Separation of Copper from Arsenic, Aluminium, Zinc, Tungsten, and Tin by Means of, 210
——— Hypophosphate, Quantitative Estimation of Thorium, especially in Monazite Sand, by Means of, 423
——— Oxalate, Standardisation of Potassium Permanganate Solution by, 280
——— Peroxide for Bleaching Purposes, Assay of, 476
Softening, Purification, and Sterilisation of Water Supplies, 334
Soil Analysis, Mechanical, Modification of the Method of, 589
——, Hawaiian, Humus in, Determination of, 513
—— Humus, Studies on, 466
—— Phosphates, the Solubility of, Effect of Ignition on, 523
Soils, Arable, Colloids in, Estimation of, 98
——, Arid, Mechanical Analysis of, 588
——, Calcium Carbonate in, a Method of Estimating, 128
——, Phosphoric Acid in, the Phosphomolybdate Estimation of, 130
——, the Acidity of, Study of, 466
——, ————, —— on, 422
——, the Physical Analysis of, New Method for, 36
——, Total Manganese in, Estimation of, 423
Solanidine from *Solanum Tuberosum*, 497
Solanum Tuberosum, Solanidine from, 497
Solidified (Hydrogenised) Oils, 452
Solids and Liquids, Quantitative Separation and Estimation of, Laboratory Centrifuge for, 286
———, Density of, Determination of, New Densivolumeter for, 328
———, Total, of Vinegar, Estimation of, 260
———, ———, of Wine, the Direct Estimation of, Critical Remarks on, 311
Solubility Estimations in Agricultural Chemistry, 37
Solutions, Quantitative Analysis of, by Precise Thermometry, New Method for, 333
Solvates in Mixtures of Liquids, the Detection of, and Mixtures of Associated with Non-Associated Liquids (Part III). Latent Heats of Vaporisation of Mixed Liquids, 362

Solvents, Cold Estimation of Fat by Extraction with, 102
———, Immiscible, Apparatus for Extracting Liquids with, and for Measurement of Evolved Gases, 69
———, Non-Aqueous, Rare Earth Reactions in, 524
Soot, Its Character and Composition, 63
Souring of Milk, 168
Southern Cypress, Oil of the, 364
Soxhlet Extraction Apparatus, Modified, with Distillation Arrangement, 596
Sparking, Rapid Removal of Nitrogen from Gas Mixtures by, Apparatus for, 224
Specific Gravity of Some Fatty Oils, Effect of Free Fatty Acid on, 410
Spectra, Blood, the Intensity Distribution in, Photographic Estimation of, 313
Spectroscopic Process for the Estimation of Small Quantities of Rubidium in Presence of Much Potassium, 324
Spelter, Technical Analysis of, 521
Spermatic Fluid, Microchemical Reaction of, 358
Spices, etc., Small Quantities of Essential Oils in, the Estimation of, Part II., 88
Spiral, New Silver, for Use in Organic Elementary Analysis, 289
Spirits and Ethyl Alcohol, Methyl Alcohol in, Detection of, 567
———, Estimation of Methyl Alcohol Especially in, and in Admixture with Methyl Alcohol, 514
Springs, Thermal, of Bath, Analysis of the Waters of, 478
Squibs, Miners', and Fuse, Investigations of, 291
Stability Test, Modified Form of, 573
———, New, for Nitrocellulose Powders, 572
Standard, an Acidimetric, Benzoic Acid as, 458
Standardisation, Electrolytic, of the Conditions of the Iodide Method of Copper Analysis, and Sources of Error, 277
——— of Potassium Permanganate Solution by Sodium Oxalate, 280
Standards for Malt Vinegar, 123
———, Widely Varying, Rapid Work with, Colorimeter for, 329
Starch, Banana, Polarimetric Estimation of, 560
——— Granules, Notes on, and Apparatus for the Estimation of Adulterants in Vegetable Powders, 529
———, Indigos Containing, Analysis of, 319
———, in Sausages, Polarimetric Estimation of, 498
———, Lintner's Polarimetric Method for the Determination of, 498
———, Polarimetric Estimation of, 351
Starches, Commercial, for Use in Cotton Mills, Method for Determining the Value of, 368
Statistics, Fruit-Juice, for the Year 1911, 94
———, Wine, for the Year 1909-10, 96
Statutory Rules and Orders, 435
Steel and Iron, Oxygen in, Determination of, by Reduction in an Electric Vacuum Furnace, 586
———, Paint Films and Preservative Coatings for, New Method for Testing, 213
———, Sulphur in, Volumetric Estimation of, 67
———, Carbon in, Determination of, by Direct Combustion in the Newest Form of Shimer Crucible, with the Aid of a Perforated Clay Disc, 521
the Estimation of, 392
———, Determination of Vanadium in, New Method for, 285
———, Vanadium in, Rapid Determination of, 283
Steels, Ores, etc., Rapid Method for, Determination of Vanadium in, Based on its Quantitative Inclusion by the Phosphomolybdate Precipitate, 284

Steels, Vanadium, Estimation of Chromium and its Separation from, 146
Sterilisation of Water and Dairy Materials by Ultra-Violet Rays, 196
———, Softening, and Purification of Water Supplies, 334
Stick-Lacs, and Shellacs, Various, the Examination of, Preliminary Notes on, 204
Storax, Examination of, 499
Sublimation Apparatus, New, and its Application in Food Analysis, 428
——— in a Vacuum, Simple Apparatus for, 38
——— Vacuum, New Apparatus for, 290
Succinic and Malic Acids in Wines, Estimation of, 453
Sucrose in Condensed Milk, Estimation of, 450
——— in the Presence of Reducing Sugars, Direct Determination of, 451
———, Inversion of, by the Enzymes of Honey, 194
——— Solutions, Inversion of, by Means of Ammonium Chloride, 576
Sugar Analysis by Copper Reduction Methods, a Critical Study of, 413
——— and Sodium Hydroxide, Hydrogen Peroxide in Presence of, Quantitative Separation of Copper from Arsenic, Aluminium, Zinc, Tungsten, and Tin by Means of, 210
——— Determinations, Invert, Electrolytic Apparatus for Use in, 576
——— in Blood, Estimation of, 141, 263
——— in Urine and Blood, Estimation of, 356
———, the Estimation of, Use of Charcoal as a Clarifying Agent in, 57
———, Trommer's Test for, 406
———, Invert, Expanded Meissl-Hiller Table for, 575
———, ———, in the Presence of Alkali and Hydrogen Peroxide, Behaviour of, 28
———, Reducing, Methods (A Correction for Lactose), Unification of, 145
Sugars and Alcohol, the Iodimetric Titration of Sulphites in Presence of, 439
——— in Natural Products, Estimation of, 145
———, Other, Estimation of Cane-Sugar in Urine in the Presence of, 506
———, Reducing, Direct Determination of Sucrose in the Presence of, 451
———, ———, the Determination of the, New Method for, 205
———, ———, the Estimation of, by Fehling's Solution, Influence of Peptones on, 367
———, the Estimation of, New Process for, 63
Sulphates in Solution, Estimation of, by the Physico-Chemical Volumetric Method, 282
——— in Water, the Determination of, Modification of the Modified Winkler Method for, 220
Sulphides in Lime Liquors, Estimation of, 325
———, Insoluble, Sulphur in, Estimation of, 283
Sulphite Pulp, Bleaching Quality of, Determination of, 511
Sulphites in Presence of Alcohol and Sugars, the Iodimetric Titration of, 439
Sulphonation Test for Creosote, Modification of, 269
Sulphur and Halogens in Small Quantities of Organic Substances, Estimation of, 216
——— and Pyrites, Selenium in, Iodimetric Estimation of, 215
———, ———, Method for the Estimation of, 67
——— Compounds in Commercial Benzol, Estimation and Elimination of, 100
———, Free, Estimation of, Rapid Volumetric Method for, 151
——— in Illuminating Gas, Estimation of, 152
——— in Insoluble Sulphides, Estimation of, 283
——— in Iron and Steel, Volumetric Estimation of, 67
——— in Nitrocellulose, Estimation of, 152, 273
——— in Petroleum, Estimation of, 217
——— in Pyrites, Estimation of, 34
———, Exact Determination of, 524
——— in Roasted Blende, Determination of, Rapid Method for, 150

Sulphur in Siderurgical Products, the Method of Arnold and Hardy for the Rapid Estimation of, Modification of, 283
——— in Steel and Iron, Volumetric Estimation of, 67
Sulphuric Acid, Boiling, Action of, on Platinum, 590
————, Estimation of, 152
————, Nitric Acid, and Nitrous Acid, in Nitrating and Waste Acids, Volumetric Estimation of, 381
————, Rapid Method of Purifying, 381
————, Saponification of Fats by, 256
———— Solution, the Method of Precipitating Metals as Iodides, etc., from, Applications of, 519
Sweeney Method for Crude Fibre, Modification of the, 447
Sweetened Condensed Milk, Australian, Composition of, 49
Syrups, Formic Acid in, Detection and Estimation of, 558
——, Gum in, Estimation of, 94
——, Process of Extracting Alkaloids from, 138

Tablets, Medicinal, Lecithin in, Estimation of, 449
Tannin in Wines, Estimation of, 195
Tannins, Vegetable, Detection and Differentiation of, 577
———, ———, Quantitative Reactions of, 31
Tar in Producer Gas, Estimation of, 275
Tartaric Acid, the Estimation of, General Method for, 516
Tea-Seed Oil and Cake, 500
Temperatures, Low (−36° to −83° C.), Ebullioscopic Determinations at, 287
Tertiary Alcohols, Detection of, 197
——— Amines, the Separation of, from Secondary and Primary Amines, New Method for, 201
Tetrabromide, Estimation of Caoutchouc as, 361
Tetraformal-trisazine, from Formaldehyde and Hydrazine Hydrate, a New Reducing Agent for Analytical Use, 369
"Tetramethyl Base," the Reagent, Use of, 105
Textile Fibres and Woods, Cellulose in, Estimation of, 268, 510
——— Finishes, Analysis of, 200
Thermometer, Beckmann, with a Modified Arrangement for Setting the Mercury Thread, 429
Thermometry, Precise, Quantitative Analysis of Solutions by, New Method for, 333
Thermo-Regulators, 108
Thermostat, Vapour, Easily Adjustable, 430
Thermostats, Shaking and Stirring Apparatus, etc., Notes on, 70
Thimble, Extraction, New Form of, 288
Thorium, New Reagent for, 382
———, Quantitative Estimation of, Especially in Monazite Sand, by Means of Sodium Hypophosphate, 423
———, the Separation of, New Method for, 219
Thymol, Salicylates, and Allied Compounds, Estimation of, 369
Thyroid Glands, Iodine Content of, 456
Timber, Creosote Oil and Other Oils Used for Preserving, Antiseptic Effect of, 56
Tin and Antimony, Bronzes Containing, Chromium in, Estimation of, 374
——, Arsenic, Aluminium, Zinc, and Tungsten, Quantitative Separation of Copper from, by Means of Hydrogen Peroxide in Presence of Sodium Hydroxide and Sugar, 210
——, Copper, Antimony, and Bismuth, Electro-Analysis of, with Acidified Chloride Constituents, 584

Tin, Volumetric Determination of, 477
Tissue, Horny, and Other Proteins, the Quantity of Tryptophane in, and Colorimetric Method for the Estimation of Tryptophane, 565
Tissues, Animal, the Drying of, Loss of Fat during, 355
———, Living, Waters, and Minerals, Minute Quantities of Fluorine in, Detection and Estimation of, 517
Titanium, New Colorimetric Method for, 590
————, Separation of Iron from, 323, 469
————, Volumetric Determination of, 590
Titanous Chloride, Titration of Copper Salts with, 516
Tobacco Extracts, Nicotine in, Methods of Estimating, 452
———, Nicotine in, Estimation of, 311
Tobaccos, Ceylon, Analyses of, 500
Toxicity of Mushrooms: Their Hæmolytic Action, 563
Toxicological Cases, Detection of Savin Oil in, 357
Traces of Arsenic and Antimony, Detection of, 581
Tragacanth, Gum, Volatile Acidity of, Compared with that of Indian Gum, 318
Trommer's Test for Sugar in Urine, 406
Tryptic Activity, Relative, Measurement of, 457
——— Value of Pancreatin, New Method for Determining, 26
Tryptophane, the Estimation of, Colorimetric Method for, and the Quantity of Tryptophane in Horny Tissue and other Proteins, 565
Tube, Modified Butyrometer, for the Estimation of Fat in Cheese, 221
Tungsten Alloys, High-Grade, Analysis of, 424
———— and Molybdenum, Sensitive Reagents for, Potassium Iodide and Mercurous Nitrate as, 378
————, Arsenic, Aluminium, Zinc, and Tin, Quantitative Separation of Copper from, by Means of Hydrogen Peroxide, in Presence of Sodium Hydroxide and Sugar, 210
———— in Ferrotungsten, Rapid and Exact Estimation of, 220
————, Separation of, from Iron, Beryllium, and Aluminium. Fusion of Certain Rare Earths with Alkali Carbonates, 591
Turmeric and Aniline Dyes in Mustard, Detection of, 557
Turpentine, Examination and Valuation of, 370
—————, Other Hydrocarbons in, Detection of, 311
—————, Oil of, the Purity of, Tests for Determining, 371
————— -Petroleum Spirit and Benzene Hydrocarbons in, Estimation of, 274
—————, Pine Oil in, Detection of, 143
—————, Petroleum in, Estimation of, 371

Ultrafiltration in Analytical Chemistry, Application of, 223
Ultra-Microscope, Value of Direct enumeration of Bacteria in Water by Means of the, 317
———-Violet Rays in Ozone, Absorption of, and its Application to the Estimation of Ozone in Small Concentrations, 472
————————, Sterilisation of Water and Dairy Materials by, 196
Uranyl Solutions, Determination of Phosphorus in Food-Stuffs and Other Organic Substances by Titration with, 258
Urea, Estimation of, 27

OBITUARY.

PERCY GERALD SANFORD.

We regret to announce the sudden death, from apoplexy, on November 26, of Mr. Percy Gerald Sanford, F.I.C., at the age of fifty years. Mr. Sanford was a very old member of the Society of Public Analysts, and was Public Analyst for the Borough of Penzance and additional Public Analyst for the Borough of Croydon. He was educated at Dulwich College and at the Royal School of Mines, and was subsequently assistant for three years to the late Dr. C. Meymott Tidy at the London Hospital Medical College. He was also for a time research assistant to Professor Pickering at Bedford College. Mr. Sanford gave much attention to the chemistry of explosives, and was for a time resident chemist to the Stowmarket Explosives Company, and subsequently at the National Explosives Company's Works at Hayle, Cornwall. He also acted as consulting chemist to the Cotton Powder Company, Limited, and was the author of a well-known treatise on "Nitro-Explosives." During later years Mr. Sanford had been engaged in the practice of general analytical and consulting chemistry in London, carried on in conjunction with his work as a Public Analyst under the Sale of Food and Drugs Act. He leaves a widow and an infant daughter.

* * * * *

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

The monthly meeting of the Society was held on Wednesday evening, December 6, in the Chemical Society's Rooms, Burlington House. In the absence of the President the chair was occupied by Mr. Arthur R. Ling, F.I.C., Vice-President.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. S. G. Agar, G. S. Barton, S. W. Bridge, A.I.C., R. V. Briggs, F. A. Mason, W. B. Saville, G. A. Stokes, and F. C. Dyche-Teague, B.Sc., A.I.C., were read for the second time; and certificates in favour of Mr. Herbert Hawley, M.Sc. (Birmingham), City Analyst's Laboratory, Council House, Birmingham, assistant to Mr. J. F. Liverseege, F.I.C.; and Miss Maud Gazdar, B.Sc. (Lond.), A.I.C., Fox Hall, Upminster, Essex, assistant analyst to Messrs. Dakin Bros., manufacturing chemists, were read for the first time.

Messrs. R. D. Carty, W. K. Walton, and G. F. Wesley Martin, were elected members of the Society.

The following papers were read: "The Estimation of Small Quantities of Essential Oil in Spices, etc." (Part II.), by J. A. Brown, F.I.C.; "The Determination of Furfural by Means of Fehling's Solution," by Lewis Eynon, B.Sc., F.I.C., and J. Henry Lane, B.Sc., F.I.C.; "The Examination of Petroleum Mixtures," by J. H. Coste, F.I.C., E. T. Shelbourn, F.I.C., and E. R. Andrews, F.I.C.; "A Method for Determining the Amount of Insoluble Particles in Raw Rubber," by Clayton Beadle and Henry P. Stevens, M.A., Ph.D., F.I.C.; "Note on Oil of Male Fern," by Ernest J. Parry, B.Sc., F.I.C.; "Note on Ground Almonds," by G. Cecil Jones, A.C.G.I., F.I.C., and Reginald F. Easton; "Note on the Determination of Small Quantities of Methyl Alcohol," by C. Simmonds, B.Sc.; and "The Composition of Australian (Victoria) Milk," "The Composition of Sweetened Condensed Milk," and "The Aldehyde Figure of Butter," by E. Holl Miller.

The CHAIRMAN announced the Council's nominations of Officers and Council for 1912 as follows:

President.—L. Archbutt, F.I.C.

Past-Presidents (limited by the Society's Articles of Association to Eight in Number).—Edward J. Bevan, F.I.C.; Bernard Dyer, D.Sc., F.I.C.; Thomas Fairley, F.I.C.; W. W. Fisher, M.A., F.I.C.; Otto Hehner, F.I.C.; R. R. Tatlock, F.I.C.; E. W. Voelcker, A.R.S.M., F.I.C.; J. Augustus Voelcker, M.A., B.Sc., Ph.D., F.I.C.

Vice-Presidents.—W. H. Willcox, M.D., B.Sc., M.R.C.P., F.I.C.; Arthur R. Ling, F.I.C.; John E. Stead, F.R.S., F.I.C.

Hon. Treasurer.—H. Droop Richmond, F.I.C.

Hon. Secretaries.—A. Chaston Chapman, F.I.C.; P. A. Ellis Richards, F.I.C.

NOTES ON SHREWSBURY AND KNAPP'S PROCESS FOR ESTIMATING COCOANUT OIL.

BY HERBERT S. SHREWSBURY, F.I.C., AND ARTHUR W. KNAPP, B.Sc., F.I.C.

(*Read at the Meeting, November* 1, 1911.)

MESSRS. CRIBB AND RICHARDS, in their paper on "Margarine Analysis" (ANALYST, 1911, **36**, 328), make the following statement: "Ample illustration of this is afforded by Shrewsbury and Knapp (ANALYST, 1910, **35**, 385) and other authors, who show that the differences between the figures for cocoanut oil and butter fat, upon which calculations are based, are not so great as in the Polenske process. The Polenske figure for cocoanut oil (17·5) is between five and six times that of butter (2 to 3·5), and, as far as we are aware, none of these other processes will improve on this ratio."

We cannot reconcile the first part of this statement with the figures actually given in our paper. The following table compares our method with the Polenske process in this respect. The figures are strictly comparable, being in both processes the number of c.c. $\frac{N}{10}$ alkali required for 5 grms. of fat:

	Figure for Cocoanut Oil.	Limit Figure for Genuine Butters.	Difference between Cocoanut Oil and Butter Figures.	Ratio of Cocoanut Oil and Limit Butter Figures.
Shrewsbury and Knapp...	163·0*	32·0*	131	5·1
Polenske	17·5†	3·5†	14	5·0

This comparison shows that the difference between the figures for cocoanut oil and butter fat is not *less* than that given by the Polenske method, but, on the contrary, more than nine times as great; and in practice we find that 5 per cent. of cocoanut oil increases the Polenske figure by about 0·5 c.c., and our figure by 5 c.c. This should be remembered when considering the very interesting figures found by H. T. Cranfield (ANALYST, 1911, **36**, 446). He showed that for butters from cows fed on cocoanut cake both the Polenske and our figure indicate the addition of cocoanut oil. Evidently the limit figure for genuine butters needs raising in both processes, to allow for the inclusion of these special butters amongst genuine butters. He showed, further, that genuine butters with a Reichert-Meissl value of 29·5 may give Polenske figures from 1·7 to 3·7—*i.e.*, a difference of 2. This difference has about the same significance as 20 in our process, for which the greatest variation found by Cranfield was 15·4 (40·1 – 24·7).

Again, Lewkowitsch found for edible cocoanut oils Polenske figures from 15·49 to 20·45. This wide range produces the same possible error in calculation as would a range for our process of 154·9 to 204·5. Happily, the range for cocoanut oils in our process is much less.

Whilst our method estimates the bulk of the fatty acids which occur as glycerides in cocoanut oil, the Polenske method depends upon the small percentage of water-insoluble volatile acids that are present. This difference is important, because it is not impossible that cocoanut oil could be treated to remove these, and thus give a Polenske figure approximating to that of butter. That the Polenske figure can be diminished by separating the liquid glycerides by pressure (as in the preparation of cocoa butter substitutes) is illustrated by the following analyses of products so obtained from a specimen of Cochin cocoanut oil:

	Reichert-Meissl Value.	Polenske Figure.	Shrewsbury and Knapp Figure.
Cocoanut "stearine" A... ...	4·2	12·1	169·0
Cocoanut "oleine" A	8·5	23·2	169·0
Cocoanut "stearine" B... ...	3·9	11·1	165·3

---

* Ross, Race, and Maudsley (ANALYST, 1911, **36**, 196) found 16·55 to 17·05 for cocoanut oil, and 35·5 as maximum for foreign butters.

† Lewkowitsch found 15·49 to 20·45 for cocoanut oil, and 4·1 for a foreign butter.

(Cocoanut "stearine" B had been subjected to the well-known method of refining with superheated steam before being pressed.) Whilst the Polenske figure is greatly reduced by this treatment, the Shrewsbury and Knapp figure is not affected to any extent. That the figure for "stearine" A and "oleine" A should be identical is accidental, and indicates that the figure for the "oleine" has been *raised* by the large percentage of the glycerides of the lower fatty acids to just the same extent as it has been *lowered* by containing the greater part of the olein present in the original oil.

It has been pointed out that the Polenske method does not give such good results with palm-kernel oil, since its Polenske figure is only about 11. It is, in all probability, still less effective for estimating palm-kernel "stearine," which doubtless has a yet lower value. An old sample of palm-kernel "stearine" gave a Reichert value of 4·2, Polenske figure 9·35, and Shrewsbury and Knapp figure 162·9. It is noteworthy that the insoluble volatile acids were solid. Since the principal constituent of palm-kernel oil is laurin, the Shrewsbury and Knapp figure is of similar magnitude to the figure for cocoanut oil. A sample of crude palm-kernel oil gave 163·7.

As modifications of, or additions to, accepted processes are considered convenient, we made one or two experiments on the fatty acids left in the Reichert flask after the usual distillation of the fatty acids. The non-volatile acids from butter were treated as described by our method, but the figures obtained were abnormally high, and seem to indicate that the oleic acid undergoes some change whilst boiling with the sulphuric acid, glycerol, and sodium sulphate. The results were useless for our purpose.

Referring to the paper of Messrs. Revis and Bolton (ANALYST, 1911, **36**, 334), we cannot see the necessity or advantage of their proposed modifications of our process. Many of these modifications we tried and discarded; they greatly increase the time taken by the method, thereby rendering it unsuitable as a *sorting test*, without apparently increasing the accuracy. In our experience we found the tedious method of cooling, with the production of supersaturated solutions from which the fatty acids crystallise slowly, not so accurate as the rapid separation of the hot liquids. Another disadvantage of the modifications is that the range for pure butters, as the published figures show, is greater than in our process. Under one circumstance our process may require modification—that is, if it is required for giving accurate estimations where *large* percentages of cocoanut oil are present. In such cases the absolute control of the final conditions is of greater importance, and, for example, the use of a bath at 37° C. might possibly improve results. However, one of us, working in the tropics, obtained by our method normal butter figures and consistent duplicate results, although the laboratory temperature was 30° C. Evidently the method as it stands can be used under winter or summer conditions for the purpose for which it was intended—*i.e.*, the rapid detection and approximate estimation of small percentages of cocoanut oil.

	Figure for Cocoanut Oil.	Limit Figure for Genuine Butters.	Difference between Cocoanut Oil and Butter Figures.	Ratio of Cocoanut Oil and Limit Butter Figures.
Shrewsbury and Knapp...	163·0*	32·0*	131	5·1
Polenske	17·5†	3·5†	14	5·0

This comparison shows that the difference between the figures for cocoanut oil and butter fat is not *less* than that given by the Polenske method, but, on the contrary, more than nine times as great; and in practice we find that 5 per cent. of cocoanut oil increases the Polenske figure by about 0·5 c.c., and our figure by 5 c.c. This should be remembered when considering the very interesting figures found by H. T. Cranfield (ANALYST, 1911, **36**, 446). He showed that for butters from cows fed on cocoanut cake both the Polenske and our figure indicate the addition of cocoanut oil. Evidently the limit figure for genuine butters needs raising in both processes, to allow for the inclusion of these special butters amongst genuine butters. He showed, further, that genuine butters with a Reichert-Meissl value of 29·5 may give Polenske figures from 1·7 to 3·7—*i.e.*, a difference of 2. This difference has about the same significance as 20 in our process, for which the greatest variation found by Cranfield was 15·4 (40·1 – 24·7).

Again, Lewkowitsch found for edible cocoanut oils Polenske figures from 15·49 to 20·45. This wide range produces the same possible error in calculation as would a range for our process of 154·9 to 204·5. Happily, the range for cocoanut oils in our process is much less.

Whilst our method estimates the bulk of the fatty acids which occur as glycerides in cocoanut oil, the Polenske method depends upon the small percentage of water-insoluble volatile acids that are present. This difference is important, because it is not impossible that cocoanut oil could be treated to remove these, and thus give a Polenske figure approximating to that of butter. That the Polenske figure can be diminished by separating the liquid glycerides by pressure (as in the preparation of cocoa butter substitutes) is illustrated by the following analyses of products so obtained from a specimen of Cochin cocoanut oil:

	Reichert-Meissl Value.	Polenske Figure.	Shrewsbury and Knapp Figure.
Cocoanut "stearine" A... ...	4·2	12·1	169·0
Cocoanut "oleine" A	8·5	23·2	169·0
Cocoanut "stearine" B... ...	3·9	11·1	165·3

---

* Ross, Race, and Maudsley (ANALYST, 1911, **36**, 196) found 16·55 to 17·05 for cocoanut oil, and 35·5 as maximum for foreign butters.

† Lewkowitsch found 15·49 to 20·45 for cocoanut oil and 4·1 for a foreign butter.

(Cocoanut "stearine" B had been subjected to the well-known method of refining with superheated steam before being pressed.) Whilst the Polenske figure is greatly reduced by this treatment, the Shrewsbury and Knapp figure is not affected to any extent. That the figure for "stearine" A and "oleine" A should be identical is accidental, and indicates that the figure for the "oleine" has been *raised* by the large percentage of the glycerides of the lower fatty acids to just the same extent as it has been *lowered* by containing the greater part of the olein present in the original oil.

It has been pointed out that the Polenske method does not give such good results with palm-kernel oil, since its Polenske figure is only about 11. It is, in all probability, still less effective for estimating palm-kernel "stearine," which doubtless has a yet lower value. An old sample of palm-kernel "stearine" gave a Reichert value of 4·2, Polenske figure 9·35, and Shrewsbury and Knapp figure 162·9. It is noteworthy that the insoluble volatile acids were solid. Since the principal constituent of palm-kernel oil is laurin, the Shrewsbury and Knapp figure is of similar magnitude to the figure for cocoanut oil. A sample of crude palm-kernel oil gave 163·7.

As modifications of, or additions to, accepted processes are considered convenient, we made one or two experiments on the fatty acids left in the Reichert flask after the usual distillation of the fatty acids. The non-volatile acids from butter were treated as described by our method, but the figures obtained were abnormally high, and seem to indicate that the oleic acid undergoes some change whilst boiling with the sulphuric acid, glycerol, and sodium sulphate. The results were useless for our purpose.

Referring to the paper of Messrs. Revis and Bolton (ANALYST, 1911, **36**, 334), we cannot see the necessity or advantage of their proposed modifications of our process. Many of these modifications we tried and discarded; they greatly increase the time taken by the method, thereby rendering it unsuitable as a *sorting test*, without apparently increasing the accuracy. In our experience we found the tedious method of cooling, with the production of supersaturated solutions from which the fatty acids crystallise slowly, not so accurate as the rapid separation of the hot liquids. Another disadvantage of the modifications is that the range for pure butters, as the published figures show, is greater than in our process. Under one circumstance our process may require modification—that is, if it is required for giving accurate estimations where *large* percentages of cocoanut oil are present. In such cases the absolute control of the final conditions is of greater importance, and, for example, the use of a bath at 37° C. might possibly improve results. However, one of us, working in the tropics, obtained by our method normal butter figures and consistent duplicate results, although the laboratory temperature was 30° C. Evidently the method as it stands can be used under winter or summer conditions for the purpose for which it was intended—*i.e.*, the rapid detection and approximate estimation of small percentages of cocoanut oil.

Discussion.

Mr. C. Revis said that in his experience the Polenske figure could be determined with much greater accuracy than the Shrewsbury and Knapp figure. In the hands of Mr. Bolton and himself the Shrewsbury and Knapp process, as originally published, had not yielded concordant results. When the process was modified as Mr. Bolton and he had suggested, they found that quite concordant results could be obtained by different observers. The final cooling was very necessary in the case of mixtures containing large proportions of cocoanut oil, because the solubility of the final fatty acids in 60 per cent. alcohol depended greatly on the temperature.

Mr. T. Macara agreed with what Mr. Revis had said as to the difficulty of getting concordant results with the Shrewsbury and Knapp process when working at the higher temperature. In an ordinary laboratory it was not always easy to regulate the temperature exactly, and to be able to work at the ordinary temperature was a great advantage.

Mr. E. R. Bolton said that the experience of Mr. Revis and himself had been that even a slight variation in the time of running off the hot solution of fatty acids was liable to cause considerable differences in the results, and their object in modifying the process had been to enable more consistent results to be obtained by independent workers who merely follow a published description. That being accomplished the process would be found to be a valuable one. It was to be noted that many of the figures given in the author's present paper related to the whole fats—cocoanut "stearine," palm nut "stearine," etc. Mr. Revis and he, even by the Polenske method, had not obtained very satisfactory results when working on the whole undiluted fats, but with such admixtures as were generally found in margarine the results were delicate and accurate, duplicate Polenske figures obtained by different observers commonly agreeing within a tenth of a c.c., and as far as their experience went they considered that the ratio between the Reichert-Meissl and Polenske numbers, reinforced by the Kirschner figure, afforded the best means of estimating cocoanut oil now available (*cf.* Analyst, 1911, **36**, 333).

Mr. Knapp agreed that an essentially practical process, such as this, ought to be capable of being satisfactorily carried out, after a little practice, by an average worker who simply followed the published description. He thought, however, that some misconception had arisen as to the comparative accuracy of the two processes, owing to the fact that in this process the figures obtained were larger than in the Polenske process, so that an agreement within 0·1 c.c. in the Polenske process would correspond to an agreement within 1 c.c. in the Shrewsbury and Knapp process. For example, Mr. Cranfield had considered that duplicate results should agree within 0·5 c.c., and he (the speaker) concurred; but to reach a corresponding degree of accuracy in the Polenske process the figures would have to agree within 0·05 c.c. With regard to the question of time, the alcoholic solution of the fatty acids should be run off after three minutes, but it seemed hardly likely that, on one hundred and eighty seconds, a variation of one or two seconds either way would make any important difference.

Mr. Richards pointed out that in the paper referred to, Mr. Cribb and he had stated that none of the other processes improved materially on that of Polenske so far as the ratio employed for calculation was concerned, and the figures given by the present Authors confirmed this, as the difference between 5·0 and 5·1 is negligible.

NOTE ON A COUNTERFEIT GOLD COIN.

By HERBERT S. SHREWSBURY, F.I.C.

(Read at the Meeting, November 1, 1911.)

Analysts are not infrequently called upon to examine counterfeit coin; but the specimen described below, which was uttered in Trinidad, appeared to be so unusual in character as to be worthy of a brief description.

The sample imitated a twenty-shilling piece of date 1861. It weighed 122 grains against 123·27 grains for a genuine coin. The milling and design were very good, but the gilding had begun to wear off in places, and the partial exposure of the underlying white metal led to the detection of the false coin. A piece of the white metal, after removal of the gilding, gave a specific gravity of 21·8 $\left(\frac{30^{\circ}}{4}{}^{\circ}\text{ C.}\right)$ as against 17·157 for standard gold coinage, and had an approximate composition of:

Platinum	91·5	per cent.
Antimony and traces of bismuth and iron ...	5·0	,, ,,
Copper	3·5	,, ,,
	100·0	

It was quite infusible and unaltered in the hottest part of the flame of a Méker burner.

One or two notes on the analysis may be of interest. The metal was somewhat difficult of solution. 0·326 grm. of the white metal required more than three hours' treatment with aqua regia on the water-bath to effect its solution, and it was quite insoluble in nitric acid of any strength.

Insufficient notice seems to be taken in most textbooks of the difficulty of solution of platinum sulphide in ammonium sulphide. Fresenius is a notable exception, and points out that the sulphide precipitate requires prolonged treatment with a large excess of hot ammonium sulphide, and that even under these conditions some of the platinum sulphide is usually left undissolved.

A difficulty occurred in the qualitative detection of the copper. The presence of platinum in solution appears to prevent the formation of the characteristic blue coloration with ammonia. Some platinum sulphide was left undissolved with the copper sulphide after solution of the bulk of platinum sulphide and all the antimony sulphide in hot ammonium sulphide. This insoluble sulphide precipitate dissolved in strong nitric acid, forming a yellowish-green solution, but the colour of the solution was scarcely affected by the addition of excess of ammonia. Copper was at once detected, however, on treatment of the ignited ammonium platinum chloride precipitate with hot nitric acid and application of the usual tests to the green nitric acid extract of the reduced impure platinum.

Although the high specific gravity of platinum permits a counterfeit of this nature to be made of the correct weight, it is somewhat difficult to understand how any profits can accrue from the proceeding. The fact of such coins actually being in circulation is corroborated by a notice in the "Counterfeit Detector," in which bankers are warned of the existence of counterfeit sovereigns made of gilded platinum and dated 1862 and 1863.

Possibly at the time of their production the price of platinum was sufficiently low to allow the realisation of a large profit.

* * * * *

THE EXAMINATION OF MIXTURES CONTAINING PETROLEUM.

By J. H. COSTE, F.I.C., E. T. SHELBOURN, F.I.C., and
E. R. ANDREWS, F.I.C.

(*Read at the Meeting, December* 6, 1911.)

In Section 3 of the Petroleum Act, 1871, it is stated that "For the purposes of this Act the term 'petroleum' includes any rock oil, Rangoon oil, Burmah oil, oil made from petroleum, coal, schist, shale, peat or other bituminous substance, and any products of petroleum or any of the above-mentioned oils, and the term 'petroleum to which this Act applies' means such of the petroleum so defined as, when tested in manner set forth in Schedule One to this Act, gives off an inflammable vapour at a temperature of less than one hundred degrees of Fahrenheit's thermometer."

The manner prescribed was the unsatisfactory one of testing, by means of a small flame, the petroleum contained in an open cup heated in a water-bath.

Section 2 of the Petroleum Act, 1879, provided that the term "petroleum to which this Act applies" should in future mean petroleum which gave off an inflammable vapour at a temperature of less than 73° F. The apparatus then newly designed by the late Sir Frederick Abel was prescribed for use, and the temperature of flash 73° F., as registered by this apparatus, was intended to correspond to a flash of 100° F. in the open cup.

In 1899 the London County Council appealed against a magistrate's decision that a composition containing 20 per cent. of petroleum did not come within the meaning of the Acts, and the higher court remitted the case to the magistrate for him to convict. In 1907 the Privy Council, acting on a provision of the Act of 1871, endorsed this view of the law, and strengthened it by an Order "that certain parts of the 'Acts of 1871 to 1881' the latter being the petroleum (Hawkers) Act should apply to any mixture of petroleum with any other substance or substances which . . . gives off inflammable vapour at a temperature of less than 73 degrees of Fahrenheit's thermometer, whether such mixture be liquid, viscous, or solid, in the same manner as if such mixture were petroleum, to which the said Acts apply."

Dismissing from consideration several questions which may arise out of the wording of the above-mentioned Acts and Order, the points at issue for the analyst in connection with any mixture are (1) Does it contain petroleum as defined by the Acts? (2) Is it to be certified as petroleum to which the Acts apply?

It might be taken from the wording of part of the Order that any mixture in respect of which the answer to (1) was in the affirmative, and which gave off inflammable vapour below 73° F., was *ipso facto* within the scope of the Acts; but this is not necessarily so, as it is stated that "mixtures of petroleum with other substances present dangers similar to those presented by petroleum without admixture." It is therefore necessary to consider the second question from a somewhat wider point of view than the mere giving off of an inflammable vapour.

The fact that petroleum which may or may not flash below 73° F. is used in paints, enamels, paint removers, polishes, solvents, etc., in admixture with alcohol, ether, and acetone which flash below 73° F., and turpentines, carbon tetrachloride, trichlorethylene and tetrachlorethane, which do not, renders a decision as to the application of the Petroleum Acts one of greater difficulty than can be solved by the class of officer to whom testing under the Acts is often entrusted.

Since the Acts do not apply to mixtures flashing at or above 73° F., it is in all cases convenient to determine the flash-point first, leaving the decision as to whether samples which do flash are, or contain, petroleum within the meaning of the Acts, to be based on subsequent chemical work.

Apart from difficulties presented by certain liquids due to their containing chloro-compounds the determination of flash-point is not so simple or satisfactory as might be thought. The three well-known types of apparatus—the original Abel, the Abel-Pensky as used in the Colonies, and the German form of the same apparatus—have recently been very carefully examined and compared by J. H. Harker, and W. F. Higgins (*Nat. Phys. Lab. Coll. Researches*, VIII. 19-39). The following points have been studied by these workers: (1) The influence of variations in the method of testing (*a*) the frequency of application of the test-flame, (*b*) variations in the time of opening the slide, (*c*) variations in the water-bath temperature, (*d*) variations in the depth of immersion of the thermometer; (2) the temperature distribution in the oil-cup of the various forms of apparatus; (3) the heat from the test-flame, differences of ½° F. may occur even in the most careful work, more especially in the apparatus provided with the oil test-flame; (4) the difference between the flash-points determined with the different forms of apparatus. These are approximately constant at all temperatures; the German form gives results about 3·7° F. and the Colonial form 1·1° F. higher than the Abel. The oil test-flame reads about ½° F. higher than the gas-flame. (5) They emphasise the fact that the flash-point of a liquid, as ordinarily determined, is an empirical constant which is largely a function of the particular apparatus used. The effect of thermometric lag has also been investigated.

If a low flash-point establishes a *prima facie* presumption of the presence of petroleum to which the Acts apply, it is necessary, in the first place, to determine whether the flash is wholly or partly due to the presence of petroleum.

We outline a general scheme which should enable such a decision to be made. It is obvious that in many cases some of the processes suggested could be omitted or modified, and that at various stages much useful information will be given by the determination of such physical properties as refractive index, boiling-point, and specific gravity, and by the consideration of the relation of these constants to one another. The odour and the nature of the flash given by liquids will often furnish useful qualitative information.

A liquid, which on agitation with water is found to be wholly miscible with it, cannot contain any appreciable quantity of the hydrocarbons which are the main constituents of petroleum as known to the law. If any loss of volume occurs, owing to the solution of a portion of the sample, it should be washed with further quantities of water until all soluble constituents (alcohol, acetone, etc.) are removed. These washings, or the water coming over with the steam distillate, may be examined by determining the initial boiling-point of the liquid and the properties of the first portion of the distillate.

The following example will illustrate the ease with which this can be done: A Russian burning oil flashing at 81° F. was mixed with 10 per cent. of ether. After washing about 80 c.c. with 6 washings, in all 1850 c.c., the flash-point was found to be 82° F., showing that the tendency is rather for traces of petroleum to be lost than for ether to be retained.

Viscous liquids which obviously contain fixed oils or solids in solution or suspension can be distilled either alone at ordinary or reduced pressure or with steam in order to obtain a suitable liquid for working on. If this be done, it is necessary to ascertain that the residue contains no matters which were present originally in liquid petroleum—*e.g.*, a sample of ordinary burning oil, flashing at 84° F., was steam distilled, and gave 45 per cent. by volume of a distillate flashing at 69° F. An unwary worker examining a mixture which contained such an oil might be disposed to certify it as containing petroleum within the meaning of the Acts, whereas the process of fractionation was the cause of the low flash. In all doubtful cases it is advisable to wash repeatedly with water, then with sodium bisulphite solution to remove alcohols and acetone, and afterwards to dry with calcium chloride, which should remove any traces of alcohol, and again to take the flash-point (*cf.* Nash, ANALYST, 1911, **36**, 577).

Whether the sample has been distilled with steam or alone, or only washed with water, the treatment with sodium bisulphite and calcium chloride should be carried out on the sample or the distillate. Only hydrocarbons and their chlorine derivatives, amyl alcohol or acetate, and carbon disulphide, are now likely to be present. The hydrocarbons may be terpenes, paraffins and cycloparaffins, and aromatic hydrocarbons. Terpenes may be removed by Armstrong's method (*J. Soc. Chem. Ind.*, 1882, **1**, 480), which has been shown by one of us to be applicable to mixtures of terpenes with both aliphatic and aromatic hydrocarbons (Coste, ANALYST, 1910, **35**, 438; Coste and Nash, *ibid.*, 1911, **36**, 207). This treatment also removes the amyl compounds mentioned above, but in presence of these substances the acid must be removed before steam distillation, as they separate from solution when the acid is diluted. The remaining liquid can only contain paraffins and cycloparaffins, homologues of benzene, carbon disulphide, and chloro compounds. If 1 c.c. is poured into a small porcelain capsule, diluted with 2 c.c. of alcohol, and the capsule placed on the bottom of a large beaker covered with a clock glass, which is moistened on the under side with a drop of silver nitrate, the appearance of silver chloride on the drop when the diluted liquid is lighted and the clock glass placed over the beaker will indicate the presence of chlorine, and, by inference, of chloroparaffins, etc. It is seldom that this treatment is necessary, as a peculiar reddish, smoky flash and an odour of hydrochloric acid will usually indicate the presence of any of these bodies. Carbon disulphide is seldom found in admixture with other solvents, and does not need much consideration.

Veley (*Proc. Roy. Soc.*, 1910, B. 82, 217) has examined tetrachlorethane and trichlorethylene, and his values (*cf.* Gowing Scopes, ANALYST, 1910, **35**, 238) for some of the properties of these are given below with figures for carbon tetrachloride and carbon disulphide:

		Refractive Index.	Boiling-Point.
CCl_4, carbon tetrachloride ...	$\frac{12{\cdot}3^\circ}{4^\circ}$ 1·6095	(12·3° C.) 1·4656	76–77° C.
$(CHCl_2)_2$, tetrachlorethane ...	$\frac{17^\circ}{17^\circ}$ 1·6013	(17° C.) 1·495587	147·2° C.
CCl_2, [trichlorethylene... ... $CHCl$,	$\frac{17{\cdot}5^\circ}{17{\cdot}5^\circ}$ 1·4702	(17° C.) 1·479141	87·55° C.
CS_2, carbon disulphide... ...	$\frac{0^\circ}{4^\circ}$ 1·2921	(20° C.) 1·6277	46·0° C.

As even the higher fractions of petroleum oil or coal-tar hydrocarbons seldom have a sp. gr. of 0·9, anything above this figure will, unless such substances as nitrobenzene or carbon disulphide are present, indicate the presence of chloro-compounds; and, conversely, anything below a sp. gr. of 1·47 will indicate the admixture of lighter substances with the chloro-compounds.

In any ordinary case if the oil freed from alcohol, ether, and acetone flashes below 73°F., and contains no carbon disulphide, it must contain "petroleum" in the eyes of the law, since chlorine compounds do not flash themselves, but raise the flashing-point of other liquids.

A mixture of carbon tetrachloride and benzene, when tested in the Abel apparatus, shows the inhibitive effect of the chloro-compound on the inflammability of the benzene vapour in a very pronounced degree. Instead of the bright, almost explosive, flash usually associated with the latter, one observes (probably after the slide has been opened several times), a reddish-coloured flame travel comparatively slowly across the surface of the liquid. No doubt the chloro-compound exerts a double effect in retarding flashing by diluting the inflammable vapour, and also (owing to its vapour density) by preventing the access of air.

From a mixture containing possibly both aromatic and aliphatic hydrocarbons and chloro-compounds of the latter, it is easy to remove aromatic hydrocarbons either by *careful* nitration followed by fractional distillation or by sulphonation. It must be borne in mind that if terpenes have been found in the liquid, the presence of aromatic hydrocarbons to the extent of from 5 to 12 per cent. of the terpenes found is probable, owing to the cymene obtained when turpentines are polymerised. This amount should be deducted from any aromatic hydrocarbons which may be found.

The approximate determination of the amount of paraffins and cycloparaffins in admixture with chloro-compounds can be made by a consideration of the physical properties of the mixture and of its probable constituents. We hope at a later date to be able to propose a fairly accurate method of estimation, but at present do no more than make the above suggestion with the warning that the accuracy of all physical methods is dependent on a qualitative knowledge of the constituents of the mixture.

We think we have shown that the examination of mixtures under the Petroleum Acts requires an amount of knowledge and judgment that places it above the powers of the ordinary "tester" to carry out efficiently, and is work which might more properly be entrusted to the Public Analyst or other chemical officer of the Local Authority administering the Acts.

We have examined several samples of liquids sold as paint removers, and have found them to consist principally of acetone and benzene; smaller amounts of other organic liquids are usually present, and we have identified alcohol, chloro-hydrocarbon derivatives and coal-tar naphtha in different samples. Several liquids labelled "non-inflammable solution" were found to consist of a wax or a mixture of waxes dissolved in carbon-tetrachloride and benzene. We have also detected light petroleum in mixtures sold for lacquering purposes. In these cases it was admixed with amyl alcohol. Amyl acetate and ethyl alcohol were also present in one instance. In some cases the dissolved substance is collodion cotton, and we understand that lacquers of this class are extensively used by silversmiths for protecting articles of silver plate from atmospheric influences.

DISCUSSION.

Mr. ARCHBUTT said that in testing the so-called "non-inflammable" mixtures he had always found it desirable not to rely simply on the fact of their flashing or not flashing in the official apparatus, but to put some of the material into a larger vessel and test it with a naked flame, and also to warm some of it in a fair-sized porcelain crucible and then test it. Under these conditions it was sometimes found that mixtures which did not actually flash in the Abel apparatus were nevertheless far from being uninflammable.

Mr. COSTE agreed with Mr. Archbutt; but the limitations as to what one might do when testing under the Petroleum Acts were very strict. They did not even allow of the correction of the flash-point for barometric pressure. The necessity for such a correction was only discovered by Sir Frederick Abel after the Act of 1881 was passed, and the Act had not since been amended to allow of it.

A METHOD FOR DETERMINING THE AMOUNT OF INSOLUBLE PARTICLES IN RAW RUBBER.

BY CLAYTON BEADLE AND HENRY P. STEVENS, M.A., PH.D., F.I.C.

(Read at the Meeting, December 6, 1911.)

CONSIDERABLE difficulties exist in separating raw rubbers from insoluble extraneous bodies in such a manner that these may be collected, examined and estimated. The most practical manner is to determine the loss on washing, but there is some difficulty in collecting the material removed in the process. For some purposes it is useful to reverse the operation and to remove the rubber and that which properly belongs to the rubber, and to collect, examine, and weigh the extraneous matter. Washing the material on the rolls in the ordinary way is the best procedure from the point of view of the examination of the rubber, but something is wanted, to supplement this test, and which will permit the examination of those impurities which are discarded and thrown away in this process. Moreover, the samples are at times too small to enable this to be done with advantage on ordinary washing rollers; further, with some kinds of scrap and tacky rubbers, the process of removal of the insoluble impurities is not sufficiently complete without overworking the rubber, and there are many cases in which the whole of the mechanical impurities are not removed even after prolonged treatment on the washing rollers. A very small amount of rubber is required for the test about to be described, and the smallness of the amount may be used as an argument against its adoption, because it may be suggested that so small a quantity cannot be taken to represent the bulk. This difficulty can be overcome by proper sampling. When the whole mass is sufficiently homogeneous, a portion of the crepe is taken for analysis. The treatment on the rolls should be as short as possible to avoid disintegration of the particles that exist in the rubber.

The insoluble constituents may be separated by dissolving the rubbers in benzene and allowing the insoluble constituents to settle out from the solution, or by filtration, but the drawback is the viscosity of the solution obtained, which hinders the sedimentation or filtration of the particles. This applies even to very dilute solutions of high-grade rubbers.

Many raw rubbers, particularly those in which the determination of the insoluble solid particles would be of most value, are difficultly soluble in naphtha or other solvents without mastication, which, however, has the disadvantage of disintegrating the insoluble matter. The insoluble matter may be estimated by decanting the top half of the solution as recommended by Schidrowitz, evaporating off the naphtha, and determining the weight of rubber. Knowing the total amount of rubber taken in the first instance and subtracting from this twice the weight of dry rubber obtained from the clear solution, the difference is the weight of the sediment. This latter, however, cannot be separated without further washing and filtration.

The method we have adopted is a modification of that employed in the case of vulcanised rubber goods. To bring about a separation of mineral in such materials, it is customary to heat the finely-ground rubber with an organic liquid of sufficiently high boiling-point to such a temperature as to bring about depolymerisation of the rubber and subsequent solution of the latter in a partly decomposed state. For this purpose nitro-benzene was introduced by Weber and subsequently nitro-naphthalene. Both these substances have disadvantages—the poisonous nature of the vapours of the former, and the fact that the latter is solid at ordinary temperatures. Subsequently xylol was suggested, the rubber and liquid being heated under pressure, and a further advance on this was a suggestion for using high-boiling petroleums which render an autoclave unnecessary. Phenetol has also been used, and we have found it very convenient for the purpose. Now it is well known that fully vulcanised mechanicals are much more difficult to treat by this process than soft rubbers. The latter, as might be expected, yield much more easily to the solvent action of the fluid. Raw rubbers are still more easily acted upon, and a very short treatment at a relatively low temperature is sufficient to dissolve the rubber and so alter its character that, on diluting the product with naphtha, the viscosity of the solution is very much lower than that of the original raw rubber when dissolved in naphtha.

For treating raw rubbers we have used nitro-benzene, high-boiling petroleum, and phenetol (of the three we prefer phenetol). One grm. of the finely-cut rubber is placed in a test-tube with 5 to 10 c.c. of the solvent. The temperature should be raised very slowly, so as to give the rubber plenty of time to swell. It is best to heat for about half an hour at 100° C., then to gradually raise the temperature to about 140° C. for one to one and a half hours. The rubber swells until the whole mass is a jelly, then, on gradually heating to a certain point, a rather sudden change takes place, and the thick, jelly-like mass becomes rapidly thin and liquid. During the heating a peculiar smell is given off, resembling hot fat or roasting meat. On cooling, the whole is poured into about 100 c.c. of benzene and the insoluble matter allowed to settle. We find it advisable to wash once or twice with benzene by decantation before transferring to a filter-paper and washing. In some cases, however, it is preferable to remove the soluble matter by repeated decantation with naphtha, evaporating off the last traces and weighing the residue in a tared dish.

We obtained the undermentioned results. The first column shows the total sediment, the second the amount of ash obtained by incinerating the sediment, and the third column the organic matter by difference. The most useful figure, according to our opinion, is the one given in the first column, but the others are useful in determining how far these insoluble particles are due to organic and how far to mineral constituents. We have also found that a repeat test gives good agreement:

	1. Grms.	2. Grms.	3. Grms.
Hard cure Para unwashed as received ...	1·50	0·66	0·84
,, ,, ,, washed and dried ...	0·36	0·20	0·16
Negro Head...	0·48	0·26	0·22
Plantation crepe	0·29	0·05	0·24
Castilloa	6·80	3·78	3·02
,, creped	5·90	1·10	4·80
Wild rubber A	6·88	2·85	4·03
,, B	6·46	1·06	5·40
Gutta...	0·80	0·40	0·40

The separated material is available for microscopic examination; and as it is structurally uninjured by the treatment, it may be possible, where it is considered of service, to determine the nature of the insoluble material. The unwashed hard-cured rubber yielded flocculent material of a membranous character which agglomerated on drying. The washed hard-cured rubber showed masses of disintegrated material, and in many cases where the sediments were examined under the microscope it would appear that they were derived from the bark of the tree. The samples of hard-cured rubber and Negro Head were obtained washed and dried from one of the leading manufacturers. The two samples of Castilloa came from the same estate. From their appearance it was evident that they were not by any means free from impurities.

The method may be employed as a useful check on the washing of rubber. As an instance, two samples of scrap crepe gave by this method (A) 1·7 and (B) 2·5 per cent. of insoluble residue. On rewashing, the amount of residue was reduced to 0·7 and 1·4 per cent. respectively. An examination of the material removed in A showed a mixture of sand with a little bark, and in B, bark only. The ash in the washed rubbers amounted to 0·7 and 0·35 per cent. respectively. As the insoluble impurities in A consisted mostly of sand and grit, with very little bark, A presents a case in which the ash determination gives a fair idea of the percentage of foreign matter in the rubber. In B the foreign matter consisted almost entirely of bark débris. In such a case the ash determination gives no idea as to the percentage of insoluble particles. A consisted of so-called "tree scrap" washed and creped, produced by the drying down of latex on the tapping surface after the flow of latex has ceased. The rubber is easily peeled off the wood in a thin strip. There is no reason why such rubber should be contaminated with bark chips to any great extent, but it may easily pick up a little sand and grit. Rubber B consisted of "bark scrap"; that is, thin shreds of bark removed by the tapping knife, collected, and macerated wet. The loose pieces of bark were for the most part washed away during the maceration process. Such rubber would naturally tend to retain a little of the bark even after prolonged washing.

It is evident, therefore, that an estimation of ash may be very misleading as regards the amount of insoluble impurities in a sample of rubber. The method we have outlined, although more troublesome than the determination of ash, is nevertheless one which can be carried out fairly rapidly and gives more accurate information as to the character and amount of the insoluble impurities.

DISCUSSION.

Dr. SCHIDROWITZ asked what advantage was possessed by nitrobenzene over benzene as a solvent in this case. He presumed that it was a question of rapidity of solution. He should like to know how the insoluble matter was weighed—whether directly or indirectly—because this was really the most difficult point in the determination.

Dr. RIDEAL said he gathered that with nitrobenzene the whole mass became semi-solid, whereas with benzene it remained fluid. From the figures given it seemed to him that the quantities of insoluble organic and inorganic matters in some of these rubbers were very small, and that after all it was the determination of soluble organic and inorganic matters that might have a value in the future. Since rubber from the same species varied in composition from month to month, according to climatic conditions, etc., to so great an extent as to affect the relative price, it seemed unlikely that these small differences in the insoluble matter were to be regarded as of any great commercial importance.

Dr. SCHIDROWITZ said that in his experience the determination of insoluble matter was one of the most valuable that could be made in rubber—a good deal more valuable, probably, than the determination of nitrogen.

Mr. CLAYTON BEADLE said that the first action of the solvent was to produce a gel, but as the heat was increased the whole mass became perfectly limpid. These insoluble particles were not rubber, but were derived from the bark or from other sources foreign to the rubber itself. In the case of impure rubbers, the insoluble particles were to a large extent removed by the manufacturer during the process of washing, etc. If the rubber was sufficiently transparent, the particles could be seen in it by the naked eye. It was first discovered by Spence that protein in rubber became insoluble when the rubber was treated with benzene and allowed to remain quiescent for a sufficient length of time, and this has since been confirmed by ourselves and other observers. The process described, however, did not leave the proteins in the insoluble residue. The advantage of using such substances as nitrobenzene, nitronaphthalene, or phenetol and other bodies of sufficiently high boiling-points, was that the temperature obtainable enabled one to bring about depolymerisation, so that the liquid was rendered less viscous, from which liquid, after dilution with benzene, the insoluble portion more readily settled out. When this thinning down had taken place, the clear liquid, after dilution with benzene, was poured off, and the insoluble matter, after being washed once or twice with benzene, was dried and weighed.

NOTE ON THE DETERMINATION OF SMALL QUANTITIES OF METHYL ALCOHOL.*

By C. SIMMONDS, B.Sc.

(*Read at the Meeting, December* 6, 1911.)

SMALL proportions of methyl alcohol, especially when in mixture with ethyl alcohol, have hitherto been somewhat difficult to determine readily and accurately. Fairly good approximate results can be obtained by comparative experiments with the well-known method of Riche and Bardy (*Compt. rend.*, 1875, **80**, 1076), or with Wolff's modification of Trillat's process (*Ann. Inst. Pasteur*, 1902, p. 8), but these methods are lengthy and rather troublesome. The process described by Thorpe and Holmes (*J. Chem. Soc.*, 1904, **85**, 1) gives good results when the quantity of methyl alcohol is not too small. It is not well adapted, however, for use when the proportion of methyl alcohol is less than about 2 per cent. of the ethyl alcohol, since the necessary subtractive correction (*loc. cit.*, pp. 2, 3) may in such cases equal or exceed the quantity it is desired to estimate. For determining very small proportions of methyl alcohol the method is quite inapplicable.

---

* Communicated with the sanction of the Government Chemist.

In such cases satisfactory determinations can be made by applying the principle of colorimetric comparison to Denigès' process for the detection of methyl alcohol (*Compt. rend.*, 1910, **150**, 832).

The possibility of thus using the process is indicated by Denigès (*loc. cit.*, p. 833). The object of the present note is to give the procedure which the writer finds most suitable for utilising the reaction quantitatively in general analytical work—as, for example, in examining spirituous beverages, medicinal tinctures, flavouring essences, and so forth.

The alcoholic mixture is first purified, where necessary, either by the method of Thorpe and Holmes (*J. Chem. Soc.*, 1903, **83**, 314), or by other suitable means. It is then diluted with water or mixed with ethyl alcohol, as the case may require, until it contains 10 per cent. of total alcohol by volume.

To 5 c.c. of this prepared liquid contained in a wide test-tube are added 2·5 c.c. of permanganate solution (2·0 grms. $KMnO_4$ per 100 c.c.), and then 0·2 c.c. of strong sulphuric acid. When the reaction has proceeded about three minutes, 0·5 c.c. of oxalic acid solution is added (9·6 grms. crystallised acid per 100 c.c.). On shaking, the liquid becomes clear and nearly colourless. One c.c. of strong sulphuric acid is now run in and well mixed with the solution, which is finally treated with 5 c.c. of Schiff's reagent. A violet colour is developed in the course of a few minutes unless mere traces of methyl alcohol were present, when twenty or thirty minutes may be required.

This colour is due, of course, to the reaction of the fuchsine solution with formaldehyde, produced by the oxidation of the methyl alcohol. A sufficient quantity of sulphuric acid is present to prevent the development of colour with any acetaldehyde formed from the ethyl alcohol during the oxidation.

A preliminary experiment carried out as described serves to detect the presence of methyl alcohol (if this is not already known) and to give some idea of the quantity. According to the indications thus obtained, another part of the prepared liquid is further diluted, if necessary, with ethyl alcohol of 10 per cent. strength until it contains from 0·001 to 0·004 grm. of methyl alcohol in 5 c.c.; and the experiment is repeated side by side with two or more standards for comparison. These contain 0·001, 0·002, 0·003, etc., grm. of methyl alcohol in 5 c.c. of 10 per cent. ethyl alcohol. The colours produced are compared in small Nessler-tubes (25 c.c.) or in a suitable colorimeter.

With properly sensitive Schiff's reagent, 0·0003 grm. methyl alcohol in the 5 c.c. of liquid taken is readily detected. The best depths of colour for comparison, however, are given by the formaldehyde produced in the manner described from quantities of 0·001 to 0·004 grm. of methyl alcohol.

It is convenient to keep a standard solution (1 grm. per litre) of methyl alcohol in 10 per cent. ethyl alcohol. This is diluted as required with 10 per cent. alcohol to form the standards for comparison. This proportion of ethyl alcohol (10 per cent.) is a suitable strength for general work, as the distillates ordinarily obtained are stronger, and can thus be diluted down instead of having to be concentrated.

The process has the advantages of (1) being rapidly executed, (2) requiring only a small quantity of material, and (3) being directly applicable to weak distillates. The degree of accuracy obtainable is shown by the following results of a typical series of experiments:

GRM. METHYL ALCOHOL PER 100 C.C.

Present.	Found.
0·005	0·004
0·028	0·029
0·044	0·046
0·072	0·072
0·100	0·104
0·500	0·492
1·000	0·968

Formaldehyde, of course, must be absent from the unoxidised solution of alcohols, or else its effect must be determined and allowed for. Glycerol must also be absent.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Detection of Caramel in Fermented Beverages. V. Pasquero and A. Cappa. (*Gazz. Chim. Ital.*, 1911, **41**, 349-358.)—A method of detecting caramel in beer and wine is based upon the distillation of the furfural in the caramel. The results obtained with fifteen samples of different kinds of Italian beer and thirty-one samples of red and white wine showed that although traces of furfural were separated by direct distillation of the sample, the distillate obtained when the liquid was neutralised with magnesium carbonate was quite free from furfural. On the other hand, when caramel was added to each of these neutralised samples the distillate invariably contained furfural. The test is applied by neutralising free acids in the beer or wine by the addition of magnesium carbonate, and distilling 100 c.c., after the addition of a little pumice stone, until 75 c.c. have passed over. The distillate is made up to 100 c.c. and 20 c.c. thereof shaken with 2 c.c. of pure glacial acetic acid, and 5 drops of colourless aniline in a colorimetric cylinder. If the sample contained any caramel, a rose coloration will be produced within fifteen minutes. By means of this test the presence of caramel was detected in three commercial samples of beer and in samples of Marsala and Coronata wine. C. A. M.

Clavicepsin: A new Glucoside in Ergot of Rye. F. M. Zuco and V. Pasquero. (*Gazz. Chim. Ital.*, 1911, **41**, 368-374.)—From 1 to 2·5 per cent. of a new glucoside, termed "clavicepsin," was separated from different samples of ergot of rye by extraction with 95 per cent. alcohol. When purified by recrystallisation from water it formed acicular crystals melting at 91° C., which were readily soluble in water. After losing its water of crystallisation at 100° to 105° C., it melted at 198° C. It had $[\alpha]_{D20} = +142{\cdot}27°$, and yielded an osazone melting at 205° C. Its elementary composition corresponded with the formula $C_{18}H_{34}O_{16} + 2H_2O$. It did not reduce Fehling's solution until hydrolysed by acids, when it was decomposed into 2 molecules of dextrose and 1 of mannite. C. A. M.

Method for Separating Mixtures of the Seven Coal-Tar Dyestuffs allowed (U.S.A.) to be employed for colouring Foodstuffs. T. M. Price. (*U.S. Dept. Agric. Bureau of Animal Industry, Circular No.* 180; through *Chem. Zentralbl.*, 1911, II., 1556.)—The dyestuffs which are permitted in the United States to be employed for colouring sausage-skins, etc., are amaranth, ponceau 3 R, erythrosin, orange I, naphthol yellow S, light green SF yellowish and indigo-disulphonic acid. An investigation of their solubility reactions led to the following method of separation: About 0·2 grm. of the mixture is triturated with a supersaturated solution of ammonium sulphate, filtered, and washed with ammonium sulphate solution; the filtrate contains amaranth and a little naphthol yellow S, which may be separated by shaking with ethyl acetate. The residue from the treatment with ammonium sulphate is dissolved in water, acidified with acetic acid, and shaken out with ether, which extracts the erythrosin. The aqueous layer, freed from ether, is salted out hot with sodium chloride; the filtrate contains the light green SF and the naphthol yellow S, the latter being separated from the former by shaking with acetone. The aqueous solution of the dyestuffs precipitated by salt, when shaken three times with ethyl acetate, yields the orange I in that solvent. The aqueous residue is heated to expel the ethyl acetate, cooled, and diluted with a 25 per cent. solution of calcium chloride, a solution of stannous chloride is added, and ponceau 3 R is thus precipitated, whilst the leuco compound of indigo-disulphonic acid remains in solution, and may be re-oxidised by hydrogen peroxide to the blue dyestuff. J. F. B.

Determination of Gliadin or Alcohol-soluble Protein in Wheat Flour. R. Hoagland. (*J. Ind. and Eng. Chem.*, 1911, **3**, 838-842.)—As usually recommended, 70 per cent. alcohol is used for this determination; but the author points out that whether this refers to weight or volume is seldom stated, and does, in fact, considerably influence the results obtained, as has been shown by Shutt (*Bull.* 57, Central Expr. Farm, Ottawa, 1907), who obtains a gliadin number of 47·4 with 70 per cent. by weight alcohol, and 53·4 when using 70 per cent. alcohol by volume. Snyder (*Bull.* 105, Bureau of Chem. U.S. Dept. of Agriculture) quotes Teller as finding the amount of protein extracted by 40-55 per cent. alcohol by volume to be practically constant in amount, and the author defends the use of such strength alcohol as will extract the maximum amount of nitrogen from flour. This strength he finds by experiment to be from 45-55 per cent. by weight; 75 per cent. alcohol by weight extracts about the same amount of protein as distilled water. No advantage is obtained by using hot or boiling alcohol. The method used by the author is as follows: Weigh approximately 2 grms. of flour into an 8-ounce stoppered bottle, add 100 c.c. neutral 50 per cent. (by weight) alcohol, shake in a machine for one hour, centrifuge ten minutes, filter and determine the nitrogen in an aliquot portion of the filtrate by the modified Kjeldahl method. Tables are given of the differences obtainable by varying the method of extraction, and show that as much protein can be obtained by vigorous shaking in a rocking machine for sixty to ninety minutes as when the sample is shaken frequently by hand for three or four hours, and then allowed to stand eighteen hours or less. It is recommended that extraction with 70 per cent. alcohol either by weight or volume be discontinued.

H. F. E. H.

Hydnocarpus Fat. K. Lendrich, E. Koch, and L. Schwarz. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 441-458.)—The fat used in the preparation of a certain class of margarine which produced cases of poisoning (*cf.* ANALYST, 1911, **36**, 65) was found to be identical in its properties with the fats obtained from the *Hydnocarpus* species. The fat is known as cardamom or maratti fat, and consists of fatty acids of the constitution $C_nH_{2n-4}O_2$; from these fatty acids, chaulmoogric acid and hydnocarpic acid have been separated and identified. It does not contain fatty acids of the formulæ: $C_nH_{2n}O_2$ and $C_nH_{2n-2}O_2$; the absence of palmitic acid is noteworthy, as Power and Barrowcliff (*Chem. Soc. Proc.*, 1905, **21**, 175) found this acid to be present in *Taraktogenos* (*Hydnocarpus*) *Kurzii* fat and in *Hydnocarpus anthelmintica* fat, but not in *H. Wightiana* fat. The external appearance of the seeds of *H. Wightiana* and *venenata inebrians* is very similar to that of Ceylon cardamoms, and this is probably the reason why the fat in question is termed cardamom fat. When administered to dogs *Hydnocarpus* fat caused vomiting and convulsions. The poisonous properties of the fat appear to have a certain relation to the presence of an ethylene linkage in the structure of the optically active fatty acids of the fat. The authors do not agree with the statement of Thoms and Muller (*cf.* ANALYST, 1911, **36**, 542) that cardamom (maratti) fat is obtained from *Taraktogenos* (*Hydnocarpus*) *Kurzii*; Thomas and Muller do not state how they separated the palmitic acid found, nor do they appear to have established the identity of the hydnocarpic acid. The authors have also examined the fats obtained from the seeds of *H. anthelmintica* and *H. Alpina*, the fats being extracted by means of chloroform. *H. Alpina* fat consisted of a yellow, butter-like mass, without any particular taste or odour; it gave the following physical and chemical results on analysis: refractometer value, at 40° C., 67·5; acid value, 5·6; saponification value, 209·1; iodine value, 84·5; $[\alpha]_{D20} + 49{\cdot}0$. Its physiological action was similar to that of the other *Hydnocarpus* fats.

W. P. S.

Analysis of Candied Lemon Peel. F. Hartel and A. Kirschner. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 350-353.)—Lemons intended for the manufacture of candied peel are imported packed in brine, the fruit being cut into two parts before being thus pickled. After washing with water, the fruit is boiled for about two

hours, then cooled rapidly in cold water, and the pulp is removed. The peels are next steeped in water for one day, and then air-dried for a day or placed in direct sunlight. They are now immersed in a sugar solution of sp. gr. 1·074, and afterwards in a sugar and starch-syrup solution of sp. gr. 1·115 to 1·383, in which they are allowed to remain for about four weeks; the quantity of starch-syrup employed is from 15 to 25 per cent. of the weight of the total sugars in the solution. The peels are finally glazed with concentrated sugar solution. Twenty samples of candied lemon peel examined yielded the following results: Insoluble substances, 2·89 to 5·22 per cent.; soluble extractives, 60·83 to 79·22 per cent.; acidity (as citric acid), 0·04 to 0·20 per cent.; sucrose, 14·30 to 48·50 per cent.; starch-syrup (anhydrous), 9·45 to 25·30 per cent.; ash, 0·37 to 3·09 per cent.; sodium chloride, 0·02 to 0·09 per cent.
W. P. S.

Detection of Nitric Acid in Watered Fruit Juices. R. Cohn. (*Zeitsch. öffentl. Chem.*, 1911, **17**, 361-363; through *Chem. Zentralbl.*, 1911, II., 1613-1614.)—About 75 c.c. of the juice are made alkaline with sodium hydroxide, evaporated nearly to dryness, and the residue is extracted for several minutes with alcohol at a temperature of 40° C. The residue from the alcohol, which, if it is still syrupy, should again be extracted with alcohol, is dissolved in about 10 c.c. of water and tested for the presence of nitric acid by the diphenylamine reaction. In the case of pure natural raspberry, cherry, and currant juices, a positive reaction was never encountered. In the case of bilberry juice the test cannot be used, since this fruit contains a body which gives a blue coloration with sulphuric acid alone. In presence of bilberry juice the test for nitric acid in the aqueous solution of the alcoholic extract, prepared as above, may be carried out with nitron. In the extracts from pure natural raspberry, cherry, currant, and bilberry juices an acetic acid solution of nitron produces no precipitate; in presence of nitric acid a separation of nitron nitrate soon takes place.
J. F. B.

Changes in the Composition of the Nitrogenous Constituents of Meat-Extracts. A. M. Wright. (*J. Soc. Chem. Ind.*, 1911, **30**, 1197-1198.)—The action of hot water, in presence of the sarco-lactic and other acids of flesh and of salts, on the meat causes a certain amount of hydrolysis, the collagen of muscle-fibre yielding gelatin, and later soluble gelatin and other gelatinoids, and the albumin yielding small quantities of albumoses. During concentration, under a partial vacuum, the amount of organic matter slightly decreases (relatively), while the mineral salts increase, and a small proportion of peptone-like bodies are produced. Concentration in an open pan yields very different results, profound changes taking place. The amount of organic matter is considerably decreased, while there is a corresponding increase of mineral matters. The total nitrogen remains about the same, but the forms in which it occurs are different, about three-fifths of the insoluble and coagulable proteins being converted into soluble nitrogenous compounds. Proteoses and meat-bases are decreased in amount, while peptone-like bodies appear in considerable quantity, and the acidity is notably increased. These peptone-like bodies impart a bitter taste to the extract in the cases of those containing them to the extent of, say, 12 per cent. or over. The "burned" flavour of certain meat-extracts is doubtless due to this method of concentration.

The following analyses illustrate the differences noted. The "open" concentration was carried out by evaporation for forty-eight hours at 212° F., the resulting extract containing 17·6 per cent. moisture. The other method, followed on a portion of the same original liquor, was by a partial vacuum of 15 inches at 180° F. for three and a half hours, the resulting extract containing 18·36 per cent. moisture. All the results have been calculated to a standard basis of 20 per cent. moisture for comparison purposes:

	Extract Liquor.	Concentrated in Open Pan.	Concentrated under Partial Vacuum.
	Per Cent.	Per Cent.	Per Cent.
Moisture	20·00	20·00	20·00
Organic matter	65·60	60·48	63·04
Mineral salts	14·40	19·52	16·96
Acidity as lactic acid	8·00	10·30	8·20
Total nitrogen	7·82	7·92	7·86
Insoluble and coagulable proteins	2·65	1·16	2·63
Proteoses	13·34	12·37	13·08
Peptone-like bodies and polypeptides	nil	8·69	0·31
Total meat-bases	14·19	12·53	13·76

A. R. T.

Detection of Saponin and Glycyrrhizin in Lemonades by Means of Vamvakas' and Frehse's Tests. A. Behre. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 498-506.)—The two tests mentioned in the title were found to be unreliable. Vamvakas' test (ANALYST, 1906, **31**, 232), yielded positive results (precipitates with Nessler reagent) with lemonade which was free from saponin and glycyrrhizin, as well as with other samples containing these two substances; the colour of the precipitates was not characteristic and evidently depended on the presence of substances other than saponin and glycyrrhizin. Frehse's test (ANALYST, 1900, **25**, 10) failed owing to the fact that pure saponin is insoluble in ethyl acetate (the solvent recommended for its extraction), and the residue obtained on evaporating the solvent gives no coloration with sulphuric acid. Lemonades containing impure saponin, or so-called saponin, yielded a residue which gave a doubtful reaction with sulphuric acid.
W. P. S.

Estimation of Saponin and Saccharin in Oil Emulsions. E. Carlinfanti and P. Marzocchi. (*Boll. Chim. Farm.*, 1911, **50**, 609-615; through *Chem. Zentralbl.*, 1911, II., 1488-1489.)—One hundred grms. of the oil emulsion are diluted with an equal volume of water, and then gradually treated with 400 c.c. of 95 to 96 per cent. alcohol with constant shaking, which is frequently repeated during two hours, after which it is allowed to stand for twenty-four hours. The clear supernatant liquid is decanted, and the residual fatty mass filtered through linen, again extracted with 60 to 65 per cent. alcohol, and again filtered. The united filtrates are neutralised with sodium carbonate and concentrated to 100 c.c. on the water bath. Aromatic compounds are now extracted with ether, and the residual liquid shaken with 20 grms. of sodium sulphate and 9 c.c. of phenol, this treatment being repeated several times, until the whole of the saponin has been extracted by the phenol. The united phenol extracts are then shaken with a mixture of 100 c.c. of ether, 30 c.c. of water and 5 c.c. of alcohol, and left for twenty-four hours, after which the upper layer containing the saponin is separated and evaporated, and the residue extracted with acetone. The ethereal extract, containing the aromatic compounds, is shaken with water acidified with phosphoric acid, the ether evaporated, and the saccharin estimated in the form of alkali salicylate. C. A. M.

Separation and Identification of Saccharin and Dulcin in Beverages, Foods, and Drugs. S. Camilla and C. Pertusi. (*Giorn. Farm. Chim.*, 1911, **60**, 385-393; through *Chem. Zentralbl.*, 1911, II., 1269-1270.)—The material is treated with an excess of barium hydroxide solution, warmed, filtered, and the filtrate extracted with ether after being acidified with sulphuric acid; the saccharin and dulcin crystallise out when the ethereal solution is evaporated. For the identification of these two sweetening materials in the presence of salicylic acid, the sample is mixed with magnesium oxide, evaporated to dryness, and the residue extracted with acetone containing 10 per cent. of water. The acetone solution is filtered, evaporated, the residue dissolved in water, and the solution extracted with ether; dulcin goes into solution. The aqueous solution is then acidified with sulphuric acid, and the saccharin is extracted by means of a mixture of ether and petroleum spirit Should salicylic acid be present, the aqueous solution containing the saccharin must be evaporated to dryness, the residue dissolved in 10 per cent. sulphuric acid, and the solution treated with an excess of potassium permanganate; after filtration the saccharin is extracted from the filtrate with a mixture of ether and petroleum spirit (*cf.* ANALYST, 1910, **35**, 436).

Alteration of the Acid-Content of Distilled Vinegar when Stored in Wooden Casks. A. Behre. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 506-509.) —The acidity of a cask of vinegar increased in the course of nine months from 7·10 to 9·12 per cent.; the total solids also increased from 0·30 to 0·39 per cent., and the concentration of these constituents was evidently due to the more rapid diffusion of the water through the pores of the wood. Further experiments were made in which acetic acid solutions of various strengths were exposed to the atmosphere in glass vessels. In glass cylinders solutions containing from 7·44 to 61·2 per cent. of acetic acid scarcely altered in strength during ten weeks, but when exposed in flasks having narrow necks the more concentrated solutions remained unaltered, whilst those containing less than 19 per cent. of acetic acid increased in strength to a slight extent.

Considerable changes took place when the solutions were exposed in open beakers; the stronger solutions lost large quantities of acetic acid, whilst the weaker solutions became stronger. Under these conditions, a vinegar containing 3·17 per cent. of acetic acid was found to have 4·68 per cent. after the lapse of four weeks; a solution containing 19 per cent. of acetic acid did not alter in strength; whilst a solution containing 61·2 per cent. lost 2·2 per cent. of acetic acid during this period.

W. P. S.

Estimation of Phosphorus in Wine. J. Dormane. (*Bull. Assoc. Chim. Sucr. Dist.*, 1911, **29**, 63-67; through *Chem. Zentralbl.*, 1911, II., 1376-1377.)—Three samples of Burgundy wine yielded the following results: Total phosphorus (as P_2O_5), 0·231 to 0·461; phosphoric anhydride (P_2O_5), 0·160 to 0·390; phosphoric anhydride *plus* phosphorus in organic combination (as P_2O_5), 0·205 to 0·422 grm. per litre. The total phosphorus was estimated by igniting the total solids of the wine in the presence of calcium oxide and potassium carbonate; the phosphoric anhydride (phosphate) by extracting a further quantity of the total solids with cold, dilute hydrochloric acid; whilst the phosphoric anhydride *plus* the organically combined phosphorus was obtained by boiling the total solids for two hours with concentrated hydrochloric acid. The solutions were then treated in the usual way for the precipitation of the phosphoric acid. It is evident that wine contains phosphorus compounds which are not decomposed by hydrochloric acid.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Detection of Albumoses in Urine. E. H. Fittipaldi. (*Deutsch. Med. Woch.*, 1911, **37**, 1890-1891; through *Chem. Zentralbl.*, 1911, II., 1489-1490.)—From 10 to 20 c.c. of the urine are treated with six times the quantity of absolute alcohol, and the resulting precipitate separated by decantation after twenty-four hours, and dissolved in the smallest possible quantity of 31 to 32 per cent. sodium hydroxide solution. This alkaline solution is tested with a freshly-prepared ammoniacal solution of nickel (equal parts of strong ammonia and 5 per cent. nickel sulphate solution), and in the presence of albumoses or peptones gives an immediate orange-red coloration. The reaction is not obtained with albumins, uric acid, cyanuric acid, xanthin, hypoxanthin, sarcosin, or urobilin. The method may also be used for the detection of albumoses in blood, after the latter has been heated with animal charcoal, cooled, and filtered. The reaction is not given by C-deutero-albumose or A-peptone, but neither do these bodies give the biuret reaction. Albumoses may thus be detected in urine in cases of albuminuria, especially when large amounts of albumin are excreted. This is attributed to the presence of proteolytic enzymes in the urine.

C. A. M.

Application of the Biochemical Method to the Analysis of Uva-Ursi Leaves. A. Fichtenholz. (*J. Pharm. Chim.*, 1911, **4**, 441-446.)—The leaves of *Arctostaphylos Uva-ursi* are the source from which the glucoside arbutin is extracted commercially. The biochemical method, depending on the hydrolysis of the arbutin by emulsin after the extract has first been subjected to the action of invertase, may be applied advantageously to the analysis of the dried leaves. The leaves are first extracted with boiling 90 per cent. alcohol, the extract is evaporated to dryness under reduced pressure, the residue is taken up with water, the solution is clarified with basic lead acetate and filtered, the precipitate being washed on the filter. The excess of lead in the liquid is removed by sulphuretted hydrogen, and the solution is then concentrated at a temperature not exceeding 45° C. under reduced pressure. Alcohol is added, and evaporation continued to dryness. The residue is dissolved in thymolated water, the solution is filtered and polarised; the cupric reducing substances calculated as dextrose are also estimated. If the presence of free hydroquinone is to be feared, this solution should be exhausted by ether; it is then ready for treatment with enzymes. It is first treated with 0·15 grm. of invertase (top-fermentation yeast, treated with 95 per cent. alcohol and dried), and is digested at 15° to 18° C. for about five days. The flask is then placed in a boiling water-bath for twenty minutes, cooled, and the emulsin (0·15 grm.) is added. During the whole period of digestion samples are taken at intervals and polarised, the cupric-reducing value being also estimated. After the action of the invertase, the lævo-rotation of the liquid will have increased, but when the emulsin begins to act the lævo-rotation decreases; the results are calculated on the assumption that under the action of emulsin a decrease of 60′ corresponds to the hydrolysis of about 0·5 grm. of arbutin per 100 c.c. The action may continue over ninety-five days. From the comparative rise in cupric-reducing value, some idea may be obtained of the relative proportion of methyl arbutin also present. J. F. B.

Composition of Hens' Eggs. K. Kojo. (*Zeitsch. physiol. Chem.*, 1911, **75**, 1-2.)—Fluid white of egg was found to contain an average of 87·71 per cent. of water, 11·88 per cent. of organic substances, and 0·4 per cent. of ash; the nitrogen-content was 1·75 per cent., whilst the quantity of dextrose amounted to 0·55 per cent., or 4·64 per cent. calculated on the organic substance. The fluid yolk contained 49·73 per cent. of water, 48·83 per cent. of organic substances, and 1·44 per cent. of ash; 2·49 per cent. of nitrogen, and 0·27 per cent. of dextrose were present. Calculated on the organic substance, the percentage of dextrose was 0·55, a much smaller proportion than was present in the white of egg. Only traces of creatinine were found. W. P. S.

Tests for Ascertaining the Freshness of Milk. W. Morres. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 459-464.)—The alcohol test for milk, which depends upon the fact that milk containing upwards of 8 degrees of acidity (Soxhlet-Henkel) usually curdles when mixed with twice its volume of 70 per cent. alcohol is not always a reliable test of the acidity of milk, as the curdling may be caused by means other than the formation of lactic acid. For instance, milk may be on the point of curdling owing to the presence of rennet produced by bacteria, although it may contain but little free acid. Various strengths of alcohol have been proposed for use in the test, and the author considers that the use of 50 per cent. alcohol will afford useful information. A more stringent test with 68 per cent.

alcohol may be applied when the milk is intended for feeding infants, etc. The coloration produced when milk is treated with a solution of alizarin in 68 per cent. alcohol gives an indication of the kind of fermentation which has taken place in the milk. Should the milk curdle, but the coloration remain lilac or red, the milk contains only rennet products; acid formation is shown by a yellow coloration.

W. P. S.

Relations between the Reductase Test, Acidity, and Alcohol Test in Milk. W. Morres. (*Milchw. Zentralbl.*, 7, 441-445; through *Chem. Zentralbl.*, 1911, II., 1614.)—The alcohol test in combination with alizarin, which the author calls the alizarol test, gives easily and rapidly the most reliable indication of the degree and nature of the decomposition of the milk. A comparison of the reductase test with the alizarol test showed: (1) That the alizarol test is equivalent to the reductase test both as regards the degree of curdling and the change of colour in the case of pure lactic acid fermentation; (2) that the smallest degree of decomposition which the alizarol test will show definitely (8 degrees of acidity) corresponds to a decolorisation time of sixteen minutes at 40° C., corresponding to more than 20,000,000 germs per 1 c.c. In the testing of milk from a hygienic point of view it is desirable to express the results in terms of its contamination with germs. Milk "rich in germs" would be one which decolorises the test in from five to fifteen minutes at 40° C., whilst "very rich in germs" would describe a sample which decolorises in less than five minutes at 40° C. Such milk can be very surely detected by the alizarol test more rapidly than by the reductase test. In the case of samples poor in germs, which require more than fifteen minutes for decolorising the methylene blue, the reductase test is the only practical method for the estimation of the approximate contamination with germs. As to the nature of the bacteria present, the fermentation test, or the fermentation-reductase test, of Orla-Jensen affords further information. Since, in practice, the carrying out of the reductase test at 40° C. presents certain difficulties, the author recommends that the test be performed at about 20° C., and the results calculated at 40° C. by multiplying them by $\frac{1}{4}$.

J. F. B.

New Method for Determining the Tryptic Value of Pancreatin. C. F. Ramsay. (*J. Ind. and Eng. Chem.*, 1911, 3, 822-823.)—The United States Pharmacopœia method for determining the tryptic value of pancreatin is unsatisfactory owing to the uncertainty of the end reaction, and consists in finding the amount of enzyme preparation capable of peptonising milk to such a degree that no coagulation follows the addition of nitric acid. The results depend on the amount of acid used, since a little acid gives no precipitate; more acid will always give a precipitate, and still more acid redissolves it. However long the digestion, acid will always cause a precipitation in peptonised milk. The author's method consists in finding the amount of the enzyme preparation which in fifteen minutes will so peptonise milk that no coagulation or precipitate is formed on the addition of slightly acidified rennin solution. The milk is rendered slightly alkaline with sodium bicarbonate to prevent the pancreatin curdling the milk. The materials required are:

(1) 0·5 grm. pancreatin diluted to a volume of 50 c.c. with distilled water, (2) 900 c.c. milk containing 1·8 grm. of sodium bicarbonate; and (3) 2 grms. of rennin and 1 c.c. of 6 per cent. acetic acid (U.S.P.) added to 50 c.c. of distilled water. The pancreatin is first tested at wide ranges of strength, such as 1 grm. to 700 c.c. milk or 1 grm. to 1,000, and a second series is then carried out over a narrower range. In each of several tubes of 100 c.c. capacity are placed 50 c.c. of the milk; the tubes are placed in a bath at 40° C., and varying volumes of the enzyme preparation are added corresponding to (say) 1 in 600, 1 in 650, 1 in 700, etc. After fifteen minutes' digestion, 5 c.c. of the digested milk are withdrawn, 3 c.c. of the rennin solution added, and the whole well shaken. No precipitation indicates that the casein is all peptonised, and the enzyme is stronger than the dilution tested. The amount of acid in 3 c.c. of the rennin solution will exactly neutralise the amount of bicarbonate in 5 c.c. of the milk; the rennin then acts under favourable conditions, since no precipitate is formed in an alkaline solution. Pancreatin in neutral solutions deteriorates rapidly, and consequently should only be made up immediately before use. The author claims an accuracy of 2 to 3 per cent. for the method, and suggests a standard of 1 to 800 or 1 to 1,000 as being a suitable strength for pancreatin preparations. Commercial samples showed variations of from 1 to 120 to 1 to 1,750.

H. F. E. H.

Estimation of Urea. Desgrez and Feuillié. (*Comptes rend.*, 1911, **153**, 1007-1010.)—The following modification of Bouchard's method, which is based upon the decomposition of urea by Millon's reagent—

$$CH_4N_2O + HNO_3 + HNO_2 = N_2 + CO_2 + NH_4NO_3 + H_2O$$

—is rapid, and requires only simple apparatus. The ureometer is immersed in a cylinder containing chloroform or carbon tetrachloride, and having round its exterior a metal band with a projection, which may be heated. After the lower part of the ureometer has been filled with chloroform, there are introduced successively 1 c.c. of the urine, about 5 c.c. of water, and 8 to 10 c.c. of Millon's reagent, and the chloroform is then brought to 30° to 35° C. by heating the metal projection. Decomposition of the urea is effected within twenty to twenty-five minutes by shaking the ureometer from time to time. As soon as the volume of gas ceases to increase, the tube is transferred to a cylinder of water, and the gas washed with sodium hydroxide and water, after which the tube is removed to a second cylinder of water, where the last traces of carbon dioxide are removed, and a final washing is given before measuring the quantity of nitrogen. If the temperature of reaction is not allowed to exceed 35° C., no decomposition of ammonium salts, uric acid, amino acids, creatin, creatinin, hypoxanthin, xanthin, tyrosin, leucin, or guanin takes place. Allantoin, however, begins to decompose at that temperature; but since human urine contains only about 0·014 grm. of that substance after twenty-four hours, this does not interfere with the applicability of the method to human urine, whatever the case may be with herbivora. The non-dialysable substances extracted from several litres of urine did not yield any trace of nitrogen when treated with Millon's reagent under the conditions of the estimation.

C. A. M.

Urobilinogen of Urine and Ehrlich's Reaction for Aldehydes. H. Fischer and F. Meyer-Betz. (*Zeitsch. physiol. Chem.*, 1911, **75**, 232-261.)—The crystalline urobilinogen which may be separated from pathological urine is identical with hemibilirubin. Non-stabile pyrroles (dimethylpyrrole, hæmopyrrole, phonopyrrole, carboxylic acid, etc.), to which class of substances belong the crystalline blood-pigment derivatives and the bile-pigment derivatives, are converted in the body into urobilin, and all these pyrroles give a reaction with Ehrlich's reagent (*p*-dimethylaminobenzaldehyde in hydrochloric acid solution). After the administration of these substances, a positive reaction does not necessarily denote the presence of urobilinogen and urobilin in urine; at the same time, urine may contain considerable quantities of urobilinogen and fail to give a reaction with the test. The substance which yields the reaction with Ehrlich's reagent is a dipyrrylmethane colouring-matter derived from the leuco-bases. W. P. S.

ORGANIC ANALYSIS.

Champaca Oils. B. T. Brooks. (*J. Amer. Chem. Soc.*, 1911, **33**, 1763-1772.)—A quantity of the yellow flowers of *Michelia champaca* L. yielded 0·37 per cent. of an oil containing phenyl-ethyl alcohol (free and as ester), cineol, iso-eugenol, benzyl alcohol, benzaldehyde, and benzoic and acetic acids, with a small quantity of a fluorescent substance (? methyl anthranilate). The oil had the following characters:

	I.	II.
Sp. gr., 30°/30° C.	0·9040	0·9107
Refractive index $[n]_D$, 30° C. ...	1·4640	1·4688
Ester number	124·0	146·0
Ester number after acetylation	—	199·0

On standing, the oil deposits comparatively large quantities of a crystalline unstable ketone, melting at 165° to 166° C., and optically active ($[\alpha]_D$, 30° C. = $-82·5°$ in alcohol).

The white flowers of champaca (*Michelia longifolia* L.) yielded 0·08 per cent. of an oil free from fluorescence, and containing linalol, the methyl or ethyl ester of methylethyl-acetic acid, and methyl-eugenol. No crystalline ketone was present. The oil had the following characters:

Sp. gr., 30°/30° C.	0·897
Ester number	180
Refractive index $[n]_D$, 30° C.	1·4470

The flowers of both species of *Michelia* contain an oxidase. A. R. T.

Behaviour of Invert Sugar in the Presence of Alkali and Hydrogen Peroxide. A. Jolles. (*Biochem. Zeitsch.*, 1911, **36**, 389-393.)—When a 2 per cent. invert sugar solution in $\frac{4}{5}$ N sodium hydroxide solution is treated with an excess of hydrogen peroxide, and heated to a temperature of 37° C., the optical rotation of the sugar diminishes gradually. After an hour or so the rotation becomes *nil*, then slightly dextro-rotatory, and finally *nil* again. This is due to the lævulose being more rapidly oxidised than the dextrose. W. P. S.

Analysis of Lactic Acid. A. A. Besson. (*Chem. Zeit.*, 1911, 35, 1209-1210.) —In the estimation of anhydride in commercial lactic acid it is sufficient to add an excess of 2·5 c.c. of $\frac{N}{1}$ sodium hydroxide solution to the neutralised lactic acid (1 grm.), allow the mixture to stand for ten minutes, neutralise the alkali, and to heat the solution just to boiling with an excess of 1 c.c. of $\frac{N}{1}$ sulphuric acid in order to obtain the quantity of anhydride present (*cf.* ANALYST, 1911, **36**, 235, 556).

W. P. S.

Determination of Malic Acid. P. B. Dunbar and R. F. Bacon. (*J. Ind. and Eng. Chem.*, 1911, 3, 826-831.)—The authors have worked out a polarimetric method for the estimation of malic acid on similar lines to that described by Yoder (ANALYST, 1911, **36**, 498), based on the increase of rotation produced by the addition of uranyl acetate. The acidity of the solution is first titrated on a separate portion with standard alkali in presence of phenolphthaleïn; 75 c.c. of the solution are then placed in a 100 c.c. flask, together with the requisite quantity of standard alkali; if dark in colour, 10 c.c. of alumina cream are added, the liquid is made up to the mark and filtered. Twenty-five c.c. of the filtrate are treated with sufficient powdered uranyl acetate, so that a small amount remains undissolved after two hours; 2·5 grms. are generally sufficient, unless the quantity of malic acid is large. After two hours with frequent shaking, the solution is filtered and polarised, if possible, in the 200 mm. tube. The result is called reading (1). The remainder of the original filtrate is treated with powdered lead acetate until no further precipitation results. The liquid is cooled in ice, and filtered clear; the filtrate is rewarmed to the ordinary temperature, and a crystal of lead acetate is added to determine whether precipitation is complete; if so, the excess of lead is removed by anhydrous sodium sulphate, and the liquid is filtered and polarised, the result being called reading (2). The lead acetate precipitates the malic acid, but as lead malate is soluble in excess of lead acetate, care is necessary in performing this operation. Solutions which contain less than 10 per cent. of reducing sugar may be polarised without treatment with lead. If reading (2) is negative, a portion of this solution is treated with uranyl acetate as above described and polarised; this is called reading (3). If (2) is positive, reading (3) need not be made. All readings are made with white light on the Ventzke scale, and calculated for the 200 mm. tube. If reading (3) is less numerically than reading (2), reading (3) is accepted, otherwise reading (2) is used. Then the algebraic difference between reading (2) or (3), whichever be used, and reading (1) is multiplied by the factor 0·036, and the product represents the percentage of malic acid in the solution polarised. For this determination the most favourable limits of concentration lie between 0·2 and 2·5 per cent. of malic acid; the error seldom amounts to more than 5 per cent. of the malic acid present. Reading (3) is intended to correct the slight lowering effect of uranyl acetate on the rotation of the sugars. If less than 10 per cent. of reducing sugar and more than 0·25 per cent. of malic acid be present, reading (3) may be dispensed with; in presence of large amounts of sucrose, reading (2) gives better results than reading (3). The method cannot be used for the estimation of malic acid if *d*-tartaric acid be also present.

J. F. B.

Fluorescence Test for Mineral and Rosin Oils. P. H. Walker and E. W. Boughton. (*J. Ind. and Eng. Chem.*, 1911, **3**, 816.)—The Outerbridge method for the detection of mineral and rosin oils in fatty oils is based on the observation that the fluorescence of mineral and rosin oils is greatly magnified by performing the examination by the light of an enclosed electric arc, and that samples which appear non-fluorescent in sunlight become strongly fluorescent when observed in the proper light. The test may be made quantitative by comparison with a set of standards. The authors have confirmed the fact that the light of an enclosed arc has the effect described, but they show that fluorescence in an oil does not necessarily prove the presence of mineral or rosin oil. Out of sixteen samples of linseed oil of authenticated purity, only eight showed no fluorescence, three showed slight fluorescence, and five showed marked fluorescence. A number of other samples of fatty oils of known purity, some having been cold-pressed from the seed, showed marked fluorescence, in some cases as strong as that of many mineral oils. A pure linseed oil which showed no fluorescence was heated to 300° C., and, after cooling, was found to be strongly fluorescent. The same occurred with a pure olive oil after heating. In the case of turpentine oils also, many show no fluorescence; some known to contain mineral oil likewise show no fluorescence, whilst others, certainly pure, show marked fluorescence.

J. F. B.

Catalytic Action of Light on the Oxidation of Phenolphthalin to Phenolphthaleïn. G. Rossi. (*Giorn. Farm. Chim.*, **60**, 433-436; through *Chem. Zentralbl.*, 1911, II., 1659.)—Phenolphthaleïn is reduced by nascent hydrogen to phenolphthalin. The reversed reaction is used by the author for the detection of blood. Hydrogen peroxide is employed as the oxidising agent; any blood which may be present acts as a catalyser; in the absence of blood the oxidation is extremely slow and only takes place after some days. The procedure is as follows: An alkaline solution of phenolphthaleïn is decolorised by shaking with zinc dust, the solution is filtered and added, together with a few c.c. of 12 per cent. hydrogen peroxide, to the liquid to be tested. If blood be present, a pink or red coloration will be developed within three hours. The prolonged action of light will also bring about a similar acceleration of the oxidation of the phenolphthalin. According to the author's experiments the light of an electric arc will cause the liquid in a sealed tube to turn red within two hours.

J. F. B.

Colorimetric Estimation of Phenols in Effluents. H. Bach. (*Zeitsch. anal. Chem.*, 1911, **50**, 736-740.)—Small quantities of phenols in effluents—*e.g.*, from coke by-product plants, etc., may be estimated colorimetrically, in absence of salicylic acid, by means of Millon's reagent. As a preliminary test, 10 c.c. of the effluent, 0·2 c.c. of Millon's reagent, and 0·1 c.c. of strong nitric acid are heated to boiling-point in a test-tube, in such a way that none of the liquid spurts up. If a faint pink or pale red coloration is developed, the effluent is fit for the test; if it shows deep red it must be suitably diluted, and if only a faint yellowish-colour is developed, 100 c.c. of the water are treated with 5 c.c. of concentrated sulphuric acid, and 20 c.c. are distilled off, of which 10 c.c. are tested. If the last case indicates that a concentration of the phenol is required, 1 litre of the effluent is made alkaline with 5 to 10 c.c. of strong caustic potash lye and evaporated to 50 c.c. The residue is placed in a flask, cooled, acidified with 10 to 20 c.c. of strong sulphuric acid, diluted to 150 c.c., and 100 c.c are distilled over; the phenol is thus concentrated ten times. For the colorimetric test, the above-mentioned quantities of the effluent and reagents are heated in a test-tube as described; if the coloration is yellowish to pale pink, 0·2 to 0·7 mgrm. of phenol is present in 10 c.c.; if pale pink to medium red, 0·8 to 1·8 mgrm.; and if medium to deep red, 1·8 to 3 mgrms. These colours change on cooling, but the above indications are sufficient for the preparation of the standard tests, which are made up in a similar manner with a solution containing 0·1 mgrm. of pure phenol per 1 c.c. No comparisons are made until all the tubes are quite cold (*i.e.*, after half an hour), when the colorations become stable and remain fixed for several hours. Comparisons should be made against a white ground both by reflected and transmitted light. With some practice, the quantity of phenol may be estimated with an accuracy of a few mgrms. per litre, unless the effluent is extremely dilute. J. F. B.

Estimation of Water in Soap. R. M. Fitzpatrick. (*Chem. News*, 1911, **104**, 247.)—One grm. of the soap is treated with 50 c.c. of absolute alcohol, a fragment of porous tile added, and the liquid heated on a water-bath under a reflux-condenser till solution is complete. After partial cooling, the liquid is filtered through filter-paper, the soap, etc., remaining in the flask being transferred to the filter by the addition of 20 c.c. of absolute alcohol and warming, and the residue on the paper also washed with absolute alcohol. The residue on the paper is dried and weighed, and the amount of alcohol-insoluble matter thus found. Five grms. of anhydrous sodium sulphate are next added to the cold filtrate, and the closed flask allowed to stand for at least twelve hours. If the solution shows any tendency to form soap jelly, more alcohol must be added before the sodium sulphate is put in. The solution, after standing, is filtered into a flask weighed with a small portion of porous tile, and the sodium sulphate washed several times with warm absolute alcohol. The alcohol is evaporated off, the residual soap dried for fifteen minutes at 100° C. and weighed. The weight of anhydrous soap, *plus* the weight of alcohol-insoluble matters, subtracted from the weight of soap taken, gives the weight of water in the soap. A. R. T.

Qualitative Reactions of Vegetable Tannins. E. Stiasny and C. D. Wilkinson. (*Collegium*, 1911, 318-324, 325-333; through *Chem. Zentralbl.*, 1911, II., 1384-1386.)—The behaviour of some thirty-four different tannin solutions towards various reagents is described; amongst the latter were ammonium acetate, tartar emetic, lead acetate, bromine, copper sulphate and ammonia, and formaldehyde.

INORGANIC ANALYSIS.

Simplification of Gravimetric Analysis. E. Murmann. (*Zeitsch. anal. Chem.*, 1911, **50**, 742-747.)—The author describes means of simplifying the operations of filtering, washing, and drying precipitates. Slimy precipitates may be mixed with fine rice starch or fine paper pulp before filtering. J. F. B.

Detection of Fluorides. E. Rupp. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 496-497.)—The ash of the substance to be tested for the presence of fluorides is moistened in a platinum or lead crucible with three drops of water and 1 c.c. of sulphuric acid is added. The crucible is loosely closed with a rubber stopper through which passes a piece of glass rod; the lower end of the latter is moistened with a drop of water, and the crucible is heated on a water-bath for about twenty minutes. Should fluorides be present, the rod becomes coated with a film consisting of silica, sodium silicofluoride and calcium silicofluoride, the drop of water having evaporated during the heating. When only traces of fluoride are suspected to be present, the portion of the glass rod below the stopper may be covered with a piece of rubber tubing, leaving only the end of the rod exposed. In this way the action of the hydrofluoric acid is concentrated on a small surface of the glass.

W. P. S.

Estimation of the Ferrous Ion by Means of Iodine. G. Romijn. (*Chem. Zeit.*, 1911, **35**, 1300.)—Ferrous salts may be oxidised to ferric by means of iodine, provided the reverse reaction be inhibited by suppressing the ferric ion in the solution as it is formed. This may be done by the addition of sodium acetate or tartrate, but the reaction is a slow one, and the complex ferric salts produced are highly coloured. According to the author's observations, sodium pyrophosphate serves a similar purpose; the reaction is complete in five minutes, and the ferric sodium pyrophosphate complex is nearly colourless; sufficient acid must be present to insure that the greater portion of the salt is in the state of the acid salt $Na_2H_2P_2O_7$, whilst a little still remains as the unchanged neutral salt. The iodometric method is applicable to cases where ferric salts and organic matters exist in presence of the ferrous salt to be estimated, also for the analysis of drugs, such as Blaud's pills and ferric iodide syrups, where permanganate cannot be used. The ferrous compound to be analysed is dissolved in such a quantity of sulphuric or hydrochloric acid that the quantity of free acid remaining is equivalent to about 20 c.c. of $\frac{N}{1}$ acid. To this solution are added 20 c.c. of $\frac{N}{10}$ iodine solution and 5 grms. of powdered sodium pyrophosphate; the liquid is rotated until the salt is completely or nearly dissolved. After five minutes the excess of iodine is titrated back with $\frac{N}{10}$ thiosulphate. The results are somewhat lower than those obtained with permanganate (97·5-99 per cent.), probably owing to the oxidation of some of the ferrous pyro-phosphate by the air. J. F. B.

Estimation of Small Quantities of Iron in Organic Substances. F. Jahn. (*Zeitsch. physiol. Chem.*, 1911, **75**, 308-338.)—The following process is recommended for the estimation of iron in cases where only a few mgrms. of the latter are present: The organic substance is heated with sulphuric and nitric acids until all carbonaceous matter has been destroyed and the excess of nitric acid has been expelled. The solution is then diluted with water, boiled, 5 c.c. of concentrated sulphuric acid are added, and the warm solution is rinsed into a flask with water free from dissolved oxygen. Carbon dioxide is now passed into the flask while the contents of the latter are cooled to a temperature below 10° C.; 5 c.c. of 40 per cent. potassium thiocyanate solution are added, and the solution is then titrated with titanous chloride solution. A very small excess of the latter is added, and this excess is titrated back with a standard iron solution. The titanous chloride solution must be kept in a bottle under an atmosphere of carbon dioxide and standardised against the iron solution before and after each estimation. The standard iron solution is best prepared from pure ferric oxide (Kahlbaum). Particular care should be taken that the acid used in the process be free from iron; some 500 c.c. of the nitric or hydrochloric acid should be evaporated to a volume of 10 c.c., then heated with pure sulphuric acid until the latter fumes, and the residual solution, after dilution, tested with thiocyanate. Nitric acid free from iron frequently yields a red coloration with thiocyanate, when tested directly, owing to the presence of traces of nitrous acid. W. P. S.

Gravimetric and Volumetric Methods for the Analysis of Mercury-ammonium Chloride. G. A. Sutterheim. (*Pharm. Weekblad,* 1911, **48**, 1085-1087; through *Chem. Zentralbl.*, 1911, II., 1378-1379.)—A quantity of about 0·1 grm. of the substance is boiled with a small volume of water, 0·5 grm. of potassium cyanide, and 5 c.c. of sodium hydroxide solution until all the ammonia has been expelled. Ten c.c. of formaldehyde solution are then added, the mixture is heated for some time, and the separated metallic mercury is collected, washed successively with water, alcohol, and ether, and weighed. In the volumetric process, 0·2 grm. of the substance is heated with 5 c.c. of water and 3 c.c. of sodium hydroxide solution until the ammonia has been removed, the mixture is cooled, an excess of $\frac{N}{2}$ potassium cyanide solution is added, and, when the mercuric oxide has dissolved completely the solution is nearly neutralised with nitric acid, using phenolphthaleïn as indicator. The uncombined cyanide is then titrated with $\frac{N}{10}$ silver nitrate solution.

New Reaction of Nitrous Acid. W. Vaubel. (*Chem. Zeit.*, 1911, **35**, 1238.)—A sensitive test for nitrites is based upon the fact that mineral acid salts of amino compounds react with nitrites to form aminoazobenzene, which, according to the quantity, either separates as a brown precipitate or causes a yellow turbidity or coloration. Thus, on adding aniline hydrochloride to water containing nitrites, the reaction is produced, and in this way it is possible to detect as little as 0·00035 per cent. of nitrite by the yellow coloration, which, however, in the case of so dilute a solution, takes several hours to develop. C. A. M.

Estimation of Perchloric Acid in Certain Perchlorates. H. Golblum. (*Zeitsch. anal. Chem.*, 1911, **50**, 741-742.)—The method for the estimation of perchlorates, which depends on their conversion into chlorides, when strongly heated with ammonium chloride, is only applicable to the perchlorates of alkali metals; in other cases it fails owing to the decomposition of the resulting chlorides when heated. The author has devised an electrolytic method, which he has employed successfully in the analysis of nickel and cobalt perchlorates, in order to determine the relations between acid and base in these salts. It is based on the fact that the ion of perchloric acid is the last stage in the anodic oxidation of chlorides, and is therefore stable towards complete electrolysis when the metals are deposited on the cathode. Simple titration of the residual liquid with phenolphthaleïn as indicator should therefore afford a quantitative estimation of the perchloric acid, provided other chlorine compounds, derived from any possible decomposition of the perchloric acid, be absent. The results obtained for the metals were very satisfactory. In order to obtain adherent deposits, a platinum wire-net cathode was employed, and a weak current of only 0·1 ampère at the ordinary temperature; the terminal voltage was 10 to 12 on account of the high resistance. In order to decompose 0·2 grm. of the salt dissolved in 300 c.c. of water, it was found necessary to pass the current for seventy hours. J. F. B.

Volumetric Estimation of Small Quantities of Potassium. L. T. Bowser. (*J. Amer. Chem. Soc.*, 1911, **33**, 1752-1757.)—The author has adapted the qualitative cobaltinitrite method previously described by him (ANALYST, 1911, **36**, 606) to the determination of small quantities of potassium, the precipitate of dipotassium sodium cobaltinitrite being filtered and titrated in acid solution with dilute permanganate.

The potassium solution is evaporated nearly to dryness, cooled, and 2·5 c.c. of the sodium cobaltinitrite reagent and 10 c.c. of acid-alcohol (equal parts of glacial acetic acid and 95 per cent. alcohol) added, the mixture being well stirred. The precipitate is filtered through asbestos under suction, only very short contact with the reagent (half an hour) being allowed. The asbestos filter is laid on a perforated aluminium plate in a tube 2 inches long by ½ inch wide. The excess of reagent is removed from the precipitate by washing with acetic acid (20 per cent.). The asbestos and precipitate are transferred to a beaker, using a few c.c. only of water, an excess of 0·005 N potassium permanganate added, the liquid boiled, acidified with exactly 1 c.c. of diluted sulphuric acid (1 : 1), and the excess of permanganate almost immediately titrated at boiling temperature by means of 0·005 N oxalic acid. A blank experiment, to allow for the permanganate used up by the asbestos and sulphuric acid, must be made in each case, and the same asbestos then made into a filter and used for the determination. One c.c. of the permanganate solution is equivalent to 0·000043 grm. K. The presence of sodium, calcium, and magnesium in moderate amounts is without effect upon the results, which are fairly accurate. A. R. T.

Estimation of Sulphur in Pyrites. A. Heczko. (*Zeitsch. anal. Chem.*, 1911, **50**, 748-753.)—For the estimation of the available sulphur in pyrites, Dennstedt's combustion method (ANALYST) is rapid and accurate. The use of a quartz combustion-tube instead of one of Jena glass is advantageous, since quartz does not retain sulphuric acid, and it is unnecessary to rinse out the tube after each experiment. A tube 50 cm. long and 16 mm. in bore is employed, and as a contact material the platinum star recommended by Dennstedt is quite satisfactory; it is placed in the middle of the tube, and heated to redness by a Teclu burner placed underneath. The products of combustion are absorbed by 4 grms. of pure calcined sodium carbonate contained in two boats, the one nearest the platinum star being 15 c.m. long, and the other of the usual dimensions. The boat containing the weighed material for analysis is heated in an oven and introduced hot into the tube, lest the presence of moisture might cause decrepitation of the absorption material. The connections to the tube are fitted in corks, and both ends are kept cool by water-circulation through lead piping wound round the tube. A piece of sheet-iron channel is placed under the portion of the tube containing the absorption-boats to distribute the heat; the central portion of the tube is heated with direct flame. The oxygen is dried by sulphuric acid, and the progress of the combustion is indicated by the glow of the pyrites. A bubble-counter containing dilute permanganate is placed at the end of the tube, and serves to indicate the completeness of combustion. Combustion is started by heating one end of the boat containing the pyrites; it then proceeds by itself, and is finished off by heating with increasing strength by the Teclu burner. The sodium carbonate is dissolved in bromine water, and neutralised with hydrochloric acid; the pyrites residue is dissolved in 2 c.c. of hydrochloric acid, the iron is precipitated by ammonia, and the filtrate is added to the solution of the sodium carbonate. The sulphuric acid is precipitated by adding to the solution double the theoretical quantity of barium chloride required for precipitation; this is an important detail. The results are in satisfactory agreement with those afforded by Lunge's method; usually they are very slightly higher than the latter.

J. F. B.

Rapid Method of Estimating Zinc. K. Voigt. (*Zeit. angew. Chem.*, 1911, **24**, 2195-2198.)—The following rapid method of estimating zinc in ores, slags, etc., is shown to give results agreeing within about 0·36 per cent. of the gravimetric results, even in the case of substances rich in iron and poor in zinc: From 1 to 3 grms. of the finely powdered sample are decomposed with about 10 c.c. of nitric acid (sp. gr. 1·2) and 20 to 30 c.c. of hydrochloric acid (sp. gr. 1·19), care being taken to break up any deposit of silica. The mass is then transferred to a 300 c.c. flask, and treated with an excess (50 to 60 c.c.) of strong ammonia, which precipitates silica, iron, aluminium, and lead, but forms sufficient ammonium salts to keep the zinc in solution. After being boiled for a short time the contents of the flask are cooled, made up to the mark with dilute ammonia solution (1 : 3), well shaken, allowed to settle, and filtered. Two portions of 100 c.c. each of the filtrate are collected, one of which may be kept for a control gravimetric estimation if required. In the other portion the manganese is precipated by adding bromine and boiling the liquid, after which about 1 grm. of aluminium is added and the boiling gently continued for some minutes until any copper present has been precipitated. About 5 c.c. of a solution of sodium sulphite (1 : 4) and a few c.c. of ammonia solution are next added, and the liquid once more heated to the boiling-point, and immediately filtered. The filter is washed with a dilute ammoniacal solution of sodium sulphite, and the filtrate and washings treated with dilute hydrochloric acid (1 : 3), an excess of 10 c.c. beyond that required for neutrality being added. Finally, the solution (about 150 c.c. in all) is titrated with a solution of 21·63 grms. of potassium ferrocyanide and 14 grms. of crystalline sodium sulphite per litre, the end-point of the reaction being found by spotting tests with a solution of ammonium molybdate (9 grms. per litre) as indicator. Any yellow coloration due to phosphates may be easily distinguished from the brown tint produced by the excess of ferrocyanide solution. An excess of about 0·25 c.c. of the latter in 150 c.c. of liquid is required to give a sharp end-point, and this amount should therefore be deducted from the number of c.c. consumed. C. A. M.

Separation of Zirconium from Iron and Aluminium, and a New Method for the Analysis of Ferro-zircon. M. Wunder and B. Jeanneret. (*Zeitsch. anal. Chem.*, 1911, **50**, 733-735.)—Zirconium oxide is totally unaffected by fusion with sodium carbonate; hence it may be readily separated from aluminium and chromium. The oxides of iron, aluminium, and zirconium are fused in a platinum crucible with about 6 grms. of sodium carbonate; the melt is taken up with water, and, after the addition of 1 grm. of sodium carbonate, the solution is boiled for a few minutes. The mixture of iron and zirconium oxides is collected on a close filter, and if much aluminium or chromium be present, the filter is incinerated and the fusion repeated. The aluminium is precipitated from the filtrate by the addition of an excess of ammonium nitrate. The precipitate is treated on the filter with hot hydrochloric acid (1 : 1), whereby the iron oxide is completely dissolved and the zirconium oxide is unaffected.

The author describes a rapid method of analysing ferro-zirconium alloys; these alloys contain zirconium, iron and silicon, sometimes also aluminium. The alloy is heated with bromine and hydrochloric acid on the water-bath, whereby the zirconium and iron are dissolved, whilst silica remains. The silica is dehydrated by baking at 110° C., taken up with dilute hydrochloric acid, and filtered off; the zirconium, iron, and aluminium in the filtrate are precipitated by ammonia. The weighed silica is volatilised with hydrofluoric acid, any co-precipitated zirconium oxide being left behind and added to the ammonia precipitate. The mixed oxides are fused with sodium carbonate and separated in the manner described above. The presence of bromine will cause loss of iron by volatilisation of ferric bromide during the dehydration of the silica, unless expelled by boiling with nitric acid before evaporation. J. F. B.

APPARATUS, ETC.

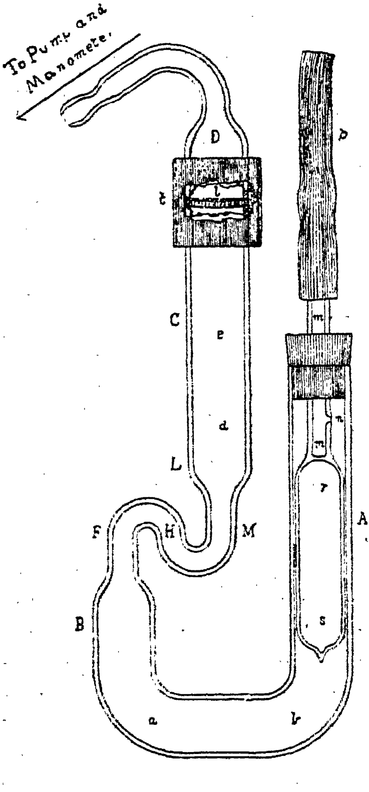
New Method for the Physical Analysis of Soils. J. Dumont. (*Compt. rend.*, 1911, **153**, 889-891.)—The sandy particles of soil separated by simple levigation are generally covered by a humo-argilaceous layer, which in the case of heavy soils may easily lead to false results; this layer may be loosened by cleansing the sand with dilute oxalic acid; further, the slimy and argilaceous matters may be more rapidly and perfectly separated by centrifuging than in the ordinary way. These observations form the basis of a new system of soil analysis. (1) Estimation of the carbonates and cleansing of the fine earth: Two to 5 grms. of the finely powdered dry soil are treated in the calcimeter with an equal weight of oxalic acid for the estimation of carbon dioxide. After the evolution of the gas, the amount of residual acid is calculated, and the liquid is diluted with water to produce a concentration of 2 per cent. of the acid. The earth is boiled with this liquid for half an hour, collected on a filter, extracted with dilute nitric acid, and washed with boiling water. (2) Estimation of humus and separation of the sand: The residue is removed from the filter into a dish, using 75 to 80 c.c. of dilute ammonia, 20 c.c. of ammonia are added, the whole is brought to the boil in order to dissolve the humus, and transferred to a graduated tube. The tube is filled up to a height of 15 cm., shaken, and left at rest for two hours; the liquid is decanted off the sandy layer, the residue is again shaken with dilute ammonia, and the liquid is poured off the coarse sand after settling for five minutes, the fine sand being also collected, dried, and weighed. (3) Separation of the slimy and colloidal components: The liquid from the first decantation is generally coloured by ammonium humate; it contains in suspension the mineral colloids (silicates) and slimy constituents which are to be separated by centrifuging. The liquid is poured into centrifuge tubes closed at the bottom by a small cup in which the deposits are collected, removed, and dried. The time of centrifuging may be varied if it be desired to classify the slimes, but in current practice these are separated as a whole by centrifuging for fifteen minutes at an average speed of 1,000 to 1,200 revolutions per minute. During centrifuging, the colloidal silicates remain in suspension in the ammoniacal solution of humus; they are readily coagulated by ammonium carbonate, and the coagulum is separated by a further centrifuging. These matters are collected and removed in the cups, and the liquid is finally evaporated to dryness on the water-bath, leaving a residue of humus.

J. F. B.

Solubility Estimations in Agricultural Chemistry. A. Rindell. (*Akad. Einladungsch. Helsingfors*, 1910; through *Chem. Zentralbl.*, 1911, II., 1654-1655.)—According to the author's investigations, the usual method for the estimation of citric acid-soluble phosphoric acid in Thomas meal cannot afford a determination of a definite solubility nor show the percentage of phosphoric acid of the supposed solubility. In the case of phosphate fertilisers, the author thinks that the solubility of the phosphoric acid should be determined with a much weaker solvent than the usual 2 per cent. solution of citric acid. In pure water the phosphoric acid of most crude phosphates is considerably less soluble than that of Thomas meal. In the case of potash fertilisers, the solubility, and the acid with which the base is combined are of little importance with regard to the action of the potash. Similar remarks apply to the superphosphates. In the case of precipitated phosphates, estimations of the solubility are of importance. The solubility of the dicalcium phosphate crystallising with 2 mols. of water is about 180 mgrms. of P_2O_5 per litre. In the case of tricalcium phosphate, not too strongly dried, the solubility is about two-thirds of this value; for incinerated tricalcium phosphate the solubility is barely 5 mgrms. of P_2O_5 per litre. The first value is about ten times the concentration of the phosphoric acid solution assimilated by an average crop of barley. In the case of nitrogenous fertilisers, the estimation of solubility is of doubtful importance. For the estimation of assimilable plant-nutrients a solvent of suitable strength must be selected, and used in such a manner in the case of each nutrient that first the corresponding solubility and secondly the quantity of any compounds which may be present having a different solubility are determined. Further, the author has shown that the presence of various compounds of the same plant-nutrient must be indicated by changes in the course of the solubility curve, with concentrations as ordinates and quantities of soil per litre of the solvent as abscissæ, and that the co-ordinates of these change-points have an important meaning, in that each ordinate expresses the solubility of a definite compound, the quantity of which in the soil is shown by the relation of the ordinates to their corresponding abscissæ. J. F. B.

Modified Explosion Eudiometer. F. H. Campbell. (*Chem. News*, 1911, **104**, 235-236.)—The modification consists in the addition of a three-way capillary-bore tap at the head of the eudiometer, by means of which the tube can be filled with mercury when the tap is open to the air. Hydrogen, etc., is passed in with the tap turned so as to communicate with the connection-tubes only, thus sweeping out air, and then the tap being turned again the gas passes into the eudiometer-tube to the desired volume. Another turn of the tap then allows of the admission of the second gas. A. R. T.

Simple Apparatus for Sublimation in a Vacuum. H. Christopher. (*Proc. Chem. Soc.*, 1911, **27**, 236-237.)—Owing to the density of the vapours of some substances, their diffusion to the cool part of a sublimation tube is a very slow process, and the accompanying figure shows the author's device for overcoming the difficulty. The apparatus consists of a tube, ABCD, about 7 inches in height and $\frac{5}{8}$ inch external diameter. The portion *ab* of the tube contains the substance to be sublimed, and the apparatus is heated, immersed to the level of L, in an oil or metal bath, the part C serving as the cooling chamber into which the vapours are carried by a current of air. The constricted portion of the tube, FHM, avoids the falling back of the sublimate in *de* on to the unsublimed substance. The current of air, regulated by a screw clip at P, enters the apparatus through the orifice *n* in the tube *mm*, and passes down the space between the outer wall of the sealed and exhausted tube *rs*, and the inner wall of the sublimation tube A over the substance to the condensing limb C and through a filter *l* to the pump. The filter consists of a disc of filter-paper held against the under side of a perforated porcelain disc, and serves to prevent the blocking of the outlet-tube. The filter rests on the end of the condensing limb and is held in place by the head D and the thick rubber connection *t*. Vortices are formed in the sublimation tube if *rs* be omitted, and some of the vapours carried into A. The working pressure (internal) should be about 40 mm., using a water-jet pump. A. R. T.



New Extraction Apparatus. F. Friedrichs. (*Zeitsch. anal. Chem.*, 1911, **50**, 756.)—An apparatus (see Fig.) is described for the extraction of liquids with ether, the principle of helical contact-surfaces being employed. The ether is vaporised in the round distillation flask, which is attached by a ground-glass joint. The vapour travels up the wide tube into the extraction vessel and is condensed in the helical surface-condenser, the liquid ether then falls into the funnel and is conducted by the central tube to the bottom of the liquid to be extracted. Thence it rises in small drops following the convolutions of the helix to the surface of the liquid. When the layer of ether has risen to the level of the lower horizontal branch it flows back through this tube into the boiling-flask, and the extraction becomes continuous. By means of the tap at the bottom and the tapped funnel, the liquid may be removed and replaced by fresh liquid without interrupting the distillation. J. F. B.

REVIEWS.

Alcools. Alcool, Alcool Dénaturé, Dénaturants. Par M. Louis Calvet. Librairie Polytechnique Ch. Béranger, Éditeur. 1911. Paris and Liège. Price 5 francs.

This small work is concerned with the analysis of industrial alcohols and of the materials used in denaturation, the more interesting subject of the potable spirit obtained by the distillation of fermented liquor having been dealt with in the same series by M. X. Rocques (*Eaux-de-vie*). The first chapter deals with the sources from which alcohol for industrial purposes is obtained, the methods used for rendering such spirit unfit for use as a beverage are briefly touched on, and mention is made of the ways in which evasion of fiscal regulations is attempted.

A résumé of French and foreign legislation relating to the extraction of revenue from the distilling industry is given in the second chapter, which extends to 76 pages, whilst the third chapter of 94 pages is devoted to the methods of analysis adopted in the case of industrial spirit both for determining the alcohol and detecting and estimating the various additions made to it in compliance with legal requirements.

Since alcohol has to be frequently determined in various products, 12 pages are allotted to the methods which are used in determining the alcohol in spirit of camphor, fruit essences, soaps, etc., and to the estimation of butyl and amyl alcohols in alcoholic liquids. Remembering the divergence of opinion which obtained some years ago as to methods by which the higher alcohols could be most conveniently and accurately estimated, it is rather interesting to find a French book recommending the process of extracting the higher alcohols and oxidising them to the corresponding higher acids—in fact, adopting essentially the process associated with the names of Allen, Marquardt, Schidrowitz, and Mann. The actual modification recommended is that due to Lasserre, the extraction being effected by carbon disulphide instead of carbon tetrachloride.

Further chapters deal with unofficial methods for the detection and estimation of methyl alcohol in presence of ethyl alcohol, and methods of analysis presented officially in other countries than France.

The second part of the book is largely occupied with alcoholometric tables; whilst in the short third section a digest of French legislation concerning alcohol for consumption is given, and also tables of production of alcohol in France since 1840.

The author has done his work carefully, and much information of use to the analyst may be obtained from the work. J. T. HEWITT.

"MATIERES TANNANTS CUIRS." Par L. JACOMET. Librarie Polytechnique Ch. Béranger, Éditeur. 1911. Paris and Liège. Price 5 francs.

This volume is issued under the auspices of the chief chemist of the Ministries of Finance, Commerce, and Agriculture of the French Government, and is one of a number of approved textbooks intended primarily for the use of those chemists engaged in the French Government Laboratories in the examination of the various materials which may come before them from the Customs or other Government departments.

The author has divided this work into six parts:

Part I. deals with the tanning materials, with the qualitative reactions, the various approved methods of analysis and estimation. It gives a list of the common tanning materials, their sources, the average strength, and touches lightly on the various adulterants found in some tanning extracts.

Part II. deals with the hides and skins, methods of analysis, and physical tests.

Part III. deals with gelatine, glue and size, various chemical and physical tests. Short reference is also made to fish-glue, photographic gelatine, and vegetable substitutes.

Part IV. deals with vegetable and animal blacks.

Part V. deals with varnishes, lacquers, and enamels.

Part VI. is a collection of tables giving the qualitative tests for all the different tannins, alone and in admixture, together with useful tables appertaining to this subject.

In Part VII. the author gives a very useful résumé of the various requirements of the French Government with regard to leathers and the various allied products, and the standard of purity, etc., which they are bound to possess to satisfy the Government requirements.

The author also refers briefly to the regulations insisted upon in factories working on Government contracts.

The volume is well illustrated, and forms a useful laboratory handbook for those engaged in the chemistry connected with the leather and allied industries.

THE ANALYST.

OBITUARY.

We deeply regret to have to record the death of one of the Founders and Past Presidents of the Society of Public Analysts, Dr. John Muter. He died on December 11, 1911, at Worthing. An obituary notice will appear in the next number of this Journal.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE ESTIMATION OF FURFURAL BY MEANS OF FEHLING'S SOLUTION.*

By LEWIS EYNON, B.Sc., F.I.C., and J. HENRY LANE, B.Sc., F.I.C.

(*Read at the Meeting, December* 6, 1911.)

According to J. T. Flohil, under certain conditions Fehling's solution is reduced by furfural in direct proportion to the quantity of the latter, and he has proposed a method for the determination of pentosans in which, after distilling the material with acid, the furfural in the distillate is determined by means of Fehling's solution (*Chem. Weekblad.*, 1910, **7**, 1057; Analyst, 1911, **36**, 161).

The method is conducted as follows: Fifty c.c. of the acid distillate (the total quantity of which amounts to 400 c.c.) are neutralised, treated with 20 c.c. of Fehling's solution, and made up to 100 c.c., the whole being boiled for thirty-five minutes under a reflux Liebig's condenser. In order to avoid any loss of furfural, a few pieces of ice are placed in the upper end of the condenser-tube, which is funnel-shaped. A blank determination must be made in which the same quantity of sodium chloride is present. Flohil finds that under these conditions the furfural-copper ratio is 0·3775 : 1—*i.e.*, that 1 molecule of furfural is equivalent to 4 atoms of copper or 2 atoms of oxygen. The amount of cuprous oxide may be found, not only by direct weighing, but indirectly by the iodometric determination of the unreduced copper (Schoorl, *Z. Angew. Chem.*, 1899, **12**, 633).

We have carried out series of experiments to ascertain the influence of variations in the concentrations both of furfural and of sodium chloride, and to determine the degree of accuracy that can be attained by Flohil's method. We find that, in heating the furfural solution with Fehling's solution under an ordinary Liebig's condenser, the use of ice to insure the complete condensation of the furfural is quite unnecessary. Contrary to Flohil's statement, we find that the copper-reducing power of furfural is not independent of the concentration, the furfural-copper ratio ranging from 0·376 to 0·450, as the amount of furfural present is increased from 0·01 to 0·05 grm. There appears to be no ground for Flohil's assumption of a simple stochiometric relation between the furfural and the copper.

---

* This work was carried out in accordance with the terms of the Analytical Investigation Scheme.

The furfural employed was purified by distillation in steam; it was then dried over calcium chloride and redistilled. We have found that the reducing power of dilute aqueous solutions of furfural undergoes no change in the course of several weeks. The Fehling's solution used was prepared by mixing equal volumes of a solution of 69·26 grms. of crystallised copper sulphate per litre, and a solution containing 100 grms. of sodium hydroxide and 348 grms. of Rochelle salt per litre.

Method of Procedure.—A solution containing not more than 0·05 grm. of furfural was mixed with 20 c.c. of Fehling's solution and a known quantity of a salt solution in a flask of about 200 c.c. capacity, the whole being made up to 100 c.c. with water. The flask was fitted with a vertical reflux condenser, and heated on an asbestos card over a flame of such size that the liquid was brought to the boiling-point in twelve to fifteen minutes, after which it was kept boiling for exactly thirty-five minutes. The precipitate of cuprous oxide was then collected in a Soxhlet tube, washed with water and alcohol, dried at 110° to 115° C. and weighed, after which it was reduced to copper and weighed again.

Table I. gives the results of a number of blank determinations in which mixtures of 20 c.c. of Fehling's solution, various quantities of salt, and sufficient water to make up 100 c.c., were heated as above described.

TABLE I.

Weight of Sodium Chloride: Grms.	Cuprous Oxide: Mgrms.	Copper: Mgrms.
0·0	5·5	4·9
5·6	9·3	8·3
8·0	10·5	9·3
10·4	11·7	10·4

Table II. shows the reducing power of furfural at various concentrations and in absence of salt. The weights of cuprous oxide given in column 2 are those found less 5·5 mgrms., the correction required under these conditions (see Table I.). The weights of copper given in column 3 (*a*) are those found less 4·9 mgrms., the correction required. The weights of copper given in column 3 (*b*) are calculated from the weights of cuprous oxide given in column 2. The close agreement between the figures in column 3 (*a*) and (*b*) shows that there is no necessity to reduce the cuprous oxide to metallic copper. The reducing power of the furfural is not independent of the concentration, the furfural-copper ratio increasing from 0·362 to

0·452, as shown in column 4. This may be the result of mass action; in presence of 0·05 grm. of furfural, the greater part of the copper in 20 c.c. of Fehling's solution is reduced. In addition to the results given in the table, fourteen other determinations were made with 0·05 grm. of furfural (the maximum quantity employed). In most cases the results agreed well with those given in the table, but in five cases differences of as much as 4 to 6 mgrms. in the weight of cuprous oxide (*i.e.*, 3 to 5 per cent.) were found.

TABLE II.

1.	2.	3.		4.
Weight of Furfural employed: Grm.	Weight of Cuprous Oxide (corrected): Mgrms.	Weight of Copper (corrected)— (*a*) Mgrms. found.	Weight of Copper (corrected)— (*b*) Mgrms. calculated.	Ratio $\frac{\text{Furfural}}{\text{Copper}}$.
0·0100	30·8 31·8	27·1 28·0	27·3 28·2	0·362
0·0200	57·2 54·8	50·8 48·6	50·8 48·7	0·402
0·0300	80·5 81·3	72·1 72·1	71·5 72·2	0·417
0·0400	101·7 101·4	90·1 89·7	90·3 90·0	0·444
0·0500	126·0 123·7	111·6 109·6	111·9 109·8	0·452

In the well-known process of determining pentosans which involves distilling the material with 12 per cent. hydrochloric acid, a distillate containing about 10 per cent. of the acid is obtained. Since, according to Flohil's method of copper reduction, 50 c.c. of the distillate are used, we have determined the reducing power of furfural at various concentrations, in presence of a quantity of sodium chroide (8 grms.), equal to that obtained by neutralising 50 c.c. of 10 per cent. hydrochloric acid with sodium carbonate.

Table III. shows the reducing power of furfural at various concentrations in presence of 8 grms. of sodium chloride. The weights of cuprous oxide given in column 2 are those found less 10·5 mgrms., the correction required under these conditions (see Table I.). The weights of copper given in column 3 (*a*) are those found less 9·3 mgrms., the correction required. The weights of copper given in column 3 (*b*) are calculated from the weights of cuprous oxide given in column 2. Here again the reducing power of the furfural is not independent of the concentration.

TABLE III.

1.	2.	3.		4.
Weight of Furfural employed: Grm.	Weight of Cuprous Oxide (corrected): Mgrms.	Weight of Copper (corrected)— (a) Mgrms. found.	Weight of Copper (corrected)— (b) Mgrms. calculated.	Ratio $\frac{\text{Furrural}}{\text{Copper}}$.
0·0100	29·3	25·6	26·0	0·399
	28·7	25·4	25·5	
	27·0	23·6	24·0	
0·0200	58·1	50·9	51·6	0·394
	56·3	49·2	50·0	
	58·7	52·1	51·0	
0·0300	82·5	72·5	73·3	0·418
	81·9	72·0	72·7	
	80·7	71·4	71·7	
0·0400	103·4	91·6	91·8	0·429
	106·9	95·4	94·9	
	104·8	93·0	92·1	
0·0500	125·9	—	111·8	0·445
	127·2	112·9	113·9	
	126·5	110·7	112·3	

It is evident from a comparison of Tables II. and III. that the reducing power of the furfural *per se* is independent of the presence of salt—*i.e.*, the weight of cuprous oxide obtained by the action of a given weight of furfural on Fehling's solution in presence or absence of salt, less the weight of cuprous oxide obtained in a blank experiment with the same quantity of sodium chloride, is constant. The values given in Tables II. and III. being, therefore, practically the same, they have been employed in plotting the curve shown below; the points indicated by the small circles represent the mean weights of cuprous oxide from Table II., whilst those indicated by the crosses represent the mean weights of cuprous oxide from Table III. The values given in Table IV. have been taken from the curve. By means of Tables I. and IV. the quantity of furfural corresponding to the weight of cuprous oxide obtained by the above-described method may be found. We have confirmed Flohil's statement that the unreduced copper in the liquid after boiling may be determined by Schoorl's iodometric method (*loc. cit.*). For this purpose the contents of the flask are cooled in running water, treated with 10 c.c. of a 20 per cent. solution of potassium iodide and 10 c.c. of a 25 per cent. solution of sulphuric acid

(1·5 parts of concentrated acid to 8·5 parts of water by volume), and then titrated with $\frac{N}{10}$ thiosulphate solution.

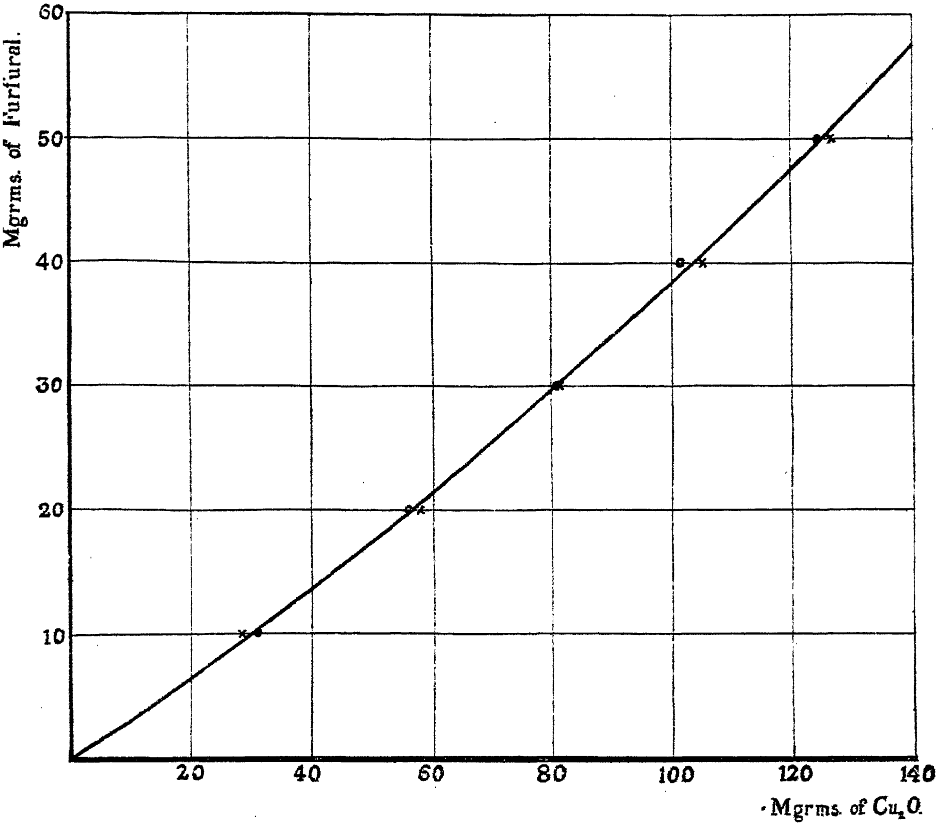

TABLE IV.

Weight of Furfural : Grm.	Weight of Cuprous Oxide (corrected) : Mgrms.	Weight of Copper (corrected) : Mgrms.	Ratio $\frac{\text{Furfural}}{\text{Copper}}$.
0·0100	30·0	26·6	0·376
0·0200	57·0	50·6	0·395
0·0300	81·0	71·9	0·417
0·0400	103·5	91·9	0·435
0·0500	125·0	111·0	0·450

DISCUSSION.

The CHAIRMAN (Mr. LING) remarked that the estimation of furfural was of great importance in the estimation of pentoses and pentosans, and two methods had hitherto been available, the furfural being estimated in the one case as phenyl hydrazide, and in the other as phloroglucide. Both of these methods emanated from Professor Tollens. The estimation as phenyl hydrazide was very uncertain in its results, and the phloroglucide method was more satisfactory, but phloroglucinol was a somewhat expensive substance. He had tried the copper-reduction method some years ago, but had not been successful with it. He had applied it in what seemed to him to be a rational manner, by adding an excess of Fehling's solution and heating the mixture in a closed vessel for a certain time in the water-bath. About twelve months ago, however, Flohil had found it possible to obtain much better results by using a reflux condenser, and it was at his (Mr. Ling's) suggestion that the present authors undertook the revision of Flohil's results under the Society's Research Scheme; and having seen their experiments and read their paper, he must say that he considered their investigation to be an ideal one from the point of view of the Research Scheme. Such a method had been much needed, and, as the result of Messrs. Eynon and Lane's work, it was rendered quite as satisfactory as the phloroglucinol method, whilst it had the additional advantage of being more expeditious.

Mr. A. E. PARKES asked whether it would be possible to apply this method to the determination of furfural in spirits.

The CHAIRMAN observed that, the method being a reduction method, could not be used in the case of spirits, which contained other reducing substances as well as furfural.

Dr. SCHIDROWITZ remarked that some ten years ago Dr. Hewitt had tried a method of this kind for the estimation of aldehydes in spirits, but had found it to be inapplicable owing to the smallness of the quantities of aldehydes that were present.

Mr. A. CHASTON CHAPMAN asked at what degrees of furfural concentration the respective ratios of 0·376 : 1 and 0·450 : 1 were obtained.

Mr. W. BACON asked what were the limits of concentration most applicable to this process.

Mr. EYNON, in reply, said that the ratio of 0·376 : 1 was obtained at a furfural concentration of 0·01 grm. in the reaction mixture, and that of 0·450 : 1 at a concentration of 0·05 grm. The quantity of furfural present must be within the limits of 0·01 and 0·05 grm., unless a larger quantity of Fehling's solution be taken, and then, of course, the tables they had given would not apply.

COMPOSITION OF AUSTRALIAN (VICTORIAN) MILK.

By E. HOLL MILLER.

(*Read at the Meeting, December* 6, 1911.)

The average composition of 11,140 samples of milk from farms, analysed in the Anglo-Australian Milk-Preserving Company's laboratory during the year September, 1909, to August, 1910, inclusive, is given in the following table. The period chosen is one complete year; spring embraces the months September to November, summer December to February, autumn March to May, and winter June to August.

	Morning Milk.				Evening Milk.				Mean.				Approximate Corresponding English Month.
	Sp. Gr.	Total Solids.	Fat.	Solids-not-Fat.	Sp. Gr.	Total Solids.	Fat.	Solids-not-Fat.	Sp. Gr.	Total Solids.	Fat.	Solids-not-Fat.

Average ...	1·0304	12·62	4·07	8·55	1·0310	12·96	4·23	8·70	1·0307	12·79	4·15	8·62	

It will be noticed that the poorest milk occurs in the month of January, which month approximates to the English month of June. The average difference between morning and evening fat is 0·16 per cent. This figure is lower than that given by Richmond for English milk—viz., 0·35 per cent.

It will be noticed that the evening milk is the richer in fat, while the sp. gr. of the morning's milk is lower than that of the evening's milk. With English milk the sp. gr. of the morning's milk is generally higher than that of the evening's milk.

On comparing the mean average composition with that given by Richmond ("Dairy Chemistry") for English milk, the sp. gr. is found to be lower, and the fat higher.

The lowness of sp. gr. for the months of December, January, and February, is ascribed to a flush of green herbage caused by copious rains.

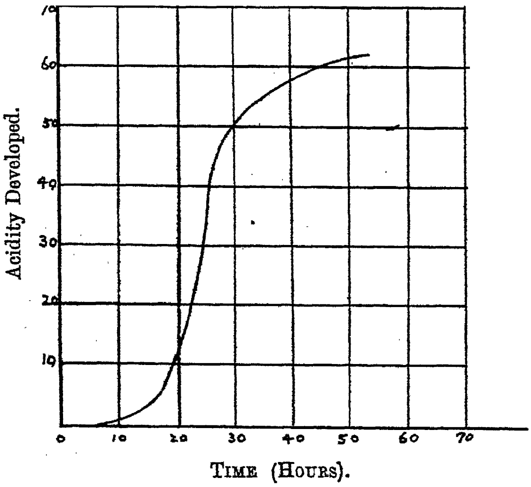
Aldehyde Figure.—The aldehyde figure of a considerable number of the above samples has been found to average 18·5° using $\frac{N}{10}$ strontia, and 17° using $\frac{N}{10}$ soda.

This is a ratio of approximately 1·1, and corresponds with the results of Richmond and Miller (ANALYST, 1906, **31**, 224).

The ratio $\frac{\text{protein}}{\text{aldehyde}}$ has been found to be 0·173 (using strontia), the figure given by Richmond (ANALYST, 1911, **36**, 9) being 0·170.

It was found that milk curdles on boiling when it had developed an acidity of 13° above its normal acidity. This figure is in accordance with that given by Harrison and Richmond (ANALYST, 1900, **25**, 116).

The following curve graphically illustrates the souring of milk:



Time.	*Acidity.*
6	0
16	4
23	20
25	33
27	49
31	50
33	55
50	61
53	63

It will be noticed that there is the usual break in the curve, occurring at 45° and corresponding to the acidity at which the micro-organisms cease to increase.

Acidity.—The average normal acidity was found to be 18°.

Ash.—The percentage of ash determined from a considerable number of samples was found to average 0·72 per cent.

Cl, CaO, and P_2O_5.—The average percentage of these constituents was found to be as follows: Cl, 0·08 per cent.; CaO, 0·18 per cent.; P_2O_5, 0·21 per cent.

A sample of tinned sterilised milk of German origin, imported into Java, gave the following results on analysis:

Sp. gr.	1·0325	Acidity	23°
Total solids	12·21 per cent.	Aldehyde figure ...	21° (strontia)
Fat (Gottleib)	3·21 ,,	Ratio $\frac{\text{protein}}{\text{aldehyde}}$ ...	0·171
Ash	0·72 ,,		
Solids-not-fat	9·00 ,,	Chlorine	0·090
Protein (N × 6·38) ...	3·60 ,,	CaO	0·160
Lactose	4·68 ,,	P_2O_5	0·230

COMPOSITION OF AUSTRALIAN SWEETENED CONDENSED MILK.

By E. HOLL MILLER.

(*Read at the Meeting, December* 6, 1911.)

The following two tables give the composition of samples of five different brands of sweetened condensed milk purchased in Victoria, and six purchased in New South Wales.

These figures are of some interest, as all the milks were manufactured in Australia.

TABLE I.

Purchased in Victoria.

	Brand No. 1.	Brand No. 2.	Brand No. 3.	Brand No. 4.		Brand No. 5.		
				Sample *a*.	Sample *b*.	Sample *a*.	Sample *b*.	Sample *c*.

TABLE II.

Purchased in New South Wales.

	Brand No. 1.	Brand No. 2.	Brand No. 3.	Brand No. 4.	Brand No. 5.	Brand No. 6.
Total solids ...	75·87	67·53	76·14	74·77	71·38	75·87
Fat	10·68	9·41	9·28	9·81	9·93	9·05
Ash	2·10	1·82	2·11	1·82	1·84	2·10
Solids-not-fat ...	65·19	58·12	66·86	64·96	61·45	66·82
Protein (N × 6·38)...	10·25	9·14	9·84	8·95	9·39	9·10
Total sugars ...	52·84	47·16	59·91	54·19	50·22	55·62
Chlorine	0·36	0·20	0·21	0·19	0·19	0·24
Acidity	51°	56·8°	51·84°	44·64°	50·05°	49·75°

For analysis the whole of the contents of the tin were turned out into a basin and thoroughly mixed, and the portions required were taken from the mixed sample.

The fat was estimated by Richmond's modification of the Rose-Gottleib method. Other constituents were estimated in the usual manner.

Tyrosin was detected in all the above samples with the exception of Nos. 1 and 3, Table I.

I have found that tyrosin makes its appearance in sweetened condensed milk between the end of the third and fourth month after manufacture. Samples six months old show distinct crystalline tufts of tyrosin, which can generally be detected on the first slide prepared, when examined under the microscope with a one-sixth inch objective.

Samples twelve months old show fairly large round crystalline feathery tufts. These tufts of crystals all approximate to the same size in the same tin of milk, and the size and number of them form a fairly good criterion of the age of the sample.

* * * * *

THE ALDEHYDE FIGURE OF BUTTER.

By E. HOLL MILLER.

(*Read at the Meeting, December* 6, 1911.)

It has been pointed out by Steinegger that formaldehyde combines with milk proteins to form additive compounds, probably of the type $\mathrm{R}<\begin{matrix}\mathrm{NCH_2}\\ \mathrm{COOH}\end{matrix}$, with an increase in the acidity of the milk, which is proportional to the total nitrogen present. Steinegger's method has been modified by Richmond and Miller (chiefly by substituting the use of strontia for soda), who have shown that under their conditions the method is a rapid and approximately accurate one for estimating the percentage of proteins in milk; and it has been further shown by Richmond (Analyst, 1911, **36**, 9) that the degree of accuracy of the determination is of the same order as the Gerber method for the estimation of fat.

A number of experiments have been carried out in order to determine whether use could be made of this method to estimate with a fair degree of accuracy the proteins in butter, as it was recognised that a rapid method for such would be of considerable value in butter-factory routine analysis.

The following procedure was found to be the best for carrying out the determination: Approximately 10 grms. of butter are weighed into a tared beaker, which is placed in a water-bath at 60° to 70° C., until the butter is completely melted. Twenty-five c.c. of water at about 65° C. are added, and followed by 1 c.c. of a 0·5 per cent. solution of phenolphthaleïn. The contents are well agitated. Approximately $\frac{N}{20}$ alkali is then run in until a faint permanent pink tint is formed. If it is found that the end point is masked by the yellow colour of the butter-fat, the contents of the beaker should be allowed to settle, and the bottom aqueous layer observed, and the addition of alkali continued until the pink tint is obtained. Five c.c. of strong formaldehyde solution are next added, and the contents of the beaker well agitated; $\frac{N}{20}$ strontia is then run in until the pink tint is again produced in the aqueous portion.

The number of c.c. of $\frac{N}{20}$ alkali used in the second titration, less the amount equivalent to the acidity of the formaldehyde solution added, is proportional to the protein present. One c.c. of $\frac{N}{20}$ strontia is equivalent to 0·01355 grm. of protein nitrogen, assuming the proportion of casein to albumin to be 7 to 1 (Richmond and Miller, ANALYST, 1906, **31**, 224).

Thus, when 10 grms. of butter are taken, the number of degrees of acidity produced when multiplied by 0·170 gives the percentage of protein.

The following are some of the results obtained:

SALTED BUTTER ONE MONTH OLD, PREPARED FROM RIPENED CREAM.

Aldehyde Figure, °.	rotein (Kjeldahl, × 6·38) per Cent.	Ratio $\frac{\text{Protein}}{\text{Aldehyde.}}$	Protein calculated, ° Aldehyde × 0·170.	Difference.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Estimation of Water in Butter. A. C. D. Rivett. (*Chem. News*, 1911, **104**, 261-263.)—The author employs the calcium carbide method, and determines the loss of acetylene by weighing, thus arriving at the amount of water present in the sample. A special form of apparatus is employed, in which a known weight of the butter in a lower chamber can be heated, in the weighed apparatus, after allowing it to become mixed with a quantity of calcium carbide placed in an adjacent chamber. The acetylene passes through a tower of glass-wool mixed with carbide, which traps any moisture, and is finally swept out of the apparatus by means of a current of dried air. Experiments show that 0·696 grm. of acetylene represents 1 grm. of water (theory = 0·722 grm. C_2H_2), and the calculation is made on this basis. The butter and carbide mixture should be heated with the direct flame to a temperature similar to that ordinarily reached in the direct heating method. The results are usually 0·2 to 0·3 per cent. lower than by the last-named method, in which probably volatile matter other than water-vapour escapes during heating. The method of heating butter with alcohol at 100° C. to expel the water gives results about 0·1 per cent. higher than the carbide method. A. R. T.

Influence of Certain Preservatives on the Keeping Properties and Composition of Butter. K. Fischer and O. Greunert. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 553-582.)—Parallel experiments carried out on the effect of various substances on the preservation of butter and margarine showed that benzoic acid, salicylic acid, and boric acid, failed to prevent the butter and margarine from becoming rancid after the lapse of a short time, even when added in quantities up to 1 per cent. On the other hand, butters and margarine containing 3 per cent. of common salt remained fresh as regards taste and odour for from two to three months. The changes taking place in the butter and margarine containing the first-mentioned substances were due to decomposition of the glycerides and the proteins; this decomposition was not decreased proportionally to the quantities of the preservative substances added. W. P. S.

Estimation of Cocoa-Husks in Cocoa. C. Ulrich. (*Arch. Pharm.*, 1911, **249**, 524-597.)—Analyses of many samples of the different kinds of cocoa upon the market are given, and the methods of estimating cocoa-husk are critically examined (*cf.* ANALYST, 1909, **34**, 134). The iodine value of the fat of the roasted beans examined ranged from 32·20 to 35·6 (mean, 34·1), whilst in the case of unroasted beans the limits were 34·7 to 36·5 (mean, 35·5). Prochnow (*Dissertation*) confirmed the results of Welmans (*Z. öffent. Chem.*, 1901, **7**, 500), that the fat from the shells had a considerably higher iodine value (43·2 to 46·2 for six samples) than the bean fat; but the author has obtained lower values than these—34·8 to 37·9 (mean, 36·3) for the fat from roasted shells, and 36 to 38 (mean, 37·3) for the fat from unroasted shells. Hence it is not possible to detect the presence of even 30 per cent. of husks, as claimed by Welmans, by means of the increase in the iodine value of the fat. With regard to the elutriation method of separating the husk, devised by Filsinger and Drawe (ANALYST, 1903, **28**, 216), the author's experiments indicate that as little as 7·5 per cent. of added husk may be detected and estimated in normal cocoa (30 per cent. of fat and moisture), provided that the husk is present in a very finely powdered condition, and that the factor (for the loss) of 1·43 proposed by Drawe be increased to 1·72. Estimation of the amount of crude fibre by the method of König (ANALYST, 1898, **23**, 47), and the modification of Matthes and Müller (ANALYST, 1906, **31**, 362), gave the following results with eight different kinds of cocoa: Roasted kernels 5·79 to 7·9, and roasted husks 13·5 to 17·7 per cent., calculated on the fat-free substance. The method would not enable a smaller quantity than 27·5 per cent. of husks to be detected. In like manner, estimation of the pentosans (see Hehner and Skertchley, ANALYST, 1899, **24**, 178) is only of value in the case of mixtures containing more than 25 per cent. of husk. The following new method, based on the precipitation of cocoa-red by means of ferric chloride from an acetic acid extract of the cocoa, is claimed to detect with certainty the addition of 10 per cent. and upwards of cocoa-husks to a normal cocoa: One grm. of the finely-powdered, anhydrous, fat-free sample is boiled for three hours beneath a reflux condenser with 120 c.c. of pure 50 per cent. acetic acid, after which the contents of the flask are cooled, made up to 150 c.c., well shaken, and allowed to stand for at least twelve hours. The liquid is then filtered, and 135 c.c. of the filtrate are treated with 5 c.c. of concentrated hydrochloric acid and 20 c.c. of 20 per cent. ferric chloride solution, then boiled for ten minutes under a reflux condenser, rapidly cooled, and transferred to a beaker. After standing for at least six hours, the precipitate is collected upon a dried tared filter, washed until the washings are free from iron, dried for six hours at 105° C., and weighed. The following results, calculated upon the anhydrous and fat-free cocoa-beans and upon the original air-dried material, were thus obtained:

Cocoa.	Roasted Beans.				Raw Beans.			
	Estimations.	Ferric Chloride Precipitate.			Estimations.	Ferric Chloride Precipitate.		
		Extremes.	Mean.	On Original Material.		Extremes.	Mean.	On Original Material.

Mixture of all	7	13·02—13·78	13·51	5·81	1	14·33	14·33	6·33

Extracts of the husks gave no precipitate under the same conditions, whilst mixtures of the different kinds of cocoa with 10 per cent. of husks gave results corresponding within 0·9 per cent. of the calculated smaller amounts of precipitate. Bahia and Guayaquil cocoa thus give results deviating considerably from those of the other kinds of cocoa, but it is pointed out that, in practice, commercial (normal) cocoa usually consists of a mixture of two or more brands, and that in the case of such mixtures the method will readily detect 10 per cent. of husks. If the cocoa is known to be a Bahia product alone, the amount of the precipitate must be as low as 9·68 per cent. before the presence of 10 per cent. of husk is indicated. In like manner, in the case of Guayaquil cocoa it is also necessary to know the brand, since otherwise a precipitate of 13·70 per cent., as obtained from a mixture of that cocoa with 10 per cent. of husks, would indicate a pure sample. Not until as much as 21 per cent. of husks has been added to Guayaquil cocoa does the iron method give a value of 11·28, which in the case of a normal cocoa would indicate the presence of 10 per cent. of husk. C. A. M.

Composition of Honey from Various Countries. **K. Lendrich and F. E. Nottbohm.** (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 633-643.)—The following average results were obtained on the analysis of sixty-three samples of honey imported into Germany, the samples being taken either from the packages in the holds of the vessels or in the Customs warehouses:

Country of Origin.	Water.	Ash.	Sodium Chloride.	Acidity (c.c. $\frac{N}{1}$ Alkali per 100 Grms.)	Invert Sugar.	Sucrose.	Non-Sugars.	Proteins (N×6·25).
	Per Cent.	Per Cent.	Per Cent.		Per Cent.	Per Cent.	Per Cent.	Per Cent.
France (2 samples)	19·81	0·30	—	3·50	75·86	0·15	4·18	0·58
Italy (1 sample) ...	17·20	0·06	0·02	1·80	76·62	3·19	2·99	0·21

The fat from *B. butyracea* is harder and whiter than that from the other two species, but it is not exported, the available supply being consumed locally. Bassia kernels at present are chiefly crushed in France and Germany, since in England the expressed cake is considered poisonous for cattle. It has been shown (*Bio-Chemical J.*, 1910, 93) that such cake contains a saponin-like glucoside with marked physiological activity when subcutaneously injected, but apparently without action when fed to cattle. H. F. E. H.

Characteristics of Palm Oil from Different Varieties of Palm. A. Hébert. (*Bull. Soc. Chim.*, 1911, [iv.], **9**, 1083-1085.)—The samples of palm oil examined were extracted by means of petroleum spirit from the fruit of palm-trees grown in Dahomey. All the fats are used by the natives as food, with the exception of that obtained from the variety *repanda*, which is reputed to cause headache and sickness. The yields and analytical values were as follows:

C. A. M.

Analysis of Mustard Flour. A. Domergue. (*J. Pharm. Chim.*, 1911 [vii.], **4**, 494-496.)—In estimating the proportion of essential oil in mustard flour it is necessary to prevent the distilling vapours coming into contact with rubber connections. For this purpose the author employs an apparatus in which one end of the condenser is connected with the flask by means of a ground-in stopper, whilst the other end is bent downwards at a right angle into a graduated cylinder. From 60 to 65 c.c. of the distillate are collected as described by Lenormand, after which 20 c.c. of $\frac{N}{10}$ silver nitrate solution are added, the volume made up to 100 c.c. and the estimation completed. The proportions of essential oil most usually found in commercial samples of mustard flour are from 0·2 to 0·9 per cent. The French Codex specifies 0·70 per cent. as the minimum for black mustard seed. C. A. M.

Composition of Capsicum (Cayenne Pepper). A. von Sigmond and M. Vuk. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 599-605.)—Analyses of twenty-five samples of Hungarian capsicum yielded the following results: *Pericarp*: water, 16·6; ether extract (on the dry substance), 14·6 to 15·0 per cent.; iodine value of the oil, 134. *Seeds*: water, 6·0; ether extract, 31·8 to 32·4 per cent.; iodine value of the oil, 140. *Green Portions* (stalks, etc.): water, 9·1; ether extract, 2·5 to 2·6 per cent.; iodine value of the oil, 110·0 to 112·6. Analyses are also given of specimens of Turkish, Spanish, Japanese, and Indian capsicums; the quantities of the various constituents varied considerably, the ether extract ranging from 9·2 to 10·47 per cent., and the ash from 8·19 to 9·46 per cent. for the fruit free from seeds, whilst samples of ground capsicums yielded from 15·5 to 22·08 per cent. of ether extract and from 5·63 to 9·86 per cent. of ash. As regards the detection of added oil in ground capsicums, the author is of opinion that this cannot be done by taking the iodine value of the oil extracted from a sample. As this added oil would remain on the outer portions of the particles constituting the powder, whilst the natural oil would be still partly enclosed in the cellular tissue, it might be possible to separate the added oil by shaking with water, and the authors are carrying out experiments in this direction. It is pointed out that the United States regulations require that ground capsicums, excluding seeds, shall yield not less than 15 per cent. of ether extract; this portion of the fruit, however, according to the authors' analyses, contains only 14·5 per cent. of ether-soluble substances. W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Antiseptic Effect of Creosote Oil and Other Oils used for Preserving Timber. J. M. Weiss. (*J. Soc. Chem. Ind.*, 1911, **30**, 1348-1353.)—The author has investigated the behaviour of pure cultures of *B. subtilis*, *Sacch. glutinis*, and *Penicillium sp.*, all of which can grow on moist sterile wood towards three classes of antiseptics: (1) Oils prepared in the laboratory, mostly separated creosote oil with varying proportions of filtered tar or tar acids added; (2) pure substances such as phenol, cresol, naphthalene, anthracene, quinoline, and paraffin; and (3) commercial creosoting oils. In no case was the antiseptic used in higher proportion than 10 per cent. in the medium, the lowest dilution being 0·05 per cent. A culture medium composed of Liebig's extract, peptone, sodium chloride, maltose, lactose, dextrose, and calcium nitrate in agar was used. The author's conclusions are as follows: (1) The neutral oils of creosote are strong antiseptics; (2) the middle fraction of these neutral oils, boiling from 235° to 270° C., is the strongest: the higher boiling oils are considerably weaker, the lower oils slightly so; (3) coal-tar bases having high boiling-points are strong antiseptics; (4) coal-tar acids are very strong antiseptics, rising in efficiency with the boiling-point; (5) the solid hydrocarbons, naphthalene and anthracene, have low antiseptic values; (6) the addition of filtered tar in moderate amounts to creosote does not materially reduce its antiseptic value; (7) paraffin has no antiseptic value; (8) producer gas-tar distillates have lower antiseptic value and are decidedly inferior to the neutral coal-tar oils; (9) coal-tar creosote is greatly superior as an antiseptic preservative to producer gas-tar distillates and petroleum residues. H. F. E. H.

Use of Charcoal as a Clarifying Agent in the Estimation of Sugar in Urine. A. C. Andersen. (*Biochem. Zeitsch.*, 1911, **37**, 262-265.)—The results of a number of experiments carried out by the author show that the addition of hydrochloric acid, as recommended by Bang and Bohmannsson (ANALYST, 1910, **35**, 70), does not prevent the absorption of sugar by blood-charcoal when the latter is employed for clarifying and decolorising urine. When bone-charcoal is used but little absorption takes place, the quantities of sugar found being practically identical with those obtained by using lead acetate or mercuric nitrate as clarifying agents; bone-charcoal, however, decreases the reducing power of normal urine to a less extent than does blood-charcoal. More satisfactory results are obtained if 50 per cent. acetic acid be employed in place of hydrochloric acid, as the absorption of the sugar by either bone or blood charcoal is almost entirely prevented. Forty c.c. of the urine should be treated with 10 c.c. of 50 per cent. acetic acid and 4 grms. of powdered blood-charcoal, shaken for ten minutes, and then filtered. W. P. S.

Observations on the Assay of Digestive Enzymes. H. T. Graber. (*J. Ind. Eng. Chem.*, 1911, **3**, 919-921.)—According to the U.S. Pharmacopœia, the activity of pepsin preparations is to be tested on "fresh eggs," but the author has found that the digestibility of egg albumin varies considerably according to the age of the egg. The albumin of an egg twenty-four hours old is not in a readily digestible condition, and the maximum condition of digestibility by pepsin is only reached when the egg is five to seven days old; after this the digestibility decreases, and about the tenth day it becomes the same as it was on the second day. It is advisable to retain a sample of pepsin standardised against eggs of known ages, and to use the same for control purposes in future work. In digestion experiments with pepsin extremely small variations in acidity cause large differences in the results. In testing the diastatic activity of pancreatin, various kinds of starch show very different results—for instance, a sample of pancreatin may show an activity towards potato starch one-third greater than towards maize starch. In testing papaïn, finely-minced raw beef-steak should be used; the enzyme does not dissolve cooked beef. Ten grms. of minced beef, 0·325 grm. of papaïn, and 85 c.c. of 0·3 per cent. hydrochloric acid, are digested at 52° C. for six hours; the undigested residue, after settling in a measuring-tube for three-quarters of an hour, should not amount to more than 2 c.c. The coagulating power of rennet is influenced by the condition of the milk and its chemical composition, particularly the proportion of calcium salts; also the manner of mixing the rennet with the milk, the kind of cows from which the milk was taken, and, lastly, the temperature at which the milk was kept before and during the test. The milk should not be stirred, but the rennet should be mixed by pouring from one vessel to another. J. F. B.

Diastatic Power of Malt. C. G. Matthews and F. E. Lott. (*J. Inst. Brew.*, 1911, **17**, 638-642.)—The Lintner process for estimating diastase measures only the saccharifying power, since soluble starch is employed, and this the authors consider a defect, as failing to take account of the starch-liquefying power of the extract. Soluble starch, if over-converted, yields results which are too high; while soluble starches prepared from malt, barley, and potato starches all yielded the same result with the pale malt used. The use of potato starch paste in place of soluble starch is shown to be satisfactory for the majority of malts examined, the average difference being 3·5 units Lintner, the maximum discrepancy being a fall of 16 per cent. with a vinegar malt (D.P. 99·5). Two malts of normal diastatic activity showed values of 3 and 5 units higher when starch paste was employed.

The authors describe the method they recommend, which consists in adding 0·75 grm. of finely-ground malt to 500 c.c. of 2 per cent. starch paste, standing one hour at 70° F., checking the action with soda, diluting to 1 litre, and then titrating the maltose formed with Fehling's solution, the grains being allowed to settle out without filtering. For highly diastatic malts the concentration of starch may be increased to 3 per cent. The vinegar malt mentioned above shows a value of 20 per cent. low by this method (2 per cent. starch), and 11 per cent. low with 3 per cent. starch. The other samples examined show an average difference of 7 units Lintner, the new process values being in all cases but one lower than the standard values.

H. F. E. H.

ORGANIC ANALYSIS.

Estimation of Asphalt in Mineral Oils, Pitch, etc. F. Schwarz. (*Chem. Zeit.*, 1911, **35**, 1417-1419.)—The author recommends the use of butanone (methylethyl ketone) for the separation of asphalt from mineral oil distillates, lubricating cylinder oils, etc. Dry butanone has a sp. gr. of 0·805 at 20° C., but its solvent action is too powerful to permit of a proper separation of the asphalt, especially in presence of a large proportion of oil. A litre of butanone dissolves about 110 c.c. of water at the ordinary temperature, and the saturated mixture has a sp. gr. of 0·835 at 20° C. For the treatment of thick mineral lubricants, a preliminary extraction with saturated aqueous butanone, followed by extraction with aqueous butanone of sp. gr. 0·812, affords a satisfactory separation of the hard asphalt. Two to 4 grms. of the oil to be tested are placed in a 200 to 300 Erlenmeyer flask, fitted with a fractionating column tube, together with 40 to 80 c.c. of saturated aqueous butanone; the contents of the flask are boiled with vigorous agitation for one minute, and the solution is decanted off hot through a No. 589 filter, care being taken to leave all the residual oil in the flask. The operation is repeated twice again with 20 to 40 c.c. of the saturated butanone. Next, the oily residue is treated in exactly the same manner, three times, with aqueous butanone of 0·812 sp. gr., the same filter being used and the extracts collected separately or together with those of the first series. Any oily particles on the filter should be thoroughly washed with the final hot extraction liquid. The residue in the flask is then dissolved in benzene or chloroform, and the solution is poured through the same filter into a dish. The residue after evaporation often contains traces of oily matters, which should be removed by treatment with 5 to 10 c.c. of light petroleum spirit (b.p. 30° to 50° C.); the asphalt is filtered off, washed with the same spirit, dissolved in chloroform or benzene, and collected in a tared dish; it should be quite hard and brittle at 100° C. The results are usually lower than those obtained by the alcohol-ether method, but the latter generally yields soft asphalts containing bodies not included in the hard asphalt separated by the butanone method. The butanone method may likewise be employed for the fractionation of solid bituminous materials and pitch residues. About 1 grm. of the bitumen, soluble in chloroform, is treated as described four or six times, each time with 20 c.c. of butanone of sp. gr. 0·812. The extraction with the saturated aqueous butanone of sp. gr. 0·835 may be omitted with these materials, since the quantity of oily constituents is relatively small. The extracts are filtered hot, and the filter is washed with the same solvent; the asphalt is then dissolved in chloroform and filtered into a tared dish. The matters in the butanone extract may be further fractionated by saturating the extract with water (about 10 c.c. of water per 100 c.c.). The precipitated resins are filtered off, washed with saturated aqueous butanone, and weighed separately, the oily constituents being estimated by evaporating the butanone extract. J. F. B.

Analysis of Mixtures of Ceresin and Paraffin Wax. N. Chercheffsky. (*Ann. de Chim. anal.*, 1911, **16**, 456-463.)—The lowering of the melting-point caused by the addition of paraffin wax to ceresin is sometimes disguised by adding carnauba wax or a similar product. Hence it is necessary in the first place to separate the unsaponifiable matter in the sample by the usual methods. The following table shows the comparative solubility of a typical paraffin wax (melting-point 52° to 54° C.) and of a pure Galician ozokerite ceresin (melting-point 68·7° C.) in different solvents at 15° C.

Solvents.	Pure Ceresin (m.pt. 68·7° C.).	Paraffin Wax (m.pt. 53·7° C.).
	Grms. per Cent.	Grms. per Cent.
Ethyl alcohol, 96·5 per cent.	0·056	0·108
Methyl alcohol, 99·25 per cent.	0·016	0·004
Amyl alcohol	0·100	0·496
Carbon bisulphide	1·9716	19·072
Carbon tetrachloride	1·948	11·784
Chloroform	1·276	5·332
Crystallisable benzene	0·784	4·540
Acetone	0·028	0·120
Ether	0·592	1·920
Petroleum spirit (sp. gr. 0·710)	1·416	5·940

The critical temperature of solution is best estimated in 96·5 per cent. alcohol, and a table is given showing that the results obtained with mixtures of the two waxes are in close agreement with the calculated values. The turbidity temperatures given by 2 c.c. of the melted sample in 4 c.c. of the solvent in a tube 7 to 8 cm.

in length by 1 cm. in diameter also afford valuable indications, as is shown in the following results in ° C., obtained with the same samples of waxes:

	Amyl Alcohol.	Carbon bisulphide.	Carbon tetrachloride.	Chloroform.	Benzene.	Toluene.	Xylene.	Petroleum Spirit (Sp. gr. 0·6886).	Petroleum Spirit (Sp. gr. 0·8725).
Ceresin...	66·4	40·3	42·1	41·8	47·4	41	46·2	45·1	51·3
Paraffin Wax...	51	14·8	23·5	24·9	24·7	24·5	26·4	28·8	29·8

In most cases benzene (boiling-point 80·5° C.) will be found the most satisfactory solvent for this test, and it may even be used to effect a partial separation of ceresin from paraffin wax. The general physical characters of certain typical paraffin waxes and ceresin are summarised in the following table:

Wax.	Origin.	Melting-point.	Refractive Index—		Critical Temperature of Solution in Alcohol (96·5 per Cent.).	Turbidity Temperature in Benzene.	Solubility in Carbon bisulphide at 15° C.
			At 78° C.	At 100° C.			
		° C.			° C.	° C.	Grms. per Cent.
Paraffin 3 RB	America	53·7	1·4280	1·4185	148	24·7	19·07
,, from Schist 3 R	Autun	42·1	1·4238	1·4152	136·5	—	38·68
,, ,, ,, 4 R	Autun	46·5	1·4246	1·4161	141	—	34·65

C. A. M.

Chemical Examination of Calabar Beans. A. H. Salway. (*J. Chem. Soc.*, 1911, 99, 2148-2159.)—The ripe seed of *Physostigma venenosum* contains, in addition to the alkaloid physostigmine or eserine, some new substances which the author describes. He obtained two interconvertible modifications of physostigmine itself, $C_{15}H_{21}O_2N_3$, which appears to be dimorphous, one melting at 86° to 87° C., and the other at 105° to 106° C. The total amount separated amounted to 0·179 per cent. of the bean. Physovenine, $C_{14}H_{18}O_3N_2$, a new alkaloid, melts at 123° C., and has, like the previous substance, a powerful myotic effect on the pupil of the eye. Another alkaloid eseramine melts at 245° C. Calaberol, $C_{23}H_{36}O_4$, a new dihydric alcohol, melts at 245° C. Trifolianol, $C_{21}H_{36}O_4$, is a dihydric alcohol previously isolated from red clover flowers. Stigmasterol, $C_{30}H_{48}O$, and sitosterol, $C_{27}H_{46}O$, were obtained, and in addition glycerides of behenic, stearic, palmitic, oleic, and linolic acids, and a sugar yielding *d*-phenylglucosazone (melting-point 205° C.). H. F. E. H.

Aromatic Grass Oils. Part I. (*Bull. Imp. Inst.*, 1911, **9**, 240-253.)—These volatile oils are derived from members of the genera *Cymbopogon*, *Andropogon*, and *Vetiveria* (Nat. Ord. *Graminaceæ*), and the chief are citronella, lemon grass, palmarosa, and vetiver oils. The "total alcohols" were calculated from the acetylated oil, and the amount of geraniol recorded was found by the phthallic anhydride method, the citronellal being the difference between these two amounts. Three kinds of grass yield oils of the citronella type: (1) The wild mana grass; (2) the cultivated maha-pengiri grass; and (3) lena-batu grass:

	Mana Grass Oils.							Lena-Batu, *Cymbopogon nardus* (Rendle, Lena-Batu).	Maha-Pengiri, *Cymbopogon winterianus* (Jowitt).
	Oils from *Cymbopogon nardus*, var. *Linnæi* (*typicus*).				Oils from *Cymbopogon nardus*, var. *convertiflorus*.				
	Maha-naran-pengiri Oil.	Heen-naran-pengiri Oil.	"Small-Leaved Mana" Grass Oil.	"Very Broad-Leaved Mana" Grass Oil.	"Glaucous-Leaved-Mana" Grass Oil.	"White-Stemmed Mana" Grass Oil.	"Red-Stemmed Mana" Grass Oil.

H. F. E. H.

New Philippine Essential Oils. B. T. Brooks. (*Philippine J. Science*, 1911, **6**, 333-351.)—*Oil of Michelia Champaca* (*L*) and of *Michelia Longifolia* (*Bl*) (Analyst, 1912, 28).

Oil of Toddalia Asiatica (*L.*) *Kurz* (*T. Aculeata Pers.*).—The leaves of this species yield 0·08 per cent. of oil, of sp. gr. 0·9059 at 30° C., and $[n]_{D\ 30^\circ\text{ C.}} = 1{\cdot}4620$. It consists chiefly of linalol, together with about 18 per cent. of a volatile crystalline compound of camphoraceous odour melting at 97° C.

Oil of Clausena Anisum-Olens (*Bl.*) *Merr.*—The oil from the fresh leaves (1·2 per cent.) has the following constants: Sp. gr. at 30° C., 0·963; $[n]_{D\ 30^\circ\text{ C.}} = 1{\cdot}5235$;

saponification number, 3·6. No optical activity. Ninety-one per cent. distils between 212° to 214° C., and consists of methyl-chavicol. *Clausena* and rosemary are used in the preparation of aromatic liquors.

The oil from Limnophila species (*Scrophulariaceæ*) has a sp. gr. of 0·850, indicating a high proportion of terpenes.

Citrus Oils.—Philippine orange-peel oil is of the usual character: $[n]_{\mathrm{D}\ 30^{\circ}\mathrm{C.}}=1{\cdot}4700$; $[\alpha]_{\mathrm{D}\ 30^{\circ}\mathrm{C.}}$, 90°·85; ester number, 8·0; limonene, about 92 per cent. The freshly-pressed oil deposits about 0·3 per cent. of a crystalline stearoptene.

Citrus Decumana.—The oil of the leaves of this species, which yields the well-known grape fruit, is present to the extent of 1·7 per cent., and has sp. gr. at 30° C., 0·870; ester number, 10; $[\alpha]_{\mathrm{D}\ 30^{\circ}\mathrm{C.}}$, 22°·9; $[n]_{\mathrm{D}\ 30^{\circ}\mathrm{C.}}=1{\cdot}4644$. It is miscible with 70 per cent. alcohol. The oil contains 25 per cent. dipentene, 15 per cent. linalol, and aldehydes in small quantity (? citral). The oil from *C. hystrix* (0·08 per cent.) has sp. gr. at 30° C., 0·915; $[n]_{\mathrm{D}\ 30^{\circ}\mathrm{C.}}=1{\cdot}4650$; $[\alpha]_{\mathrm{D}\ 30^{\circ}\mathrm{C.}}=-10^{\circ}{\cdot}5$; saponification number, 50·2. A. R. T.

Reaction for Detecting Sesamé Oil in Other Oils. Utz. (*Chem. Rev. Fett- u. Harz-Ind.*, 1911, **18**, 292-293.)—Guarneri's test for sesamé oil (*Chem. Zentralbl.*, 1909, II., 869) consists in treating the sample with a few drops of an ethereal solution of hydrogen peroxide and a little nitric acid of sp. gr. 1·4, when a blue coloration should be obtained in the presence of sesamé oil. The author describes a series of systematic tests made upon different oils and fats, from which he concludes that the colours obtained in the case of mixtures are not sufficiently distinctive, and that the reaction is not sensitive enough. The Baudouin test and Soltsien's tin chloride reaction are much more reliable and sensitive than Guarneri's reaction.

C. A. M.

Estimation of Phenol and *p*-Cresol in the Presence of Each Other. H. Ditz and F. Bardach. (*Biochem. Zeitsch.*, 1911, **37**, 272-312.)—Results of a series of investigations are given with the object of confirming the accuracy of the method proposed some years since by Ditz and Cedivoda (ANALYST, 1900, **25**, 74). The method is reliable, provided that the prescribed procedure be followed, and is stated to be more trustworthy than that described by Siegfried and Zimmermann (ANALYST, 1911, **36**, 79). W. P. S.

New Method for Determining the Melting-Point of Pitch. H. F. French. (*J. Ind. Eng. Chem.*, 1911, **3**, 907-910.)—The method consists in heating a suspension of the pulverised material in a liquid until it coagulates. The liquid is heated by the passage of an electric current in an Erlenmeyer flask, which is rotated during the period of observation. The electrodes are $\frac{3}{16}$ inch copper rods encased in rubber tubes and tipped with lead at the bottom; these are bound together with a thermometer. A 220-volt direct current circuit is used, and the electrolyte is dilute sulphuric acid standardised so that a current of 2·2 ampères passes at 25° C., whilst the flask is rotated. The correct grinding of the material is of extreme importance: 20 grms. of pitch are ground until the powder passes through a 40-mesh sieve of No. 32 wire, having holes 0·0137 inch in size. Two grms. of the freshly-ground pitch are placed in the flask with 50 c.c. of the electrolyte and thoroughly shaken; the electrodes and thermometer are introduced and fixed parallel to one of the sides of the flask, which is then rotated at a high speed whilst the current is passed. When the suspended pitch coagulates to a distinct clot the current is switched off and the temperature noted. It is important that the pitch should not be kept longer than an hour or so after grinding, as the melting-point rises considerably on keeping. J. F. B.

Soot: Its Character and Composition. J. B. Cohen and A. G. Ruston. *J. Soc. Chem. Ind.*, 1911, **30**, 1360-1364.)—The character of coal, method of combustion, and distance from place of combustion, all influence the composition of soot. The table shows the main differences observed in domestic and boiler samples of soot:

	Ash, per Cent.	Carbon, per Cent.	Tar, per Cent.	Nitrogen, per Cent.	Number of Lbs. per Bushel.	Value per Ton calculated from Nitrogen.			Acidity, per Cent.
						£	s.	d.	
Boiler, base	75·0	16·7	0·09	—	35·8		—		1·33
,, top	62·0	27·0	1·66	1·21	34·3	0	14	6	0·56
Brass foundry, liquid fuel, base	82·0	11·4	1·02	0·11	63 3	0	1	2	—
Brass foundry, liquid fuel, top	31·4	47·7	10·62	2·32	40·1	1	7	0	0·65
Domestic, kitchen ...	17·8	52·3	12·5	4·11	22·0	2	9	4	0·28
,, room 5 feet up	5·1	36·5	34·9	6·89	16·5	4	2	8	0·92

The lighter and more bulky the soot, the higher, as a rule, is the nitrogen content, and it is advisable to buy by the bushel rather than by weight. The purchaser should demand that there be at least 4 bushels to the hundredweight. The average loss of coal in the form of soot is 6 per cent. in the case of domestic consumption and 0·5 per cent. for factories. The average deposit of soot over the City of Leeds is 220 tons per square mile per annum, the amount of tar varying from 4 to 110 hundredweight per square mile per annum according to locality. The adverse effect of soot in the air on the growth and development of plants is very marked, the assimilating power of leaves having been found to fall from a standard of 100, two and a half miles from the city, to 42 and even 12 in the University and the city itself respectively. The weight of lettuce crops was reduced from 140 to 44 over the same area. The acidity of soot is such that the corrosion of rails is six times as great in towns as in the country, this acidity having a very injurious effect on soil bacteria, and therefore on the fertility of town soils, when present in excessive amounts. H. F. E. H.

New Process for the Estimation of Sugars. F. von Fillinger. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 605-607.)—For the estimation of reducing sugars in such substance as blood, etc., the author describes a process which is a combination of Bang's and Pavy's methods. The following solutions are required: (1) Potassium thiocyanate, 250 grms.; potassium carbonate, 250 grms.; and potassium hydrogen carbonate, 25 grms., per litre. (2) Crystallised copper sulphate, 4·278 grms. per litre. (3) Potassium thiocyanate, 200 grms.; potassium carbonate, 250 grms.; potassium hydrogen carbonate, 50 grms.; and crystallised copper sulphate, 10·42 grms., per litre. The sugar solution under examination should contain approximately 0·1 per cent. of reducing sugars; in the case of solutions of unknown concentration, a preliminary estimation is made by boiling small definite amounts for two minutes with quantities of 10 c.c. of solution (3). The amount of sugar solution which just decolorises the 10 c.c. of reagent solution contains 0·01 grm. of sugar, and the strength of the solution is adjusted accordingly to make it contain 0·1 per cent. of sugar. For the actual estimation 20 c.c. each of solutions (1) and (2) are placed in a flask, and the flask is closed with a rubber stopper, through which passes the nozzle of a burette containing the sugar solution. A side-tube on the neck of the flask is connected by means of a T-piece with two small wash-bottles containing alkaline pyrogallol solution; the tubes in these wash-bottles are so arranged that the air leaving the flask must pass through one of the bottles, whilst air entering the flask passes through the other. The contents of the flask are now boiled until all air has been expelled from the flask, and the sugar solution is then run in gradually until the blue colour has been discharged, the contents of the flask being kept at a boiling temperature meanwhile. The percentage quantity of sugar is found by dividing 1 by the number of c.c. of sugar solution used. For the estimation of sugar in blood or other fluids containing proteins it is recommended that the latter be removed by treatment with ferric hydroxide; from 3 to 4 grms. of sodium chloride may also be added to the 40 c.c. of mixed reagent solutions in order to render the results more concordant.

W. P. S.

INORGANIC ANALYSIS.

Estimation of Antimony in Red Rubber Goods. W. Schmitz. (*Gummi-Zeit.*, 1911, **25**, 1928-1930; through *Chem. Zentralbl.*, 1911, II., 1710.)—Three grms. of the finely rasped rubber are treated in a Kjeldahl flask with 40 to 45 c.c. of strong sulphuric acid. A small quantity of mercury or mercury salt is added, and a piece of paraffin wax about the size of a pea. The mixture is heated until the rubber is dissolved and the black liquid begins to clear; 2 to 4 grms. of potassium sulphate are then added, and the heating is continued until a colourless liquid is obtained. After cooling, 1 to 2 grms. of potassium metabisulphite are added, and an excess of tartaric acid; the liquid is diluted sufficiently to prevent the charring of the tartaric acid, and boiled until the odour of sulphur dioxide has disappeared. A few c.c. of dilute hydrochloric acid are added, the liquid is diluted to 200 c.c., filtered through a dry filter, and 195 c.c. are titrated either with iodine and thiosulphate or, more simply, with potassium bromate, the latter titration being made in acid solution. The above procedure gives accurate results, and is far simpler than the usual gravimetric method for the estimation of antimony. Decomposition of the rubber by means of fuming nitric acid in presence of sulphuric acid gives good results, but the method recommended by Frank and Birkner (ANALYST, 1910, **35**, 131), in which ammonium persulphate and nitric acid are employed, is difficult in operation.

J. F. B.

Estimation of Antimony in Red Rubber Goods. W. Schmitz. (*Gummi-Zeit.*, 1911, **25**, 2002-2003; through *Chem. Zentralbl.*, 1911, II., 1711.)—The method recommended by the author (see preceding abstract) is preferable to that of Frank and Birkner (ANALYST, 1910, **35**, 131), because it can be performed on a relatively large quantity of material (2 to 4 grms.) and because in the latter method the rubber tends to ignite unless the nitric acid be suitably diluted. The oxidation of the rubber by sulphuric acid can, however, be accelerated by the use of ammonium persulphate. When the rubber is completely dissolved and the black liquid begins to clear, solid ammonium persulphate is added to the contents of the flask until the liquid becomes colourless. If small particles of carbon remain floating in the clear liquid, heating must be continued and more persulphate added. The liquid is then diluted and boiled for a long time in order to destroy the residual persulphate. When using this method, the titration with iodine is more suitable than that with potassium bromate, since the persulphate sometimes yields a liquid of yellow colour. The author's method possesses the advantage of being extremely rapid (total time no more than two hours), and of avoiding the presence of nitric acid and oxides of nitrogen, which would interfere with the titration. J. F. B.

Detection, Separation, and Estimation, of Arsenic and Antimony. G. Bressanin. (*Boll. Chim. Farm.*, 1911, **50**, 691-694; through *Chem. Zentralbl.*, 1911, II., 1964.)—The method of Blattner and Brasseur (ANALYST, 1904, **29**, 167) for the estimation of small quantities of arsenic in hydrochloric acid and sulphuric acid yields inexact results: 2 per cent. low, for example, in concentrated hydrochloric acid. With sulphuric acid (sp. gr. 1·45), even if it contained one-third hydrochloric acid, accurate results were obtained. Washing the precipitate of arsenious iodide with hydrochloric acid containing potassium iodide involves the danger of liberating iodine; and 2·5 c.c. or less of the potassium iodide solution should be used instead of the 5 c.c. prescribed. To determine the arsenic in hydrochloric acid, the author mixes 1 part of the acid with 2 of sulphuric acid (sp. gr. 1·45). In sulphuric acid free from lead or tin, the precipitation is carried out without the addition of hydrochloric acid. Commercial sulphuric acid is first brought to a sp. gr. of 1·45, and one-third of hydrochloric acid added; nitroso compounds, if present, are destroyed with urea. For washing, a mixture of 4 parts of sulphuric acid (sp. gr. 1·45) and 1 part of hydrochloric acid is used. The sulphuric acid under examination may be over a sp. gr. of 1·45—*e.g.*, 1·52. Thus modified, the method gave good results. Antimonious iodide was found to be soluble in concentrated hydrochloric acid, and the method, for antimony, is thus confined to estimations in sulphuric acid. The reactions may be followed under the microscope: the yellow hexagonal plates of arsenious iodide are easily distinguished from the purple-red antimony iodide crystals of similar shape. To determine arsenic and antimony occurring together, the sample is dissolved in sulphuric acid (sp. gr. 1·52) to a standard volume, the antimony iodide and arsenious iodide precipitated in an aliquot part, without the addition of hydrochloric acid, and the arsenic and antimony determined together by titration. The precipitate from a second portion to which one-third hydrochloric acid had been added is washed three times in the usual manner, dissolved, neutralised, and the arsenious iodide titrated; the antimony iodide is found by difference. Arsenates and antimonates are estimated similarly. O. E. M.

Detection and Estimation of Arsenic in Organic Compounds. G. Bressanin. (*Boll. Chim. Farm.*, 1911, **50**, 727-730; through *Chem. Zentralbl.*, 1911, II., 1695.)—The author applied the method (see preceding abstract) to the estimation of arsenic in sodium cacodylate, arrhenal, atoxyl, and salvarsan. In sulphuric acid of sp. gr. 1·45, these compounds, except salvarsan, even in dilute solution, gave characteristic, various-coloured precipitates with potassium iodide. The cacodylate always gave the smell of cacodyl. For estimation, 0·2 to 0·4 grm. of the substance was heated carefully in a long-necked flask for two hours with 10 c.c. concentrated sulphuric acid. Sulphur dioxide was expelled by a strong current of air, the contents of the flask transferred, with repeated washings with sulphuric acid (1·45 sp. gr.), to a 100 c.c. flask, and made up to the mark with the same acid. The arsenic was determined as described (see preceding abstract) in an aliquot portion. Results for sodium cacodylate, arrhenal, atoxyl, and salvarsan, agreed well with the theory. Salvarsan, unlike other organic arsenic compounds, in solution in sulphuric acid, gives no precipitate with potassium iodide. It reacts violently with sulphuric acid of sp. gr. 1·84 with evolution of sulphur dioxide; if then diluted with sulphuric acid of 1·45 sp. gr., it gives a precipitate with potassium iodide. O. E. M.

Determination of Copper: A Modification of the Iodine Method. C. Kendall. (*J. Amer. Chem. Soc.*, 1911, **33**, 1947.)—The modification is intended to make the iodide method as rapid as the less accurate, but hitherto more convenient, cyanide method. The removal of the nitrous acid formed by solution of the copper, as metal, oxide, or sulphide, is effected by means of sodium hypochlorite, instead of by evaporation to dryness, or by the use of bromine. The chlorine liberated is converted into chlorophenol, which is not ionised. If the sample is metallic copper, 200 to 300 mgrms. are dissolved in 5 to 10 c.c. of 50 per cent. nitric acid; if cuprous oxide, it is collected on asbestos in a Gooch crucible, and thence dissolved with 10 to 15 c.c. of 30 per cent. nitric acid; if cuprous sulphide, it is collected on a $\frac{1}{8}$-inch layer of asbestos in a Gooch crucible, the crucible with its contents boiled in a 50 c.c. beaker with 10 c.c. of 50 per cent. nitric acid until solution is complete, and solution and asbestos washed into a conical flask; if a solution of a copper salt, a quantity containing 200 to 300 mgrms. of copper is taken. To the solution in a 300 c.c. conical flask, its volume being between 50 and 60 c.c., its acidity equal to 4 or 5 c.c. concentrated nitric acid, and its temperature not above 25° C., are added 5 c.c. of hypochlorite solution made by boiling together 112 grms. calcium hypochlorite having 35 per cent. or more available chlorine, 100 grms. anhydrous sodium carbonate, and 1,200 c.c. water, filtering, and adjusting the hypochlorite solution until 5 c.c. are equivalent to 30 c.c. $\frac{N}{10}$ thiosulphate. A change of colour from a clear blue to a greenish tint, or the evolution of chlorine, shows that enough hypochlorite solution has been added. At the end of two minutes, 10 c.c. of colourless 5 per cent. phenol are rapidly added, chlorine above the liquid blown off, the flask washed down with water, and 20 per cent. sodium hydroxide run in until a very slight precipitate forms. This is just dissolved by the addition of 50 per cent. acetic acid, followed by 10 c.c. of potassium iodide solution containing 30 grms. per 100 c.c. The titration is made with thiosulphate (1 c.c. = 6 mgrms. Cu) until the liquid has a light straw colour. After addition of starch solution the titration is finished, thiosulphate 1 c.c. of which is equivalent to 1 mgrm. copper being used if great accuracy is required. The results appended show a percentage error ranging from −0·10 to +0·15. O. E. M.

Method for the Estimation of Selenium in Sulphur and Pyrites. P. Klason. (*Chem. Zeit.*, 1911, **35**, 1345.)—Sulphite lye containing 0·5 mgrm. selenium per litre is useless. The author estimates this small quantity by means of hydriodic acid: the selenious acid sets free iodine, which is detected by its action on starch. As a control, sulphur to which a known quantity of selenium had been added was burnt in a tube. Until all the sulphur was burnt, no oxidation of selenium took place; then, in oxygen, selenium dioxide was sublimed, and it was found that 0·1 mgrm. could be detected with certainty. Pyrites was treated similarly, but in a quartz tube. Sicilian sulphur was found to contain about 0·9 grm.; Japanese, 1 to 20 grms.; and Falun pyrites, usually 10, but sometimes 30 or 40 grms. selenium per ton. The author's method allows 92 per cent. of the selenium in sulphite liquor containing only 0·25 mgrm. selenium per litre to be determined. O. E. M.

Volumetric Estimation of Sulphur in Iron and Steel. T. G. Elliot. (*Chem. News*, 1911, **104**, 298.)—A mixture of 5 grms. of the sample with 0·25 grm. finely powdered anhydrous potassium ferrocyanide is wrapped in one 11 cm. filter-paper if the sample is a graphitic iron, in two if it is a steel or white iron, annealed in a covered porcelain crucible for twenty minutes in a closed muffle at 750° to 850° C., and allowed to cool slowly outside the muffle. If the paper is burnt away from above the drillings, the annealing has been at too high a temperature or too long, and the results will be low. The drillings are emptied into a glass mortar, loosened with a pestle, and transferred to the evolution flask, without touching its neck or sides. With the flask is connected a condensing-tube, 6 inches by 1 inch, containing 2 inches of water and standing in cold water, and with this in turn a flask containing 60 c.c. of cadmium chloride solution, made by dissolving 20 grms. of cadmium chloride in water containing a few drops of hydrochloric acid, adding ammonia until the precipitate formed dissolves, acetic acid to acidity and 20 c.c. in excess, and water to 2 litres. A safety-flask containing more cadmium solution is attached. To the sample are now added 50 c.c. of concentrated hydrochloric acid, and heat is applied until the frothing shows that solution is well begun. The flame is lowered until the stream of gas slackens, then raised, and the liquid gently boiled until appreciable evolution of gas ceases. Excess of standard iodine solution is run into the absorption-flask—usually nothing is found in the safety-flask—then about 10 c.c. of 1 in 2 hydrochloric acid, and the sulphide dissolved by shaking. The excess of iodine is titrated back with standard sodium thiosulphate. Displacement of the air by CO_2 is unnecessary in works practice. Correction may be made for any sulphur introduced as sulphates in the paper or ferrocyanide from the difference in sulphur found in samples of the same pure iron with and without annealing. The standard solutions used (1 c.c. = 0·005 per cent. sulphur on a 5-grm. sample) are standardised against a steel or iron of sulphur-content determined by the "aqua regia" or Bamber's method. An iron containing 0·2 per cent. of titanium and 0·080 per cent. sulphur (gravimetric) gave 0·018 unannealed, 0·066 after annealing at 800° C., and 0·076 per cent. after annealing at 950° C. for five minutes and above 790° C. for fifteen minutes. This suggests that with proper preliminary treatment the evolution process may be applied even to titanium pigs. O. E. M.

APPARATUS, ETC.

The Quantitative Manipulation of Small Quantities of Precipitates.

J. Donau. (*Monatsh. für Chem.*, 1911, **32**, 1115-1139.)—The author describes the apparatus and methods adopted in carrying out his improved method of quantitative microchemical analysis, and gives details of procedure in the case of twenty-six typical gravimetric estimations. The Nernst microbalance has been improved by constructing the beam and pointer in a single piece, with a glass counterpoise fused on to the beam at the end near the pointer. At the other end of the beam a piece of silver wire is fused into the glass, from which the filter-pan is suspended by means of a strand of very fine Wollaston wire, ending in a hook below. The whole balance is enclosed in an air-tight case sealed with paraffin wax to exclude moisture; the atmosphere inside is kept dry by means of quicklime, and access is obtained to the pan-hook by a circular hole 3 cm. in diameter, closed by a glass slide which is smeared with vaseline. For collecting the precipitates, the asbestos filter-bed (Analyst, 1911, **36**, 180) has been replaced to great advantage by one of spongy platinum. The filter-pan is formed out of a circular piece of thin platinum-foil 10 to 12 mm. in diameter, perforated at the bottom and provided with a wire loop for hanging on the balance. Spongy platinum is deposited on the perforated bottom of the pan, and the deposit is covered with a smaller platinum-foil tray, also perforated; in this way most of the precipitate, after weighing, may be lifted out of the filter bodily, leaving only a little to be dissolved out by chemical means.

The author describes an ingenious arrangement for producing and manipulating the precipitates. It consists of a short glass tube 1 cm. wide, open at the top, and terminating in a narrow tube at the bottom, this being closed by a piece of glass rod attached by a rubber tube. The substance is dissolved in this vessel, the precipitating reagent is added, the whole being heated if necessary. The upper mouth of the precipitating vessel is then closed with a cork carrying a glass bulb-tube which has just been heated. On cautiously opening the lower end, air is sucked up the capillary, and the bubbles stir the precipitate. Similarly, by applying a hot glass od to this bulb-tube the liquid and precipitate can be expelled down the capillary into the filter. A bell-jar is placed between the pump and filter. The precipitating vessel is washed out by similar procedure described above. Full details are given in the paper. J. F. B.

Apparatus for Extracting Liquids with Immiscible Solvents, and for Measurement of Evolved Gases. R. F. Bacon and P. B. Dunbar.

(*U.S. Bureau of Chemistry Circular*; through *Chem. Eng.*, 1911, **14**, 430-431.)—*Continuous Liquid Extraction.*—As shown in Fig. 1, the apparatus consists of a flask, *a*, of glass tubing, of 2 inches in diameter ($\frac{1}{16}$ inch thickness) and 20·5 inches in length, and enlarged to about 3 inches at its lower end; an extraction thimble, *b*, an ordinary test-tube of $1\frac{1}{2}$ inches diameter and of 100 c.c. capacity when filled to $1\frac{1}{2}$ inches of the top, having at a distance of a $\frac{1}{4}$ inch from the top and on opposite sides two holes about $\frac{1}{4}$ inch diameter; a Gooch crucible funnel, *c*, 8·5 inches long, but longer if dense liquids are to be extracted, with the lower end of the stem ground at an angle of 45 degrees; and a condenser, *d*, hanging loosely in the flask. About 100 to 150 c.c. of ether are poured into the flask, and 100 c.c. of the liquid to be extracted is placed in the test-tube; the funnel is inserted into this tube and suspended in the flask, about 3 inches above the bottom, with a copper wire passing through the holes in the tube and hooked over the rim of the flask neck. The condenser is placed in the top of the flask, and condensed ether drops from the condenser into the funnel, and is carried down to the bottom of the tube, whence it passes through the liquid, and overflows at the top. The efficiency of the extractor may be increased by using a glass spiral attached to the stem of the funnel (Kampf, *Chem. Zeit.*, 1910, **34**, 1365).

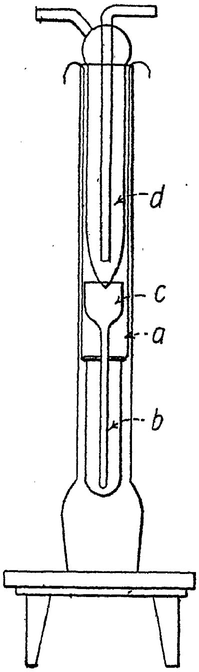

Fig. 1.

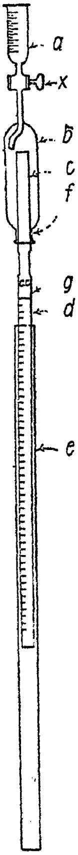

Fig. 2.

Measurement of Evolved Gases.—The solid or liquid substance to be acted on is placed in the reaction chamber, *b* (Fig. 2), and with the stopcock, *x*, open, the liquid in the eudiometer-tube, *d*, is brought to zero by raising or lowering the levelling-tube, *e*. The reagent is placed in *a*, with the stopcock closed, and, after lowering the levelling-tube, the stopcock is opened and a known quantity of reagent mixed with the material to be acted on. The reaction-chamber, *b*, may be heated if required by means of a coil wrapped round it. After cooling to room temperature, the increased volume of the air and gas in the apparatus is read off as usual, deducting the volume of the added reagent. The absorption-tube, *c*, is filled with beads, and is sealed on to the endiometer, and fits into the reaction-chamber, *b*, by means of a ground joint at *f*. The apparatus is suitable for the estimation of citric acid by Spica's method, and for amino-acids by the method of Van Slyke. A. R. T.

Notes on Thermostats, Shaking and Stirring Apparatus, etc. A. C. Cumming. (*Chem. News*, 1911, **104**, 307-309.)—A thermostat is best made of copper, and should be of such size that the introduction of the experimental apparatus does not materially alter the temperature of the contained water. A constant level is maintained in the usual way. The liquid contained in the regulator attached to the thermostat should have a low specific heat, high co-efficient of expansion, and low density. Mercury has a very low specific heat (0·03), but its great density necessitates the use of thick-walled apparatus. Benzene, toluene, alcohol, ether, carbon tetrachloride, etc., may be used, the one having the lowest density being the most efficient. A spiral to give a large surface of exposed liquid is commonly employed, thus giving a sensitive regulator (Lowry, *J. Chem. Soc.*, 1905, **87**, 1030), and this spiral is preferably made of metal. A satisfactory connection is made with rubber if a water-trap is introduced between the mercury and the organic liquid, so that the water layer covers the junction between the metal and glass. Of the forms of apparatus for cutting off the gas-supply, those of W. H. Green (*Chem. News*, 1908, **98**, 49) and T. S. Patterson (ANALYST, 1902, **27**, 234) are

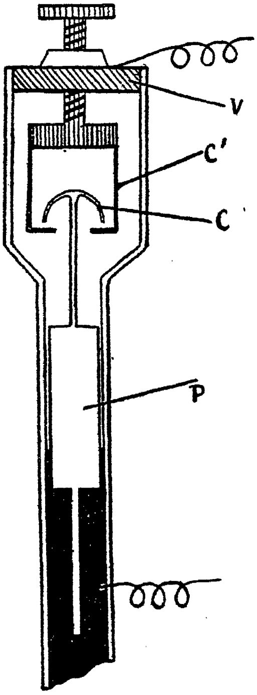

FIG. 1.

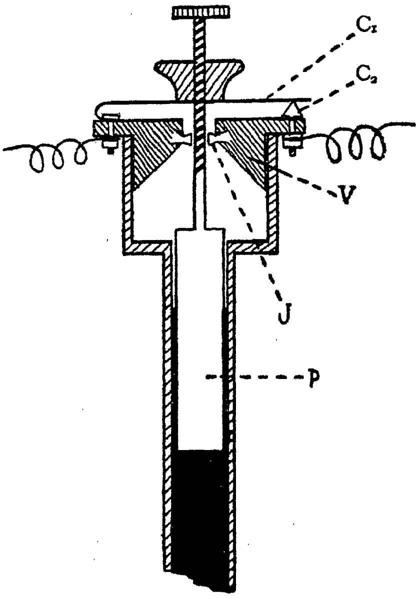

FIG. 2.

satisfactory. A novel method of altering the amount of mercury in the regulator, to produce altered temperature, has been described by A. Slator (ANALYST, 1911, **36**, 127).

Two forms of electrically-controlled regulator have been devised by C. Fraser, and have been found to be reliable. In the first (see Fig. 1), a metal plunger, *P*, floats on the surface of the mercury. This carries a curved platinum wire, *c*, at the end of a rod, and contact is made when *C* comes into contact with *C′*, the point of contact being covered with platinum. The vulcanite plug *V* serves to insulate *C′* and its connections. The adjustment is made as usual, finally by raising or lowering *C′* by means of the brass screw. Fraser regards the form shown in the next figure as an improvement on the latter. Contact between two platinum terminals (C_1 and C_2) is broken when the rise of the plunger lifts C_1. A side-to-side movement is avoided by the garnet jewel setting (*J*) in the vulcanite ring *V*. The regulating screw serves for fine adjustment, the rough alteration being made by increasing or reducing the amount of mercury in the regulator.

In connection with shaking apparatus, J. Knox uses a driving band of brass wire wound in a narrow close spiral. This is advantageous for bands to be used under water, owing to the disintegrating action on leather and gut. For stirring apparatus the author uses the glass-angle stirrer shown in the illustration. The side-tube is 2 inches long, and the vertical tube of such length that it ends about 1 inch from the bottom of the bath when the side-tube is 2 inches below the surface. A deep thermostat may be stirred by blowing a stream of air through the water, the bubbles of air ascending through a wide tube open at both ends. The temperature in any part of the bath is thus kept at not more than 0·1° variation from other parts. More vigorous stirring by mechanical means is, however, necessary for closer constancy of temperature.

REPORTS.

On the Work of Inspectors of Foods. A. W. J. Macfadden. (Appendix A, No. 8, from the Annual Report of the Medical Officer of the Local Government Board for 1910-11.)—The Report deals with work in special relation to the Public Health (Regulations as to Food) Act, 1907, meat inspection, food-poisoning, work in special relation to the Sale of Food and Drugs Acts, Conference on Methods of Analysis, Paris, 1910, and with foreign and colonial food legislation. Special inquiries were made in regard to the chemical treatment of flour, and the purity of baking-powders and self-raising flours, and reports dealing with these questions have been issued (*cf.* ANALYST, 1911, **36**, 254, 255). A report was also issued on the occurrence of parasitic nodules in meat exported from Australia (*cf.* ANALYST, 1911, **36**, 129). In order to deal more effectively with this condition in Australia, the Commonwealth Government have taken over the control of the inspection of meat for export, which was carried out previously by the various States. Several cases of illness attributed to the consumption of meat foods containing bacterial poisons occurred during the year; reference is made to the difficulty which is generally met with, of obtaining at a sufficiently early date information of the kind necessary for elucidating the causes of the poisoning.

Representations and reports received by the Board on matters relating to local administration of the Sale of Food and Drugs Acts entailed special inquiries or interviews. Particular notice is directed to the unsuitable procedure adopted in certain districts with regard to the taking of samples. Among other defects may be noted the practice of sampling officers asking for "new milk" when purchasing milk samples for analysis; this simply supplies a gratuitous warning to the vendor to be on his guard. The Sale of Milk Regulations refer to "milk," and the use of the term "new milk" is unnecessary.

Considerable attention has been given by local authorities to the question of lard and lard substitutes. Added water was reported to be present in a few of the samples of lard, and in each of these instances the lard was also found to be adulterated with foreign fat. One sample of "compounded lard," purchased in London, contained 17·8 per cent. of water.

All the samples of imported margarine taken by Customs officers during the year were examined for the presence of paraffin, and one sample imported from Holland was found to contain 3·4 per cent. of solid paraffin. Although the Board have no reason to consider that this form of adulteration is common, they would be glad to receive information as to the results, positive or negative, of any examination for the presence of paraffin which may be made by the public analyst when samples of margarine and lard are submitted to him.

Rules for the unification of the expression of analytical results, formulated by the International Conference, Paris, 1910, are printed in an addendum to the Report (*cf.* ANALYST, 1911, **36**, 536). W. P. S.

The Connecticut Agricultural Experiment Station. (Thirty-third and Thirty-fourth Reports, 1909 and 1910.)—This volume of over 800 pages forms Public Document No. 24 of the State of Connecticut, and is the biennial report for the two years ended October 31, 1910. Almost every department of agricultural activity is embraced, and the sections dealing with plant diseases and entomology are well provided with excellent illustrations and photographs. A very full report on commercial fertilisers, usefully classified, is followed by sections in which a total of 1,630 samples of foods and drugs are summarised, exactly 25 per cent. of these having been found to be adulterated or below stan ard. The methods of analysis employed in the examination of many of the materials dealt with are described. Illegal labelling and misbranding are carefully looked for, as they constitute offences against the State laws. An interesting report is that dealing with the analyses of some fifty named proprietary breakfast foods. It is curious to note that no single examination of coco or chocolate appears in the whole volume, and since the practice of adulterating cocoa with ground shell is known to exist, the omission is unfortunate.

Commercial feeding-stuffs are fully dealt with, useful tables being appended of their composition, digestibility, and price. A very full account of canned peas is a valuable feature in the present work; over 100 samples are described and analysed in detail. The American public, if they choose to avail themselves of reports like the present, are clearly afforded ample information as to the most satisfactory manufacturers to patronise for all the principal materials of domestic consumption, and the practice of publishing names in full should act as a strong inducement to sellers to provide a trustworthy and unadulterated article. H. F. E. H.

REVIEWS.

A TEXTBOOK OF PRACTICAL CHEMISTRY FOR TECHNICAL INSTITUTES. By A. E. DUNSTAN, D.Sc., Head of the Chemical Department, East Ham Technical College, and F. B. THOLE, B.Sc., Lecturer in Organic Chemistry, East Ham Technical College. Methuen and Co., Ltd. London, 1911. Price 3s. 6d.

The aim of this book is to give a concise account of the methods employed in the analysis and examination of both inorganic and organic compounds in a form suitable for a graded curriculum of instruction in analytical chemistry.

The first portion of the book is devoted to qualitative analysis, the reactions given being all based on the ionic hypothesis, a short and clear account of which precedes the reactions described. The succeeding section on volumetric analysis comprises the methods for preparing the ordinary standard solutions and their simpler applications. For the standardisation of potassium permanganate (p. 147) the use of sodium oxalate might have advantageously been included, as it is more reliable and accurate than either ferrous ammonium sulphate or oxalic acid, which are recommended. The third section of the book deals with the simpler methods of gravimetric analysis and the complete quantitative analysis of some mixtures and compounds. The selection of these is open to some criticism, but a fair choice is available, so that they can be adapted to the capacities of individual students. A reliable method for the separation of iron and manganese, such as the basic acetate method, should have been included, in preference to simply precipitating the iron in a mixture of the two substances, as hydroxide (p. 194), as the latter method can have no claim to accuracy, whilst the former is a really useful analytical method, and a good exercise in analytical procedure.

"Simple Gasometry" is the heading given to the succeeding section, which extends only to ten pages. Whilst one welcomes the inclusion of an outline of the methods employed in this important branch of analytical work in a book of this character, the selection of the apparatus described might have been more suitable. For instance, the use of Hempel pipettes is described in conjunction with the Lunge nitrometer; little additional space would have been required to include a description of the proper burette used for such estimations.

The remaining portions of the book deal with the tests for the elements in organic compounds and their quantitative estimation, some of the commoner organic estimations, familiar operations in organic chemistry—such as crystallisation, distillation, hydrolysis, nitration, etc.—and a chapter on the identification of simple organic substances. The concluding chapter is on physico-chemical determinations, and comprises methods for the determination of molecular weights, conductivity, velocity of reaction, and a description of the use of the polarimeter. The subject-matter included in these sections is carefully selected, and the accounts of the various processes are throughout clear and concise.

The total subject-matter included in the 329 pages of the volume is really remarkable, and its value is enhanced by several very useful tables and by the tabular descriptions of reactions included in the book. The writing is on the whole both careful and accurate, and but few misprints have been noted. Schrötter's carbonic acid apparatus is described as "the Schroedter apparatus" on p. 177, and phenolphthaleïn is written "phenolphthelein" on p. 156. Bearing further in mind the extremely moderate price at which the volume is published, it should prove both helpful and attractive to students in technical schools and institutes, for whom it is more especially written.

CHARLES A. KEANE.

LES MATIÈRES CELLULOSIQUES. By J. G. BELTZER and JULES PERSOZ. Librarie Polytechnique, Ch. Béranger. Paris, 1911. Price 5 francs.

This is a useful handbook, rather technological than strictly scientific, according, it would appear, to the purpose and intention of the authors.

It follows, perhaps too closely, the general plan and basis of classification of the well-known earlier textbooks, but introduces new matter of importance arising out of the investigations of the period 1895-1910. This matter, however, should have been more critically edited, and not reproduced *en bloc*. Thus a section on pp. 281-282, under "Dosage de la Cellulose de bois . . . équivalent d'hydrazine des fibres," describes the method of determining the absorption by fibrous products of phenylhydrazine from solution of the acetate, and of thus fixing a constant of these products, of presumably critical value. In a table of typical results we note the following for phenylhydrazine combining calculated to 100,000 of—

	Extreme Numbers.
Cottons	0·433 to 1·101
Flaxes	6·886 to 10·351
Jute	9·081 to 12·761

The authors introduce the method "pour servir à évaluer le degré de lignification," and the student would draw the conclusion that jute and flax are closely related *quâ* lignification!

There are other lapses which leave the critical reader in doubt as to the cause of confusion.

Thus on p. 292, under "Le Chanvre," Fig. 13, which is a section of a fibro-vascular bundle (monocotyledon), is described as of the hemp-stem, "tige de Chanvre," and representing a kidney-shaped complex of lignified fibres surrounded by parenchyma. The context suggests that only the true hemp (*Cannabis*) is under consideration, and a student would be much misled by this section (pp. 290-294). Of course, it is well known that the term "hemp" is loosely employed in commerce, being also applied to manila, phormium, sisal, etc., somewhat as "linen" is loosely applied, outside Belfast, to cotton and union goods. But the atmosphere of a textbook is supposed to be free from fog.

In the section on flax fibre the authors describe the fibre bundles as so compacted as to require an alkaline boiling for their separation. This description, apparently of only incidental moment, is a misdescription which obscures the entire practice of the flax-spinner.

We do not labour these points; they have to be noted in order to apprise the more critical student that he may be misled even by his teachers.

The second part of the volume, for which M. Persoz is responsible, deals with the analytical investigations of papers. It is in large part a reproduction of the methods adopted, and in part originated, by Herzberg. The author has lost an opportunity of a progressive contribution to the subject. Every practical worker is aware that our laboratory methods are extremely systematic and rapid, and an author, to command attention in his field, should show that his *experience* and knowledge are on the level of advanced practice.

In dealing with sizing agents, the author makes no mention of the chloramine reactions of the proteids. The reaction of the celluloses of the *Gramineæ* with anilin salts is mentioned as a recent discovery of M. Petitgout.

The examination of papers for reactions (acid or basic) is described (p. 423) in terms of the academic method of cutting the paper into strips, boiling with distilled water, and testing the extract with Congo red and litmus. This very important factor of the paper-makers' finish is usually diagnosed by rapid methods, and a gamut of indicators applied to the paper itself.

This section, however, would not appeal to English readers unless it could be commended as evidently progressive, which we are unable to do. On the whole the work is to be regarded as a useful *résumé* of scientific material which is in a condition of active growth. C. F. CROSS.

SOUDE-POTASSE SELS. By P. MÉKER. Collection des Manuels Pratiques d'Analyses Chimiques. Publiès sous la direction de MM. Bordas et Roux. Paris: Ch. Béranger. 1911. Pp. 245. Price 5 francs.

This small analytical textbook, written especially for the use of chemists engaged in the French Customs Department, consists of four separate parts. The first and second portions deal with the analytical methods employed in the analysis of the various sodium and potassium salts occurring in commerce. The methods described are generally of a satisfactory character, but, at the same time, do not present any novelty, and are already available in several English works. The third part is concerned with the analysis of brine, marine salt, and rock salt as imported, and with the analysis of the numerous salts which have been "denatured" in various ways in order to allow of their introduction into France for industrial and agricultural purposes at a lower rate of duty. The fourth section, occupying two-fifths of the book, consists of a reprint of the chief decrees and circulars of the French Customs Department.

Whilst the book will be a useful one to those for whom it is especially written, and also for those interested in the export of such salts to France, it is not one which will be of much use to chemists as a whole. H. G. COLMAN.

THE CHEMICAL WORLD. Edited by W. P. DREAPER. Published by Messrs. J. an A. Churchill. London. Price 6d. monthly.

What is likely to prove a popular addition to the growing literature devoted to chemistry is the *Chemical World*, the first number of which appears this month. As the additional title indicates, the new venture is to be "A monthly journal of chemistry and chemical engineering." To judge by the first issue, it may be fairly admitted that the new journal's claim to "fill a space in the scientific literature of this country which is not at present fully occupied" is justified, no other periodical of the kind covering such a wide field in the application of chemical knowledge. The Editor has succeeded in getting together a representative selection of writers, some twenty or more special articles being contributed by well-known chemists, each of whom is particularly well fitted to deal with his chosen subject. Thus, Dr. Russell presents a *résumé* of the recent work done at Rothamsted and elsewhere on sterilised soils, Dr. Harden treats of Progress in Biochemistry, Mr. G. T. Holloway sums up Metallurgical Progress in 1911, while many others, amongst them being Messrs. C. F. Cross, Revis and Bolton, Jago, and Drs. Kenneth Mees and S. Rideal, all contribute useful short papers upon branches of chemistry which they have made their own. Mr. Emil L. Hatschek's recent lectures at the Cass Institute on "Colloids" are being reprinted, and when completed in the *Chemical World* will be published as one of the *Chemical World* Series of text-books. A feature which should prove of general interest is an illustrated account of the Chemical Department of the Imperial College of Science and Technology, written by Dr. J. P. Philip. This is the first of a series dealing with the Chemical Departments of the Modern Universities. Several books are reviewed, among them being "Cocoa and Chocolate," by R. Whymper. One of the photomicrographic illustrations of this work has been reproduced, entitled "Pure Cocoa," but the only recognisable tissues are some particularly robust spiral vessels which are usually looked upon with suspicion when found in anything claiming to be "pure cocoa." A few misprints are to be found, "mycolderma" for "mycoderma," and "nito" for "nitro," but, speaking generally, the printing and illustrations are good.

H. F. E. HULTON.

INSTITUTE OF CHEMISTRY.

PASS LIST: JANUARY EXAMINATIONS, 1912.

OF twelve candidates who presented themselves for the Intermediate Examination, seven passed: R. M. Doidge, B.Sc. (Lond.), D. R. Frazer, S. G. Greene, G. S. Heaven, B.Sc. (Lond.), W. Honneyman, A. Wilson, and T. Wright. Of fifteen candidates who presented themselves for the Final Examination, eleven passed. In the branch of Mineral Chemistry: E. C. Evans, B.Sc. (Wales), H. W. Moss, A.R.C.Sc.I., and N. C. Nag, M.A. (Calcutta); in the branch of Organic Chemistry: D. Cardwell, B.Sc. (Manc.), H. Krall, B.A. (T.D.C.), F. H. Lees, and W. M. Roberts, B.Sc. (Manc.); in the branch of the Chemistry of Food and Drugs, and of Water: G. D. Elsdon, B.Sc. (Birm.), H. Hawley, M.Sc. (Birm.), R. L. Morris, and F. G. C. Walker.

ERRATUM.—1912, p. 4, footnote: "16·55 to 17·05" should read "165·5 to 170·5."

MARCH, 1912. Vol. XXXVII., No. 432.

THE ANALYST.

OBITUARY.

JOHN MUTER.

All active and energetic men, for whom the working hours are not long enough for the fulfilment of their duties, must feel with Renan that one of the most astonishing things in human life is its shortness. The thoughts span the bridge between youth and age; the road seemed so long, the real distance traversed is so little. It seems but yesterday since the writer of this notice attended, as a young man, in March, 1876, for the first time, a meeting of the Society of Public Analysts in Cannon Street Hotel. The cover of the first number of the Analyst was being shown by the Chairman, Wanklyn, to the members, and a paper was being read by Dr. John Muter on the analysis of butter. This was his first meeting with a man who, then already very well known, was one of the founders of the Society; one of the few who had some practical knowledge of the analysis of drugs and food, and from whom more could be learned than was contained in the then available books on the subjects interesting Public Analysts. Books, indeed, were few and feeble. There was Pereira on "Drugs" and Hassall on "Foods," both dealing mainly in generalities, and breaking down whenever one tried to dive below the surface of any subject. There was an anonymous work, "Death in the Pot," a sensational mixture of fancy with some facts, and a little book by Atcherley, with a collection of analyses of commercial articles, ranging from nuts to nightingales' dung. Knowledge, such as is now amply stored in the tables contained in "Koenig," or on the shelves that groan with the weight of thirty-six volumes of the Analyst and twenty volumes of the *Zeitschrift für Untersuchung der Nahrungsmittel* had not been born.

The little band of men who realised that the co-operation of all practical chemists was necessary in order to carry out the duties imposed upon them by the Sale of Food and Drugs Act that had been passed in 1875, and in the shaping of which they had taken an important share, comprised Dupré, Allen, Wigner, Muter, and Heisch, as the most active of the founders of the Society. The profession of Analytical Chemists was quite small; indeed, it is scarcely correct to speak of such a profession at that time. The lecturers at various hospitals, the professors at colleges and the Pharmaceutical Society, some medical men who had taken, as amateurs, to the microscope and the test-tube stand, formed the bulk of the Analytical Chemists in London. Wanklyn, a few years before, had written in the *Chemical News* epoch-making papers on the composition of milk; these had led to long and bitter controversy, which reverberated for years afterwards. The writer of this notice, with Arthur Angell, had published a pamphlet on a distinction between butter-fat and other fats, which had been promptly ridiculed by some of his experienced elders. At the meeting in Cannon Street in March, 1876, Muter had confirmed its correctness, and hinted that he had long been aware of these facts. It was not easy to grant to a mere boy that he might have ferreted out some knowledge that had escaped the attention of his elders.

In time all these little irritations and jealousies vanished in the common desire for the elucidation of facts, and John Muter became a friend with whom it was a pleasure to consult and co-operate.

John Muter came from a pharmaceutical stock. His father was Professor of Materia Medica in the Portland Street Medical School at Glasgow; his grandfather was the founder of the Glasgow Apothecaries' Company. John was born in Glasgow in 1841. He studied at the Andersonian University, Glasgow, at which the writer, a few years later, in 1873, was co-assistant to one of the lecturers with William Ramsay, who had just come, "promovirt," from Tübingen, and while Dr. Thorpe was professor. Muter became assistant to Dr. Penny. For a time he worked for Dr. Hassall, in which position he was later on succeeded by Alfred H. Allen and the writer, all unknown to each other. In 1872 he founded a laboratory of his own under the title "South London School of Pharmacy," after he had for some years earned a living as a peripatetic science lecturer. His school was mainly established in the first instance for the purpose of coaching pharmaceutical students for the minor examination, then a perfectly mechanical matter. Gradually his teaching developed into thorough and exhaustive courses, comprehensive and up-to-date, and a large number of students obtained from him effectual pharmaceutical training. For their use mainly he wrote a book on analytical chemistry, which ran through a number of editions. Many samples of drugs were sent to him for analysis, and even before the Food Acts had been passed he had founded a considerable chemical practice.

The Society of Public Analysts was formed while food legislation was being discussed before a Parliamentary Committee. In its formation Wigner and Muter bore the main share. The former was an able and most energetic organiser, the latter the more widely experienced practical chemist. Both were rather looked "down upon" by many of the "pure" chemists who then, more or less openly, despised the mere practitioner; indeed, often with good reason. Hence the Society at its start had by no means the good-will of chemists as a whole; difficulties of multitudinous kinds, scientific and otherwise, soon arose; the first President, Dr. Redwood, and several others, resigned; angry discussions and recriminations filled the air; but Wigner and Muter held on.

When the small and penniless Society started their Journal, after the *Chemical News* had hospitably for a year published the proceedings, they found that the names of responsible editors were necessary, to stand the brunt of eventual legal action. In the first year Wigner alone figured on the title-page as editor; from 1877 to Wigner's death, in 1884, Wigner and Muter jointly; and thence till 1891 Muter by himself. The Journal had really been started as the organ of the Society and its property, but, as there was no money, Wigner and Muter financed it and gradually became the *de facto* if not *de jure* owners.

It was far from easy at that time to conduct and fill a monthly journal mainly devoted to food analysis. No other society existed in the world similar to the Society of Public Analysts ; abstracts were not to be had except quite occasionally; original matter had to be created by a few, somehow. Almost every month the energetic secretaries of the Society sent urgent "whips" to a few active members, who, not then overburdened with the duties of their profession, but rather rich in unprofitable time, had ideas and energy and could work up new matter for the meetings. Dupré, Allen, Muter, Wigner, the writer, and one or two others, were the main stays of the young Society and its Journal. Thus, gradually systematic and scientific food analysis was evolved, full of weaknesses and faults of course, but yet infinitely better than anything previously available. Food legislation in other States of Europe and in America followed, and with it the co-operative work of an army of chemists, opening flood-gates of food analytical literature.

Dupré, as the first constitutional President of the Society, was followed in 1879 by Muter, who contributed a considerable number of papers on all sorts of practical subjects, many being of more or less ephemeral interest; others—like his papers on the separation of oleic acid from saturated fat-acids, his method for the estimation of glycerine, on the analysis of condensed milk—of more lasting value. He took an active and instructive share in the discussion of the papers read before the meetings, and his fund of merriment and jollity found full scope at the "informal" adjournments after the meetings at Burlington House, that were invented very early in the history of the Society by the present historian. None of the old members will forget the informal Annual Meetings, not then the serious, staid full-dress functions into which they have inevitably grown—the meetings at which Allen sang his own compositions, Sykes fiddled, John Newlands recited about Garibaldi, and Vieth and the writer duetted raucous German student songs, and Muter, by request, gave us "The Merry Little Fat Grey Man." All the jolly old meetings, getting dim in the mist of time. . . .

The fermentation among chemists that started with the birth of the Society led, in 1877, to the foundation of the Institute of Chemistry. Muter resolutely opposed this, for what were then good reasons. The founders of the Institute were largely academicians out of sympathy with the work and the aspirations of the chemical practitioners, as the years of unrest that followed in the Institute of Chemistry clearly proved. Yet gradually both the Society of Public Analysts and the Institute got over their turbulent boyhood years and grew into lusty adultness, supporting each other and raising a bounteous crop of facts and of men—a new vigorous profession that is a power in the land, a promise for the future of England. Muter in time became a fellow of the Institute and served as Censor from 1896-1898.

Muter's journalistic energies were gradually overwhelmed by his ever-growing responsibilities, and in 1891 the Society recognised that the Journal could no longer remain under the private guidance of its honoured Past-President. It was accordingly reacquired by the Society, and has since remained under the direction of the Publication Committee, which is directly responsible to the Council.

After that time the members saw little of Muter, whose school, converted into a limited liability company, required much of his energy. He also held the appointments of Public Analyst for Bermondsey, Lambeth, Newington, Rotherhithe, Southwark, and Wandsworth—in fact, for the greater part of South London—and for part of Lincolnshire. His private practice was extensive, and included the advisorship of public bodies like the Metropolitan Asylums Board.

He died on December 19, 1911, at Worthing. OTTO HEHNER.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE Annual General Meeting of the Society was held on Wednesday evening, February 7, in the Chemical Society's Rooms, Burlington House. The President, Mr. E. W. Voelcker, A.R.S.M., F.I.C., occupied the chair.

The minutes of the previous Annual General Meeting were read and confirmed.

Mr. J. H. B. Jenkins, F.I.C., and Dr. R. Lessing were appointed scrutators of the ballot papers for election of Officers and Council for 1912.

The HON. TREASURER presented the accounts of the Society for 1911. These were adopted, and votes of thanks passed to the Hon. Treasurer, Auditors, and Hon. Secretaries.

On the motion of the PRESIDENT, a vote of thanks was passed to the President and Council of the Chemical Society for allowing the Society the use of their rooms at Burlington House during the past year.

Mr. T. Macara, F.I.C., and Mr. R. G. Grimwood, F.I.C., were appointed Auditors of the Society's accounts for 1912.

The PRESIDENT having delivered his Annual Address,

On the motion of Mr. OTTO HEHNER, F.I.C., seconded by Mr. W. J. DIBDIN, F.I.C., a vote of thanks was accorded to the President for his Address and for his services in the chair.

The PRESIDENT briefly acknowledged the vote of thanks.

The scrutators having reported the result of their examination of the ballot papers,

The PRESIDENT announced the election of Officers and Council for 1912 as follows:

President.—L. Archbutt, F.I.C.

Past-Presidents (limited by the Society's Articles of Association to Eight in Number).—Edward J. Bevan, F.I.C.; Bernard Dyer, D.Sc., F.I.C.; Thomas Fairley, F.I.C.; W. W. Fisher, M.A., F.I.C.; Otto Hehner, F.I.C.; R. R. Tatlock, F.I.C.; E. W. Voelcker, A.R.S.M., F.I.C.; J. Augustus Voelcker, M.A., B.Sc., Ph.D., F.I.C.

Vice-Presidents.—W. H. Willcox, M.D., B.Sc., M.R.C.P., F.I.C.; Arthur R. Ling, F.I.C.; John E. Stead, F.R.S., F.I.C.

Hon. Treasurer.—H. Droop Richmond, F.I.C.

Hon. Secretaries.—A. Chaston Chapman, F.I.C.; P. A. Ellis Richards, F.I.C.

Other Members of Council.—E. Richards Bolton; R. M. Clark, B.Sc., F.I.C.; J. Connah, B.Sc., F.I.C.; J. Evans, F.I.C.; Charles A. Hill, B.Sc. F.I.C.; E. Hinks, B.Sc., F.I.C.; G. T. Holloway, A.R.C.Sc., F.I.C.; G. N. Huntly, B.Sc., A.R.C.Sc., F.I.C.; G. W. Monier-Williams, B.A., Ph.D., F.I.C.; F. Wallis Stoddard, F.I.C.; S. R. Trotman, M.A., F.I.C.; S. A. Woodhead, M.Sc., F.I.C.

The monthly meeting followed the annual general meeting, the newly elected President, Mr. Archbutt, being in the chair.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Mr. H. Hawley, M.Sc., and Miss M. Gazdar, B.Sc., A.I.C., were read for the second time; and certificates in favour of Messrs. Maurice E. Balston, M.A. (Cantab.), Buckland, Maidstone, analyst to Messrs. W. and R. Balston, paper manufacturers, Maidstone; Howard A. Caulkin, B.Sc. (Lond.), F.I.C., Mona Villa, Spencer Road, Belper, assistant chemist to the Midland Railway Company; and Charles Reginald Wilkins, B.Sc. (Lond.), 40, Church Lane, Hornsey, N., assistant to Messrs. Redwood and de Hailes, were read for the first time.

Messrs. S. G. Agar, G. S. Barton, S. W. Bridge, R. V. Briggs, F. C. Dyche-Teague, B.Sc., A.I.C., F. A. Mason, W. B. Saville, and G. A. Stokes, were elected members of the Society.

The following papers were read: "The Souring of Milk," by H. Droop Richmond, F.I.C., and H. C. Huish. "Notes on the Determination of Butter Fat and Cocoanut Oil in Margarine," by F. W. F. Arnaud, F.I.C., and H. Hawley, M.Sc.; and "A Flour Improver," by Edward Hinks, B.Sc., F.I.C.

* * * * *

ANNUAL ADDRESS OF THE RETIRING PRESIDENT.

(*Delivered at the Annual General Meeting, February* 7, 1912.)

THIS evening I have to address you for the last time as President of the Society, and, until comparatively recently, I was in hopes that I should be able to announce that during the year 1911 we had not lost any of our members by death. Unfortunately, these hopes have not been realised, and I have to record the death of three very old members of the Society—Mr. McCowan, Mr. Sanford, and Dr. Muter. Mr. McCowan was a life member, who invented a new method for the manufacture of caramel. Possessed of exceedingly wide knowledge, he was at once a practical brewer and an accomplished inorganic chemist, having devised several processes for dealing with ores. Mr. Sanford was a public analyst, who had devoted much of his work to the chemistry of explosives.

By the death of Dr. Muter, a link with the past history of the Society is severed. At the time of his death Dr. Muter was the senior Past-President of the Society, having held office in 1879-80. In 1877 he was, with the late Mr. Wigner, joint-editor of the ANALYST, and on the latter's death in 1884 he became the sole editor and proprietor until the year 1890, when the Journal passed into the hands of the Society itself. Although of late years he had not kept up any active participation in the affairs of the Society, his pioneer work will always gratefully remain in the memory of his colleagues. We hope to have an interesting memoir of him from the pen of one who was intimately associated with his work.

I am glad to say that we have lost only one member by resignation, while twenty-three new members have been added to our roll, and the election of eight other new members takes place this evening. This, although not a large increase, is a satisfactory one, and our total membership is now over 400. Although necessarily our membership is restricted, there are still a number of men in official positions and in professional work whom we would welcome into our ranks, and whose inclusion would be a source of strength. At no time than now was it more necessary that the profession of analytical and consulting chemists should be drawn together in a united effort to uphold and improve the position of its members, and to resist the attempts, which are all too prevalent, of reducing our profession to the level of a competitive trading business.

In my last address I referred to the lamentable results brought about by the insane competition for official positions under the Food Acts. I am glad to say there are signs that there is a better appreciation of the mischief that is done to the whole profession by analysts agreeing to undertake such responsible work at fees incompatible with its honest performance or with decent remuneration. No one, I submit, can seriously contend that the Public Analyst's remuneration is excessive, or even liberal. It is based largely on the objectionable principle that the holder of an appointment must be content with official "sprats," so that he may have the chance of catching remunerative "whales." As we all are too painfully aware, the fee mentioned in the Act, as chargeable to individual members of the public wishing to make use of the services of the Public Analyst, has in most cases come to be the maximum fee paid by Local Authorities, in spite of the fact that the advance of knowledge has been utilised by the "scientific adulterator" in such a way as to vastly increase the labour of detection of adulteration. Another very serious attack on the position of the Public Analyst and of the unofficial analyst is revealed by the action of some County Councils in establishing laboratories of their own, where analyses are carried out either gratuitously or at purely nominal fees. The system of County Authorities appointing a "whole-time" officer for carrying out the work required by them is one which, as I stated in my previous address, has "come to stay," and it cannot be denied that there is a good deal to be said in its favour if carried out on proper lines. But the establishment of a municipal or county laboratory at the expense of the ratepayer on the lines of a municipal trading concern is highly objectionable.

In the most recent case in point a County Authority has established a Bacteriological and Chemical Laboratory under the direction of the Medical Officer of Health, for the examination of waters and the solving of questions arising in connection with sanitary matters and food-supplies. This work had previously been carried out by the Public Analyst for the county, who is thus faced with a serious loss of his professional income.

We, as the society representing the Public Analysts of the country, have strenuously fought against the principle that the work of the Public Analyst can be properly merged in that of the Medical Officer of Health. The work of the latter officer ought to be *outside* the chemical laboratory, and his knowledge and training—save in rare instances—is utterly inadequate to make it desirable that he should have control of a chemical department. Unfortunately, in the past, the powers that be did not see things in this light, but the Local Government Board has now shown that it is in sympathy with our views; and, by refusing to confirm dual appointments, has done much to discourage a practice injurious alike to our professional and to the public interests. Not only in this country, but in our overseas dominions, is this question a serious one, for I understand that it is proposed to place the Government Chemical Laboratories of one of our dominions under the control of a Medical Officer, in spite of the fact that the work of the Department consists to a large extent of metallurgical and mineral investigations.

During the past session, thirty-five papers were read at the meetings of the Society, and these—with a few exceptions—have been published in the ANALYST. It is in connection with these few exceptions that I have a serious complaint to make. Last year I appealed to members to loyally support our Society by reading at our own meetings papers on subjects in which we were closely interested. It is impossible and unreasonable to expect that papers should always be read solely with the pure love of advancing knowledge and without any desire that some personal advantage should come to the author. A hard-and-fast line, however, must be drawn at papers read for the purposes of self-advertisement, or for trade purposes. In the cases to which I refer, papers were read at our meetings and simultaneously sent for publication to Trade Journals interested in pharmaceutical matters. We, as a Society, rightly object to be "exploited" in this way, and I trust that we shall have no repetition of it.

In referring to the question of advertisements, I am glad to say that I think there is a growing feeling that the practice which, in the past, has led to so much abuse—that of giving certificates for the purposes of trade advertisement—is one unworthy and discreditable to our profession. It is very necessary that the Public Analyst should be especially careful in the matter of the reports that he gives, for, not only is he liable to be exploited by the astute advertiser under circumstances which, one must admit, give some excuse for it, but he may—as a recent instance shows—be put in the position of being compelled to take legal action to prevent the unauthorised use of his name in advertisements, or else leave himself open to the suggestion that he has, for a consideration, allowed his name to be so used. I am very glad that one of our most prominent members has had the courage and the public spirit to take legal action in order to stop such proceedings. The position of a Public Analyst would be intolerable if the reports which he has to make in the course of his official duties were liable at any time to be utilised by the pushing advertising trader. I am afraid that in some cases Public Analysts are too easily cajoled into allowing their names to be used under the plea that the matter is one of great public and national importance, and that, by so doing, they are giving valuable assistance in the cause of the health and welfare of the nation. Such popular causes as the stamping out of the great white peril—consumption—have furnished an example of how a Public Analyst may be, no doubt unwillingly, associated with a most unpleasant and unsavoury suggested treatment for this disease. The great popular movement engineered by the Press in favour of "Standard Bread," and blessed in its inception by a manifesto signed by several distinguished medical men, is a very good example of the hollowness of most of these movements. They serve the purpose for which they are started, and bring grist to the mill of the enterprising advertisers and advertising agents.

Such questions as those of sophistication of flour, the composition of baking powders, and the alleged injury which has been done to the health of our working population by the use of "white" flour instead of "standard" flour, have been investigated in the laboratory of the Local Government Board, and interesting reports have been issued which have served to place these matters further on a sounder scientific basis, and they have done much to discount the alarmist, and, in a great measure, unfounded statements of the eminent medical authorities who have allowed themselves to be so exploited.

I must again congratulate our Honorary Treasurer on the very clear financial statement which he has laid before us, and upon the careful manner in which he husbands our resources.

It will be noticed that this year we have in our accounts the item "Legal Expenses." This is an item we never like to see if it is possible to avoid it, but this year the Council felt obliged to go to some expense in opposing an application which was made by the Royal Institute of Public Health to grant that Institute a Royal Charter. In the end the Privy Council did not advise the granting of the Charter.

There are two points in connection with our expenditure which will require attention in the near future. The first is that the growing increase in the cost of our Journal is every year greater than the increase in the income of the Society from the subscriptions of new members. Our policy has been—rightly, I think—to spend as much as possible on our Journal, consistent with maintaining a proper reserve of accumulated funds. The increase in our Journal is shown by the fact that the volume for 1911 contains forty-eight more pages than that for 1910. There have been 39 Papers, occupying 128 pages, and 817 Abstracts, Reviews and Reports, occupying 484 pages in all, as against 34 Papers and 662 Abstracts in 1910. It is an increasingly difficult task to wade through the enormous mass of scientific literature which steadily accumulates, month by month, and to successfully pick out for recording in the ANALYST, only that which is good, rejecting the indifferent and bad.

The Society will, I am sure, gratefully recognise the care and zeal which our Editor, Mr. Julian Baker, shows in keeping up and improving the high standard of our Journal.

Our Research Fund—which I am glad to see has received further financial support—is the means of providing valuable matter for our Journal, and some interesting investigations have been completed and the results published in the ANALYST during the past year, while a number of other investigations are still in hand.

The second point in future expenditure to which I would refer is in connection with secretarial work. To our honorary officers, and especially to our senior Hon. Secretary, Mr. Chapman, on whom the main part of the secretarial work has fallen, the Society owes a deep debt of gratitude for the time and labour which they have so constantly and ungrudgingly devoted, gratuituously, to the affairs of the Society.

When we were a smaller Society, it was possible to cope with the secretarial work without unreasonable expenditure of time and money, but now, when the mere routine work alone involves the sending out of over 400 notices every month, I feel very strongly that it is the duty of the Society to make provision to relieve our Hon. Secretaries of a burden which has involved them in considerable annual expense.

In the coming Session of Parliament two Bills, which will be of special interest to us, are to be introduced—one, the "Milk Bill," which the President of the Local Government Board will bring forward, the other, Lord Clinton's "Sales for Agricultural Purposes" Bill, which has already passed the House of Lords. With regard to the former, the President of the Board of Agriculture has quite recently indicated what he thought should be the guiding principles which should dominate the Bill. In the first place, no milk which was likely to breed disease should be sent into towns; that farmers should not be subject to prosecution for faults over which they had no control; and, lastly, that, if prosecutions took place, they should be civil and not criminal.

The President of the Board further stated that all that the consumer had a right to expect was that he should get pure milk as it comes from the cow. Unfortunately, the attitude of the Board as to standards for pure milk is eminently unsatisfactory, and, having in 1901 issued the "Sale of Milk Regulations," which fixed the standards, they appear now to be anxious to repudiate them. In the Annual Report for 1910 of the Intelligence Division of the Board of Agriculture it was stated that the Board did not require that milk should contain 3 per cent. of fat, and that, generally speaking, it was no offence against the Food and Drugs Acts to sell milk that falls below the limits mentioned in the "Sale of Milk Regulations." If this be so, what is the use of having any Milk Regulations at all? The Board have had a great deal of pressure put upon them, especially by farmers in the North-East of England, to lower the already very low standard which has been fixed, and no doubt this is the reason of the Board's action in the matter.

When one considers the labour that was expended in connection with the milk inquiry previous to the issue of the Sale of Milk Regulations, it seems incredible that the Board of Agriculture should countenance any lowering of the standard for Milk, a course of procedure which, while, no doubt, of benefit to the producers of inferior milk, would inflict a grave injury on the public in general. To suggest that everything should be regarded as "pure milk," simply because it was what the cow had yielded, is most dangerous.

The suggestion that prosecutions in the case of milk should be removed from the criminal courts, appeals in many cases to one's sense of fairness, but I cannot see why the milk producer alone should be exempted from the odium which attaches to an appearance as a defendant in a police court. Far too much stress is being laid upon the point that the regulation of the quality of a milk-supply is beyond the control of the producer, and, while admitting that, under certain circumstances, it may be a hardship for an honest producer to be summoned in a criminal court, it must not be forgotten that it is the duty of a man who produces milk for sale to see that it complies with the very moderate requirements at present laid down. By proper selection and treatment of his cows, there should be, generally speaking, no difficulty at all in the matter.

The "Sales for Agricultural Purposes" Bill introduces several alterations to the Fertilisers and Feeding Stuffs Act of 1906, among the principal ones being the abolition of the veto of the Board of Agriculture upon prosecutions, and the extension of the time during which samples may be taken and prosecutions instituted. The principal alteration affecting analysts under the Act is that further particulars are required to be given in the invoices of articles sold for use as food for cattle or poultry. Under the proposed new Act it is suggested that the percentage of "soluble carbohydrates" shall always be stated. I think it should be pointed out that the figure for the percentage of soluble carbohydrates is only a difference item, and, to arrive at it, it is necessary to quantitatively determine five other classes of bodies in every sample examined, whereas at present the determination of two only is required in samples submitted under the Act. This should certainly call for the revision of the fees which are at present deemed to be adequate remuneration to the analyst by some of the local authorities in the kingdom. The whole tendency of the action of the authorities administrating both the "Sale of Food" and "Fertilisers and Feeding Stuffs" Acts has been to throw an increasing burden upon analysts, and even in the matter of the quarterly returns that have to be made to the Local Government Board and the Board of Agriculture additional information is constantly being required. In cases where preservatives are found in any article of food, the exact percentage is constantly asked for, and where samples of milk have been reported on as falling below the limits of the Sale of Milk Regulations, detailed particulars of the analysis are demanded.

While we are ready to place all information at our disposal in the hands of the authorities, I think it would be only fair that proper recognition should be given to the increased work which is now thrown on the Public Analyst.

With regard to the question of preservatives, I would only say that it seems extraordinary that legal effect has not yet been given to the recommendations of the Committee on Preservatives, and which were reported no less than eleven years ago. It is to be hoped that ere long a serious attempt to place our Food Acts on a really satisfactory basis will be carried out by the Government.

The proceedings of the Congress which was held in 1910 in Paris, at which we were represented by our Hon. Secretary, Mr. Chapman, have been published recently in the ANALYST, and I understand that, in all probability, a further Conference to discuss the question of the Uniformity of Methods of Analysis of Foodstuffs will be held.

I have now to relinquish this chair, and, in introducing my successor, Mr. Archbutt, I heartily congratulate the Society upon having secured the services of one who has been so long closely associated with and interested in our affairs. Mr. Archbutt is, as you all know, a distinguished chemist, with a very wide field of knowledge and experience. As chemist to one of our great railway companies, he has distinguished himself by many important investigations on subjects of vast industrial importance, and, incidentally, although he is not a Public Analyst, his services have been largely requisitioned in connection with work which belongs to this branch of the profession. Mr. Archbutt has the distinction of being the first President of this Society who has, I believe, never held the post of Public Analyst, and I think that it was a very happy suggestion that the gradual enlargement of our horizon—which a few years ago resulted in our incorporation as a Society which embraced all branches of the analytical profession—should now be marked by the election of Mr. Archbutt to the presidential chair.

I now come to the most difficult part of my address, and that is to adequately express to you how deeply I appreciate the honour that has been conferred upon me in placing me in this chair for two years. I vacate it with the greatest possible regret, but I shall always look back with pleasure on the period that I was permitted to occupy it. From the general body of members I have received nothing but kindness, and I cannot sufficiently thank my colleagues on the Council—and especially the honorary officers—for their help and support always cordially given me.

Though relegated to the list of "have beens," I shall always continue to carry out what has been my great object throughout my official connection with the Society—that is, to do everything I can to promote the welfare and position of the Society and of our profession.

THE ESTIMATION OF SMALL QUANTITIES OF ESSENTIAL OILS IN SPICES, ETC. PART II.

BY J. A. BROWN, F.I.C.

(*Read at the Meeting, December* 6, 1911.)

IN a previous paper (ANALYST, 1910, **34**, 392) I described a dry-distillation-combustion process for estimating the essential oils in carraway and cinnamon spices. The method has now been applied to some other essential oils with the following results:

	Carbon Value.	Temperature of Volatilisation.	Average Time of Experiment.	Correction.	Essential Oil in Spice.
					Per Cent.
Coriander ...	75	140° C.	½ hour.	None.	—
Cardamom ...	73	140° C.	½ „	„	1·02
Rosemary ...	79·5	140° C.	½ „	„	0·60
Eucalyptus ...	74 73 } 73 72	140° C.	¾ „	„	1·40
Aniseed ...	77	150° C.	1 hour.	Deduct 0·1 per cent. oil for every ½ hour's heating.	{1·00 {2·20
Bay	76	150° C.	½ „	Deduct 0·1 per cent. oil for every ½ hour's heating.	0·75
Juniper ...	83·5	150° C.	¾ hour.	Add one-sixth oil found, and deduct 0·15 per cent. for ¾ hour's heating.	1·30
Cedar... ...	83 84 } 83·5	160° C.	¾ hour.	Add one-eighth oil found, and deduct 0·25 per cent. for ¾ hour's heating.	2·85
Santalwood ...	82	160° C.	—	Add one-sixth oil found.	—
Origani ...	79·5	—	—	—	—
Black pepper	85	—	—	—	—
Pimento ...	73	—	—	—	—

EUCALYPTUS.—In the case of three oils from different sources the carbon values were obtained lower than would be expected on theoretical grounds supposing the composition to be mainly terpenes and eucalyptol. The third result given was from a sample of oil guaranteed to be from *Eucalyptus globulus*.

ANISEED and BAY require a deduction to be made from the percentage of oil found, to allow for a slight amount of destructive distillation. When spices have to be heated above 140° C. to volatilise the essential oil, a small allowance has to be made for destructive distillation. Santalwood appears to be the only exception.

CEDAR, JUNIPER, and SANTALWOOD, containing more difficultly volatile oils, require a temperature of 150° to 160° C. There is a tendency to resinify under the conditions of the process. Thus, oil of cedar showed unburnt residues of 12·6 and 13 per cent., and santalwood 16 per cent.

Juniper berries showed a similarity to carraway-seed (*loc. cit.*) in that, after drying at 100° C. until constant in weight, further oil—viz., 0·50 and 0·72 per cent.—was obtained on combustion. A sample of spent berries supplied to me by a distiller gave 0·15 per cent., which proves the comparative inefficiency of ordinary laboratory methods compared to those of the distiller who uses superheated steam.

GINGER.—After repeated trials, the method had to be abandoned, owing to the ease with which this oil resinified.

It is hoped to apply the process to the estimation of nicotine in tobacco and oil of mustard in mustard. I have to thank Messrs. Stafford, Allen and Sons, and Mr. J. C. Umney for supplying me with samples of oils, etc., and also Dr. Woollatt for help and advice.

DISCUSSION.

Mr. E. J. PARRY considered that this method was open to criticism, on account of the large variations which occurred in the constituents of many essential oils. For instance, in the eucalyptus oil of the British Pharmacopœia, the proportion of eucalyptol was liable to vary at different times. There was rarely less than 50 per cent., but most of the genuine oil of the present year contained 75 or 80 per cent. About thirty constituents had been isolated from various eucalyptus oils. The terpenes would contain about 88 or 89 per cent. of carbon, and the less oxygenated constituents from 78 to 80 per cent., so that one might have 75 to 80 per cent. of eucalyptol with a carbon value of 88 or 89 per cent., and the remainder with a carbon value varying from 78 or 79 to 88 or 89 per cent. The result was that a carbon figure of, say, 72, 73 or 74 might mean almost anything. The position was exactly the same with regard to bay oil, rosemary oil, and many others.

Mr. A. CHASTON CHAPMAN remarked that Mr. Brown's process was in reality one for determining certain volatile constituents of spices—not necessarily the actual proportion of essential oils present. Bay oil, for example, to which allusion had been made, underwent considerable resinification on exposure to air, and this would, of course, very considerably diminish the proportion of volatile constituents obtained by the process. There could be no doubt that for certain purposes the method was a very useful one, but it seemed to him (Mr. Chapman) that it would be very dangerous to attempt to put it forward as a general method for distinguishing between genuine and exhausted spices, since there might be little or no difference between an exhausted sample and a sample in which a considerable proportion of the constituents of the essential oil had become converted into non-volatile matters by exposure to the air.

Mr. C. A. Hill remarked that to speak of "eucalyptus oil" was not definite, and drew attention to the variation in the proportion of eucalyptol. In Tasmanian (globulous) oil it was usually from 55 to 60 per cent., whilst in Australian oil it was often as much as 80 per cent.

Mr. H. E. Burgess said that he had found that, by extracting the spice with petroleum ether, and determining the refractive index, a very good indication was obtained of the quantity of essential oil present. All analytical methods for this purpose were, however, liable to such errors as had been mentioned, and probably the only way in which a true indication of the percentage of essential oil could be obtained was by actually distilling a considerable quantity under manufacturing conditions.

The Chairman (Mr. Ling) remarked that from the discussion it appeared that the weak point in the method was the application of a constant factor derived from what was supposed to be a typical oil to an extract that varied in composition according to the age of the spice. He should like to ask if Mr. Brown had tried heating the spice under reduced pressure. In this way resinification might to some extent be prevented.

Mr. Brown said that he had found combustion under reduced pressure to be of very little advantage—not sufficient to compensate for the additional trouble and difficulty of manipulation which it involved. With regard to Mr. Parry's remarks, he would point out that the estimations in the spices were made under exactly the same conditions under which the carbon figures were obtained, so that whatever error there might be would be the same in each case. As he had mentioned in the previous paper (Analyst, 1910, **34**, 392), the carbon figure did not seem to be affected to any great extent by variations in the proportions of the different constituents of the oil, and, in cases in which the proportion of essential oil was small, such differences would, he thought, not be material. Of course, however, it was not suggested that the method gave more than a fairly close approximation to the truth.

A FLOUR IMPROVER.

By E. HINKS, B.Sc., F.I.C.

(*Read at the Meeting, February* 1, 1912.)

An article forming a recent addition to the number of substances sold as flour improvers consists of potassium persulphate. According to the directions it is to be added to flour in the proportion of from ½ to 1 ounce to the sack of flour—*i.e.*, about 1 of persulphate to from 10,000 to 5,000 parts of flour. The dry persulphate is simply mixed with the flour.

It is claimed that by such treatment stronger loaves and loaves of better colour are obtained, more water can be absorbed in the doughing process, and, further, that the only residuum in the loaf as a result of the treatment is a minute proportion of a harmless salt, which is a normal constituent of wheat and of many drinking waters.

The presence of persulphate in the flour may be readily detected by the reaction with benzidine (Rothenfusser, ANALYST, 1909, **34**, 37). An alcoholic solution of benzidine gives a blue colour with extremely dilute solutions of persulphate, the limit of delicacy being 1 part in about 1,000,000 parts of water; but on applying this test to aqueous extracts of flour the reaction is much less delicate, and an extract of flour containing 1 part of persulphate in 5,000 parts of flour (the greater strength recommended), fails to give the reaction. Much smaller quantities than this, however, may be detected by making a paste of the flour with a small quantity of water and at once pouring the benzidine solution over the paste. The benzidine picks out the particles of persulphate and develops the blue colour round each particle. By proceeding in this manner, flour containing persulphate in the proportion as recommended gives strong reactions, and the limit of delicacy depends practically only on the quantity of the flour taken. With laboratory preparations carefully mixed and sieved, 5 to 10 grms. of flour with 1 of persulphate to 100,000 will, as a rule, show the reaction. A convenient benzidine reagent is a 2 to 3 per cent. alcoholic solution.

Mixtures of persulphate with flour gave the reaction with no apparent diminution of intensity after standing for three months.

The persulphate may be separated from the flour by suspending in carbon tetrachloride and centrifugal action, the benzidine being applied to an aqueous solution of the deposit. Further, the salt can be quantitatively determined by centrifugalising the suspension of flour in carbon tetrachloride, treating the deposits with small quantities of water and again centrifugalising or filtering to remove small quantities of flour unavoidably left in the tubes, warming with potassium iodide and titrating with thiosulphate in the usual manner.

In the process of baking the persulphate would appear to be entirely destroyed. Loaves were made from several mixtures, but even when the persulphate was present to the extent of 1 to 500 of flour, no benzidine reaction could be obtained on treatment of the finished loaf.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Estimation of Bitter Principles in Wort and Beer. Neumann. (*Wochensch. Brau.*, 1912, **29**, 31-36.)—Wiegmann (*Allg. Brauer- u. Hopfenzeit.*, 1911) has described a method for extracting the bitter resins from hopped worts and beer. The difficulty with the usual solvents of low boiling-point lies in the formation of emulsions which do not separate completely. Wiegmann therefore recommends the use of petroleum spirit of sp. gr. 0·7350, so that the emulsion which tends to be formed may be destroyed by heating subsequently in a water-bath at 80° to 85° C.; 500 c.c. of the wort are shaken with 100 c.c. of petroleum spirit, and transferred to an Erlenmeyer flask of 1 litre capacity, which is placed in the water-bath. The flask is connected with a condenser, by means of a short piece of rubber tubing, in such a way that the contents of the flask can be shaken vigorously in the water-bath until the emulsion is destroyed. The liquid is then poured carefully into a separating funnel, the wort is removed, the petroleum spirit is washed, filtered, treated with alcohol, and the dissolved bitter principles are titrated with alcoholic potassium hydroxide. Some beers give trouble even under the above conditions, but emulsions can generally be prevented if the sample be first boiled with 1 to 2 per cent. of phosphoric acid (sp. gr. 1·12) for about fifteen minutes under a reflux condenser.

The author describes a simpler method than that recommended by Wiegmann for overcoming the emulsion difficulty. Ether is used as the extracting solvent, and the difficulty is overcome by employing an unusually large proportion of ether, and extracting the beer in small portions at a time. Fifty or 100 c.c. of flat beer are shaken with five times their volume of ether in a long-shaped separating funnel, preferably in a shaking machine. After drawing off the extracted beer, a further quantity of 50 or 100 c.c. of the beer are treated with the same lot of ether, and so on until the whole of the sample has been exhausted. No difficulty in separating is experienced, even with dark beers.

J. F. B.

Estimation of Benzoic Acid in Margarine, Butter, and other Fats. W. Friese. (*Pharm. Zentralhalle*, 1911, **52**, 1201-1203; through *Chem. Zentralbl.*, 1912, **1**, 96.)—One hundred grms. of the sample are thoroughly mixed with 25 c.c. of 20 per cent. sodium carbonate solution, and heated on the water-bath until a milky fluid separates beneath the fat. The beaker is then cooled in an ice chest, and the layer of fat removed and washed repeatedly with ice water. The aqueous layer and washings, which will contain all the benzoic acid as sodium benzoate, are treated, without filtration and in the cold, with 40 c.c. of 10 per cent. barium chloride solution, which will precipitate barium salts of the saponified fat and barium carbonate. The liquid is filtered, and the filtrate freed from barium by means of sulphuric acid and again filtered. The new filtrate is twice extracted with ether in a separating funnel, the united ethereal extracts washed with water and dried over calcium chloride, the solvent evaporated by means of a current of air, and the residue dried in a desiccator and weighed. C. A. M.

Estimation of Camphor. H. C. Fuller. (U.S. Department of Agriculture, Circular No. 77, Bureau Chem.; through *Amer. J. Pharm.*, 1912, **84**, 40-41.)—The author employs the camphoroxime method for determining camphor in its preparations, and the following outline illustrates its application to spirit of camphor: Exactly 35 c.c. of a hydroxylamine solution (containing 20 grms. hydroxylamine hydrochloride, 30 c.c. water and 125 c.c. of aldehyde-free absolute alcohol) are added to a mixture of 25 c.c. of the sample with 2 grms. of sodium bicarbonate, and the whole gently boiled for two hours under a reflux condenser. On cooling, 6 c.c. of hydrochloric acid (sp. gr. 1·12) and 6 c.c. of water are added, the condenser and flask washed out, the liquid diluted to 500 c.c., and filtered. Fifty c.c. of the filtrate are neutralised with alkali to methyl-orange (mineral acid), when phenolphthaleïn is added and the excess of hydroxylamine titrated with $\frac{N}{10}$ alkali. A blank experiment, using 35 c.c. hydroxylamine solution and 25 c.c. alcohol, is made, and the difference in the titrations noted. Each c.c. of $\frac{N}{10}$ alkali$=$0·01509 grm. camphor.

A. R. T.

Estimation of Cinnamein in Peru Balsam. F. Lehmann and A. Müller. (*Arch. Pharm.*, 1912, **250**, 1-5.)—The method of estimating cinnamein described in the German Pharmacopœia is shown to be inaccurate owing to no account being taken of the increase in volume in the ether used for the extraction. This may cause an error of more than 1 per cent. in the estimation. The following process based on those employed by Fromme and by Stocker is recommended as accurate and rapid. The use of so large a quantity of tragacanth as 3 grms. (Fromme) is unnecessary, provided that the bulk of the water be first drawn off, leaving only a small residue to be absorbed. Two and a half grms. of the Peru balsam are shaken with 5 c.c. of water in a stoppered 75 c.c. flask, after which 30 grms. of ether are added, and the shaking continued for one minute. An addition of 5 grms. of sodium hydroxide solution is now made, and the flask once more shaken for one minute and allowed to stand for ten minutes. It is next inverted, the stopper partially withdrawn, and the aqueous layer drawn off down to about 3 c.c., after which 0·5 grm. of gum tragacanth is introduced, and the whole thoroughly shaken and allowed to stand for three to five minutes. The bulk of the ethereal layer (25 to 28 grms.) is now decanted into a wide-mouthed tared flask, which is immediately covered and weighed. The ether is evaporated on the water-bath, and the viscous residue of cinnamein dried for thirty to forty-five minutes at 100° C., cooled in a desiccator, and weighed. C. A. M.

Detection of Cocoanut Oil in Butter and Lard. E. Polenske. (*Arbeit. Kaiserl. Gesundheitsamte*, 1911, **38**, 402-414.)—The results of a critical examination of the methods proposed by Ewers (*cf.* ANALYST, 1910, **35**, 353) and Fendler (*ibid.*, 1910, **35**, 354) are recorded. Genuine butters of known origin were employed in the experiments, and it was found that the methods mentioned cannot be relied on for the purpose of detecting the presence of cocoanut oil in butter fat. As regards

Ewers' method, butter fats having Reichert-Meissl values of from 29·9 to 31·2 yielded "difference values" varying from 8·5 to 8·8; other samples, also having high Reichert-Meissl values, gave "difference values" of from 13 to 14, and these samples could be adulterated with 10 per cent. of cocoanut oil and still show "difference values" above the minimum limit of 9 fixed by Ewers.

Fendler's alcohol method (*loc. cit.*), when applied to genuine butters, yielded values varying from 28·7 to 31, whilst several butters gave from 9 to 11 c.c. of ethyl esters when examined by the ester method (*loc. cit.*).

The Polenske value of the butters used in the above investigation were normal, and showed that this method is trustworthy; further evidence is adduced that the method is also reliable for the detection of cocoanut in lard. W. P. S.

Fruit Juice Statistics for the Year 1911. A. Behre and K. Frerichs. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 733-736.)—Juices prepared from fermented fruit and examined during the year yielded the following results: *Strawberry juice* (5 samples): alcohol, 0·44—2·39; total solids, 3·49—4·78; acidity (as malic acid), 1·19—1·75; ash, 0·37—0·52. *Raspberry juice* (5 samples): alcohol, 0·30—2·26; total solids, 7·06—9·61; acidity, 3·35—4·32; ash, 0·75—0·89. *Currant juice* (6 samples): alcohol, 0—2·32; total solids, 5·73—6·74; acidity, 2·76—3·79; ash, 0·61—0·74. *Pine-apple juice* (4 samples): alcohol, 0—0·53; total solids, 7·08—16·28; acidity (as citric acid) 0·60—1·28; ash, 0·35—0·67; invert sugar, 4·03—7·15; sucrose, 0—8·33. The above figures express grms. per 100 c.c. As regards the pine-apple juices, two of the samples were unfermented, and two slightly fermented; the sucrose was completely inverted in the fermented samples. Two of the samples of currant juice yielded a positive reaction with Windisch's test for cherry juice (*cf.* ANALYST, 1902, **27**, 10); the coloration obtained was very slight, and the authors are unable to explain why the juice should contain hydrocyanic acid. W. P. S.

Occurrence of Arsenic in Gelatin. O. Köpke. (*Arbeit. Kaiserl. Gesundheitsamte*, 1911, **38**, 290-293.)—Of twelve samples of commercial gelatin examined by the author, no less than eight contained appreciable quantities of arsenic, the amounts varying from 0·05 mgrm. to 0·3 mgrm. per 10 grms. of the sample. The remaining four samples also contained arsenic, but the quantity was a mere trace. With regard to the origin of the arsenic, it is pointed out that gelatin is prepared from hide and leather residues, the hides having been treated with lime and arsenical preparations, or from bones which have been extracted with impure mineral acids, etc.; gelatin is also bleached with sulphurous acid, which is not always free from arsenic. W. P. S.

Estimation of Gum in Syrups. A. C. Chauvin. (*Ann. Falsif.*, 1912, **5**, 27-30.)—The usual method for the estimation of gum by precipitation with an alcoholic solution of lead acetate gives satisfactory results when certain precautions are observed. The author, however, prefers to precipitate the gum-acid by means of alcoholic hydrochloric acid. For instance: 5 c.c. of the solution are treated with 5 c.c. of hydrochloric acid, 5 c.c. of water, and 85 c.c. of 100 per cent. alcohol. It is particularly important to add the reagents, both acid and alcohol, in a rapid stream of drops, but not as a continuous jet, and to keep up a rotatory movement of the gum solution whilst these are being added. The precipitate is filtered off, washed with 95 per cent. alcohol, dried and weighed, and the dry weight is increased by the percentage of ash and moisture in the variety of gum present, or alternatively by 16·1 per cent., representing average values of 2·4 per cent. for ash and 13·7 per cent. for moisture. The quantity of sugar present does not interfere with the results provided the precipitate has been thoroughly washed, but pure aqueous solutions of gum nearly always give more accurate results. Ten per cent. solutions of gum generally show slightly low results, whilst 20 per cent. solutions show values ranging from 19 to 21 per cent. J. F. B.

Mutarotation of Honey. L. Rosenthaler. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 644-647.)—In order to determine the mutarotation of honey, 10 grms. of the sample were dissolved in water, with the addition of alumina cream, made up to 100 c.c., and the solution filtered. The solution of the filtrate was then observed in a 200 mm. tube fifteen minutes after the water has been added. Another similar solution was prepared and treated with ammonia gas, the solution being observed at the end of thirty minutes. The difference between the first rotation, *a*, and the second, *e*, gives the mutarotation, *m*. For purposes of comparison, the latter value may be calculated into the specific mutarotation—$[m] = \frac{100\,m}{l \times c}$, where *l* is the length of the tube and *c* the total solids of the honey solution. As the result of the examination of forty-one samples of honey, it was found that for normal honey the value *m* varied from 0·12 to 2·60, and that of [*m*] from 0·71 to 15·47. All the samples of honey which had become solid (grained) exhibited a high mutarotation, and, assuming that dextrose exists in two modifications, it appears that crystallisation is accompanied by a change of the less optically active modification into the more strongly rotatory modification. Invert sugar showed a specific mutarotation of 15·08, whilst the value in the case of two samples of starch syrup observed was 1·20 and 2·60, respectively. W. P. S.

Estimation of Mustard Oils in Oil-Cakes and Mustard Flours. C. Brioux. (*Ann. chim. anal.*, 1912, **17**, 3-9.)—In the author's experience the method of oxidising the essential oils with bromine and estimating the sulphuric acid produced is unreliable, the oxidation being only partial. The method based upon the decomposition of the essential oil by means of silver nitrate is more accurate, but the modification prescribed by the French Codex gives results about 10 per cent. too low. The following method of estimation is suggested: A mixture of 25 grms. of the finely ground oil-cake with 500 c.c. of water at about 37° C., and 2 grms. of sodium fluoride (previously dissolved in a little water) as an antiseptic, is kept for an hour in a water-bath at 37° to 40° C., the closed flask being shaken from time to time. In the case of certain foreign oil-cakes or of mustard flour, it is necessary to continue the maceration for three or four hours, or longer. After the enzymic action is complete, 20 to 25 c.c. of 95 per cent. alcohol are added, the contents of the flask distilled, and 150 c.c. of the distillate collected in a 250 c.c. flask containing 10 c.c. of concentrated ammonia solution. From 25 to 50 c.c. of $\frac{N}{10}$ silver nitrate solution (according to the probable quantity of essential oil) are now added, and the flask heated for an hour beneath a reflux condenser, on a water-bath at 80° to 85° C., after which the liquid is made up to 250 c.c. and filtered. An aliquot portion (125 c.c.) of the filtrate is acidified with 10 c.c. of strong nitric acid, and treated with 10 c.c. of a 10 per cent. solution of iron ammonium sulphate, and the residual silver titrated with $\frac{N}{10}$ ammonium thiocyanate solution. In the case of colza or rape-seed oil-cakes the essential oil consists of crotonyl thiocyanate, whilst in the case of black mustard-seed oil-cake or flour, the oil is allyl isothiocyanate. The distillate from Indian colza oil-cakes usually contains a mixture of the two essential oils, since the oil-cakes are composed of mixtures in varying proportions of *Brassica glauca*, *B. dichotoma*, *B. ramosa* and *B. campestris* with more or less *B. juncea* (Sarepta mustard). Of these seeds only *B. juncea* yields allyl thiocyanate, whilst the others produce crotonyl thiocyanate. Indian colza oil-cakes containing too great a proportion of the seed of *B. juncea* or *B. nigra* are thus dangerous to cattle. Apart from a microscopical examination, it is possible to make an approximate estimation of the amount of these seeds from the relative proportions of the two essential oils. For this purpose the liquid, after completion of enzymic action, is distilled without the addition of alcohol, and the distillate collected in the absence of ammonia. Crotonyl thiocyanate (sp. gr. 0·984) will then collect upon the surface of the liquid, whilst allyl thiocyanate (sp. gr. 1·028) will form a layer at the bottom. As a rule the temperatures employed in modern oil-factories are too low to inhibit completely the activity of the myrosin. French colza and rape-seed may yield from 0·150 to 0·250 per cent. of crotonyl thiocyanate, and their oil-cakes generally give from 0·20 to 0·35 per cent. In Danubian colza oil-cakes the author has obtained by the method described from 0·50 to 0·70 per cent. of essential oil, whilst Indian colza oil-cakes have yielded from 0·640 to 0·858 per cent. calculated as crotonyl thiocyanate, but generally containing a certain proportion of allyl thiocyanate. C. A. M.

Wine Statistics for the Year 1909-1910. A. Gunther. (*Arbeit. Kaiserl. Gesundheitsamte*, 1911, **39**, 1-470.)—The results of the analyses of 802 samples of wine and 3,991 samples of must are recorded in the present report, the samples being classified for the different vine-growing districts. As in previous reports (*cf.* ANALYST, 1910, **35**, 64, 526), the proceedings of the Official Commission on Wine Statistics are given. The variation in acidity of wine during storage has been further investigated, and experiments have been carried out regarding fermentation in the presence of ammonium compounds, the alteration undergone by wine solids during drying, the effect of neutralising or diminishing the acidity of wine by the addition of calcium carbonate, etc. With respect to the use of nicotine solutions as insecticides on vines, one investigator states that nicotine cannot be detected, either chemically or by the taste, in wine made from vines so treated, whilst another reports that nicotine could be tasted distinctly in wine made two weeks after the vines had been sprayed. The iodometric method described by Zeissl and Fanto (*cf.* ANALYST, 1909, **34**, 399) for the estimation of glycerol in wine was found to yield trustworthy results. The presence of large quantities of sugar was without influence on the results except that mannose, when present, caused the figures to be too high. The ordinary lime method gave low results when applied to wines containing much sugar, only about 75 per cent. of the glycerol present being obtained. W. P. S.

Composition of Guadaloupe Rum. J. Sanarens. (*Ann. Falsif.*, 1911, **4**, 642-644.)—The following results were obtained on the analysis of three samples of rum imported into France from Guadaloupe. The samples were taken as the spirit was discharged from the vessel, and the figures express parts per 100,000 of absolute alcohol. The maximum and minimum limits fixed by the French authorities for this class of spirit are also given:

	No. 1.	No. 2.	No. 3.	Limits.	
				Minimum.	Maximum.
Volatile acids ...	71·25	67·90	42·78	—	—
Total acids ...	148·99	140·93	77·79	80	150
Aldehydes... ...	13·92	20·13	14·58	15	30
Esters	47·14	67·78	64·82	50	140
Higher alcohols ...	100·67	92·28	120·09	120	200
Furfural	1·17	1·84	0·64	1	3
Total ...	311·89	322·96	277·92	300	450

W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Amyloclastic Secretory Capacities of the Embryo and Aleurone Layer of Hordeum. F. Stoward. (*Ann. Bot.*, 1911, **25**, 799-841, 1147-1204.)—A North African and a brewing Chilian barley were used in this investigation, the seeds being sterilised either with 10 per cent. copper sulphate solution or absolute alcohol prior to dissection. The medium which served as the basis of the culture experiments, and to which were added as required gelatin, sugars, agar, asparagine, etc., had the following composition per 100 c.c. of solution: Calcium sulphate 0·1 grm., potassium chloride 0·25 grm., magnesium sulphate 0·25 grm., potassium dihydrogen phosphate 0·025 grm., and 2 drops of $\frac{N}{5}$ ferric chloride to the litre. The enzyme activity is expressed in terms of mgrms. of copper per twenty objects per hour, "objects" being either inner endosperms, embryos, or aleurone layers, and the copper being that obtained from Fehling's solution as the result of the action of reducing sugar formed from starch during the experiment. The copper reductions were for the most part carried out by Bertrand's method (*Bull. Soc. Chim.*, 1906, **35**, 1285).

A large number of digestions under varying conditions are described, designed to throw light on the amylase secretory capacity of the barleycorn, the following being some of the principal conclusions deduced:

Both embryos and aleurone layers possess an amylo and a cytoclastic secretory function. These secretory functions are completely arrested and annulled when these objects are subjected to the action of anæsthetic reagents such as chloroform and nitrobenzene. This result, in the case of the aleurone layer, is regarded as evidence that this tissue possesses vitality.

The inner endosperm, under varying conditions of experiment described, possesses the capacity of augmenting its amylase content, not however by secretion, a function that the amyliferous cells do not possess. In contradistinction to the secretory capacities of the embryo and aleurone layer, the augmentation of amylase is not arrested or diminished by the action of chloroform or nitrobenzene. This latter fact is taken to signify that (1) the inner endosperm represents a mass of non-living tissue, and that (2) its behaviour under the conditions described is such as a dead mass of enzyme-containing tissue would exhibit.

Isolated endosperms possess the capacity of inducing complete auto-digestion and auto-depletion of their storage contents. Isolated inner endosperms are incapable of inducing auto-digestive and auto-depletive processes in any way comparable with those observed in the case of endosperms.

The augmentation of amylase by the endosperm in presence of anæsthetics such as chloroform and nitrobenzene undergoes marked reduction, being reduced to the same order of magnitude as that of the inner endosperm. The augmentation of amylase by the inner endosperm is unaffected—*i.e.*, it is of the same order of magnitude as that of non-anæsthetised inner endosperms. Anæsthetised endosperms, unlike non-anæsthetised endosperms, are capable of inducing complete auto-depletion of their reserve storage materials.

Endospermic depletion, as it occurs in the intact seed, is principally conditioned by the action of enzymes secreted by the aleurone layer and embryo; in the isolated endosperm, by the aleurone layer secretions; and in both cases the principal rôle is due to the aleurone layer; the amyloclastic enzyme pre-existent in the inner endosperm and that which it generates is adjunctive.

The amyloclastic enzymes secreted by the embryo and aleurone layer are identical, and are distinct from that existent in and generated by the inner endosperm.

Sucrose inhibits the secretion of amylase by the embryo, dextrose diminishes it, but invert sugar has apparently no influence on the phenomenon.

The suggestion that the amylase which arises as secretions of the embryo and aleurone layer may activate that of the inner endosperm is not supported by experimental evidence. H. F. E. H.

Estimation of Colloids in Arable Soils. J. König, J. Hasenbäumer, and C. Hassler. (*Landw. Vers-Stat.*, 1911, **75**, 377-441.)—The mineral and organic colloids are important factors of the fertility of a soil since they absorb and retain the soluble nutrient salts useful to the plant. A measure of the richness of a soil in colloidal constituents may be obtained by estimations of the absorption-capacity of the soil towards dyestuffs or mineral salts. A suitable dyestuff is methyl violet in aqueous solution at 1, 2 or 3 grms. per litre, according to the capacity of the soil. Five grms. of the soil are shaken with 100 c.c. of the dyestuff solution, and after thorough clarification the amount of dyestuff removed by the soil is estimated colorimetrically. The absorption of the dyestuff depends chiefly on the colloidal clay constituents of the soil. For estimating the adsorption capacity of the soil towards mineral salts, a $\frac{N}{50}$ solution of dipotassium phosphate is used, the base and acid of which are absorbed by the soil in proportions approximately the same as they exist in the salt. The potash, however, is retained mainly by the clay colloids in a state of true adsorption which is readily reversed by treatments which flocculate the colloids; the phosphoric acid, on the other hand, is taken up mostly by the lime and ferric oxide of the soil in chemical combination forming insoluble phosphates. If the soil be dried with the phosphate solution and then washed with a definite amount of water, the quantity of potash absorbed is lower and the quantity of phosphoric acid is higher than when the soil is not dried with the salt solution. For the estimation of absorbed or adsorbed ions in soils, whether natural or previously treated with nutrient solutions as above, the authors liberate these ions by flocculation or oxidation of the colloids. Two methods for effecting this liberation have already been described—viz., by steaming and by oxidation with hydrogen peroxide. A new method is now recommended which consists in treating the soil with a powerful continuous electric current. The apparatus used is a dialysing cylinder, open at the top and closed by parchment at the bottom, in which are placed 200 grms. of soil stirred to a sludge with water, and with a layer of about 4 cm. of water on the top. This is suspended in the container, and the water outside the dialyser is filled up to the same level as inside. Platinum electrodes are arranged so that the anode is at the bottom of the outer vessel and the cathode is immersed in the dialysing cylinder. A tension of 220 volts is employed, the resistance being regulated so that the current does not exceed 3 ampères. The liquid in the inner and outer vessels is renewed when the temperature rises to 50° C. The liquid in the cathode chamber becomes alkaline, whilst that in the anode chamber becomes acid and contains humus matters; the permanganate values of the two liquids afford an indication of the organic matters, and the liquids are then mixed in aliquot proportions for the estimation o total solids, mineral matter, potash, lime, and phosphoric acid. Exhaustive treatment by the electrical method generally affords results very much higher than those obtained by steaming or oxidation. The authors therefore prefer to extract the soil twice by steeping with water for ten to twelve hours and then to subject it only once to the electrical treatment until the temperature rises to 55° C. The washings and the electrical dialysates are then united for analysis. By this treatment the results for potash coincide fairly closely with those afforded by the steaming and oxidation methods, and for phosphoric acid the single electrical and the steaming methods agree fairly well. Relations between the absorption capacity for dyestuffs or for dipotassium phosphate and the crop-yield exist in the case of the upper and lower portions of the same soil but do not hold for different kinds of soil; nevertheless, the dyestuff test can be recommended as a simple and rapid preliminary test for the general character of the soils. Comparisons between the amount of nutrient ions assimilated by the crop and the results found by the three analytical methods mentioned showed good concordance only for the potash. As regards the phosphoric acid, the steaming and single electrical treatments generally gave two to five times the amount assimilated by the crop; the oxidation method only showed relationships in the case of upper and lower portions of the same soil, since the phosphoric acid results by this method depend on the quantity of humus colloids present. For the lime, the results for all three methods were far in excess of the amount required by the plant. J. F. B.

Modification of Riegler's Method for the Estimation of Urea in Urine. T. Ekecranyz and K. A. Sodermann. (*Zeitsch. physiol. Chem.*, 1912, **76**, 171-176.) —Reigler's method, which depends upon the fact that urea is decomposed into equal volumes of carbon dioxide and nitrogen when heated with nitric acid containing a small quantity of nitrous acid, may be combined with Dumas' method for the estimation of nitrogen in organic substances. The combined method consists in measuring the volume of nitrogen liberated from a given volume of urine when the latter is heated with a modified form of Millon's reagent. One c.c. of the urine is placed in a test-tube which is closed with a cork through which pass an inlet tube, a delivery tube, and the stem of a tapped funnel. The delivery tube is connected with the lower end of a nitrometer filled with 50 per cent. potassium hydroxide solution, and a current of carbon dioxide free from air is then passed through the test-tube until the complete absorption of the bubbles in the nitrometer shows that the apparatus is filled with carbon dioxide. The level of the potassium hydroxide solution in the nitrometer is then adjusted, 2 c.c. of the modified Millon's reagent are admitted to the test-tube from the tapped funnel, and the contents of the latter are boiled for a few minutes, the gases evolved being driven over into the nitrometer by means of a current of carbon dioxide. When nitrogen ceases to collect, its volume is read off, corrected to normal temperature and pressure, and calculated into urea.

W. P. S.

ORGANIC ANALYSIS.

Estimation and Elimination of Sulphur Compounds in Commercial Benzol. J. G. Ellerton. (*J. Soc. Chem. Ind.*, 1912, **31**, 10-12.)—The principal sulphur compounds occurring in benzol are carbon disulphide and thiophene. So large an amount as 20 per cent. of the former compound may be present without imparting its peculiar odour to the benzol.

The Carius method of determining sulphur in organic compounds is here inapplicable, owing to the small content of sulphur. Garrett and Lomax's method (ANALYST, 1906, **31**, 52) for sulphur in petroleum gives low results in the case of benzol, owing to the volatility of the latter. Irwin's method, generally accepted for the estimation of sulphur in benzol, is an adaptation of the well-known "Gas Referee's Test." It gives concordant but low results, as Irwin pointed out. The author finds that a factor approximating to 1·8 will give a fairly good result, as shown by the following figures:

Sulphur Present. Grains per Gallon.		Sulphur Found. Grains per Gallon.		Factor.
486	...	277	...	1·75
486	...	283	...	1·72
486	...	270	...	1·80
564	...	307	...	1·83

For the estimation of *carbon disulphide* only, Macagno's modification of Nickel's method is used. The benzol is agitated with alcohol potash, and the potassium xanthate so formed titrated with $\frac{N}{10}$ copper sulphate solution, using potassium ferrocyanide as indicator. An approximation may be made from the density of the benzol by subtracting from it the value 0·885, and dividing by 0·00346.

Thiophene is determined by Denigès' method, a strong solution of mercuric sulphate being added to the benzol dissolved in methyl alcohol, and the compound formed dried at 115° C., and weighed. Carbon disulphide masks the reaction and interferes slightly, but the method is useful for all ordinary benzols containing 1 per cent. or less of carbon disulphide.

Owing to its different boiling-point, carbon disulphide is easily removed from benzol. This is not the case with thiophene, however, which is usually washed out by means of concentrated sulphuric acid, a method entailing the loss of about 8 to 12 per cent. of benzol. The best results for removal of thiophene were obtained by washing the benzol with fuming sulphuric acid of sp. gr. 1·87, giving three washes of 6 per cent. of the acid in all. By this treatment the thiophene was reduced from 1·22 per cent. to 0·22 per cent. Various oxidising agents such as ozone, lead oxide, and hydrogen peroxide were tried as a means of eliminating thiophene, but while ozone gave the best results, with a low loss of benzol, the action was too slight to have any practical value. The following amounts of sulphur were found in commercial 90 per cent. benzols: From Durham tar, 250 grs.; Yorkshire tar, 240 grs.; Lancashire, 49 grs.; Staffordshire, 504 grs.; and crude benzol (coke-oven) 64·4 grs. sulphur per gallon. A. R. T.

Detection of Carbon Bisulphide in Oils. E. Milliau. (*Ann. chim. anal.*, 1912, **17**, 1-3.)—Twenty-five grms. of the oil are saponified with 10 c.c. of a concentrated aqueous solution of potassium hydroxide in the cold, the soap dissolved in about 150 c.c. of warm water, a pinch of sodium bicarbonate added, and the solution decomposed with 20 c.c. of pure hydrochloric acid. The vapours emitted are tested with lead acetate paper, which will be darkened in the case of extracted olive oil containing 0·05 to 0·1 per cent. of carbon bisulphide. No coloration is given by cotton-seed, kapok, colza, or expressed olive oils, or by extracted oils which have previously been heated for an hour at 130° C. Another test is to distil 50 grms. of the oil with 10 c.c. of pure amyl alcohol, and to collect the first 5 c.c. of the distillate. A mixture of 1 part by volume of kapok oil and 4 parts of the distillate together with a few cgrms. of powdered sulphur are now heated in a sealed tube in boiling water. In the case of expressed olive or other oil no coloration is produced even after three hours' heating, whereas an extracted olive oil containing 0·1 per cent. of carbon bisulphide gives a distinct red coloration. It is preferable to neutralise the kapok oil with sodium hydroxide before using it in the test. Cotton-seed oil may be used in place of kapok oil as a reagent, but gives a somewhat weaker coloration. The reducing agents in kapok and cotton-seed oils are not volatile with steam. No coloration is given by extracted oils after being heated for an hour at 130° C.

C. A. M.

Estimation of Cinnamic Acid by Means of Bromine in Aqueous Solution. A. W. K. de Jong.

(*Rev. trav. chim. Pays-Bas*, 1911, **30**, 223-224; through *Chem. Zentralbl.*, 1912, I., 162-163.)—When bromine is allowed to act for a long time on cinnamic acid in aqueous solution, more than 2 atoms of bromine are absorbed additively; this, however, may be avoided by operating in the following manner: The substance to be analysed, for instance, a mixture of cinnamic and benzoic acids, is dissolved in sodium hydroxide and reprecipitated with hydrochloric acid, bromine in the form of a $\frac{N}{50}$ aqueous solution is run in, and the absorption of bromine is considered to be at an end when the liquid assumes a yellow colour which is not discharged within five minutes. Potassium iodide is then added, and the iodine liberated is titrated in the usual manner.

J. F. B.

Dimethylglyoxime as a Reagent for Ferrous Salts. P. Slawik.

(*Chem. Zeit.*, 1912, **36**, 54.)—Dimethylglyoxime, which is frequently employed for the estimation of nickel, gives an intense red coloration with ferrous compounds, and may be used for their detection. One drop of a solution of a ferrous salt is mixed with a little tartaric acid and 1 c.c. of an alcoholic solution of dimethylglyoxime, and an excess of ammonia is then added. The red coloration is very intense, and the reaction exceeds in delicacy all the other tests for ferrous iron, but the colour gradually disappears as the ferrous compound becomes oxidised by the action of the air into the ferric state. This defect makes the test not very satisfactory for the detection of small traces of ferrous salts, since complete oxidation may occur owing to the rise of temperature occasioned by the addition of the ammonia. Ferric salts give the coloration on the addition of a reducing agent—*e.g.*, stannous chloride or metallic zinc.

J. F. B.

Estimation of Fat by Extraction with Cold Solvents. C. Grimme.

(*Chem. Rev. Fett- u. Harz-Ind.*, 1912, **19**, 1-5.)—Estimations made under parallel conditions with different non-inflammable solvents by the method of cold extraction were compared with those made by the ordinary method of extraction with ether. The following results, which are typical of those obtained, represent the average percentage of fat extracted from a sample of cotton-seed meal in five estimations:

Ether.	Chloroform.	Carbon Tetrachloride.	Dichlor-ethylene.	Trichlor-ethylene.	Perchlor-ethylene.	Tetrachlor-ethane.	Pentachlor-ethane.
7·45	8·58	7·43	8·13	7·46	7·79	7·71	9·62

Only in the case of carbon tetrachloride and trichlorethylene did the fat agree in amount, colour, and analytical values with that extracted with ether, the other solvents extracting substances other than fat. Further experiments showed that the following modification of Neumann's method (ANALYST, 1911, **36**, 542) was the most rapid and accurate: Ten grms. of the finely powdered sample are shaken for forty-five minutes with 100 c.c. of carbon tetrachloride, or for thirty minutes with the same quantity of trichlorethylene in a stoppered 150 c.c. flask, care being taken that the shaking is done in the direction of the vertical axis of the flask. After standing for thirty minutes, the contents are filtered (the funnel being covered with a clock glass), 50 c.c. of the filtrate evaporated, and the residue dried for an hour at 105° C., air being blown across it from time to time. The weight of fat multiplied by 20 may be taken as sufficiently accurate up to 10 per cent. Between 10 and 15 per cent. an addition of 0·2 per cent., and between 15 and 20 per cent. an addition of 0·4 per cent. should be made, these corrections being based upon the average specific gravity of fat (0·93). In comparative estimations of the amount of fat in thirty-eight samples of different seed cakes and fish meal, the results thus obtained with carbon tetrachloride and trichlorethylene agreed within − 0·16 to + 0·17 with those given by the usual method of extraction with ether. The percentages of fat extracted by the two first solvents were the same, with or without preliminary drying of the material (*Cf.* Gowing Scopes, ANALYST, 1910, **35**, 238). C. A. M.

Estimation of Mercury in Oxyphenyldimercuric Acetate and Mercurisalicylic Acid. R. Brieger. (*Arch. Pharm.*, 1912, **250**, 62-71.)—The mercury in oxyphenyldimercuric acetate may be quantitatively estimated by dissolving the salt in hot 30 per cent. acetic acid, adding an excess of standard iodine solution, and titrating the excess of iodine after twenty-four hours:

$$C_6H_3OH\ (HgOOCH_3)_2 + 4I = Hg(OOCCH_3)_2 + HgI_2 + CH_3OHI_2.$$

The concentration of the acid has an influence upon the velocity of the reaction, and by nearly neutralising the solution with potassium hydroxide the amount of mercury found was 99·2 per cent. of the theoretical amount after one hour's action. For estimating the mercury in mercuri-salicylic acid the following method is described: Half a grm. of the sample is dissolved in 30 c.c. of hot $\frac{N}{10}$ potassium hydroxide solution, and the liquid diluted to 100 c.c., and treated with a few drops of *o*-nitrophenol solution, after which 30 c.c. of $\frac{N}{10}$ hydrochloric acid are added, and the excess of acid titrated with $\frac{N}{10}$ alkali. One c.c. of the alkali consumed by the sample corresponds to 0·0138 grm. of salicylic acid, and the difference between 100 and the calculated percentage of salicylic acid, multiplied by the factor 0·5952, gives the percentage of mercury. The result thus obtained should correspond fairly closely with the value obtained as follows: A solution of 0·3 grm. of the sample in 10 c.c. of $\frac{N}{10}$ potassium hydroxide is mixed with 25 c.c. of water and 5 c.c. of 30 per cent. acetic acid, and treated 25 c.c. of $\frac{N}{10}$ iodine solution, the excess of which is titrated with thiosulphate after fifteen hours. One c.c. of the iodine solution corresponds to 0·0100 grm. of mercury, or to about 0·3 per cent. in the sample, under the prescribed method of estimation. C. A. M.

Valuation of Dynamite Glycerol. F. Hofwimmer. (*Chem. Zeit.*, 1912, **36**, 41.)—On account of the possible presence of polyglycerols the only satisfactory method for testing the value of a glycerol is a determination of the nitroglycerine obtained by nitration. The author's apparatus consists of a burette divided into 0·05 c.c., sealed at the top into a thin-walled cylindrical water-jacketed nitrating vessel, with a mark one-third from the bottom, and terminating upwards in a neck. Above it is clamped a weighed stoppered tap pipette, with two marks, to deliver 10 grms. of glycerol. This is dropped slowly into about 60 grms. of nitrating acid (45 per cent. nitric acid + 55 per cent. sulphuric acid) previously adjusted to the mark in the nitrating vessel and cooled to 15° C., while a brisk current of dried air is passed up the burette. A thermometer in the nitrating vessel is unnecessary if the cooling water is at 15-16° C., and the flow rapid. All the glycerol having been run in, the air is allowed to pass for one minute longer. After fifteen minutes' standing the acid is run out to the zero mark on the burette, the volume of nitroglycerine read off, and calculated to 10 grms. of glycerol, after weighing back the glycerol pipette. For comparison, a standard is made by similarly nitrating 10 grms. of chemically pure glycerol. The determination must always be carried out under the same conditions; the quantity of glycerol taken must be between 9·9 and 10·1 grms. The determination can be finished in an hour. O. E. M.

Alteration of Nitrocellulose and Nitrocellulose Powders by Heat. R. Fric. (*Comptes rend.*, 1912, **154**, 31.)—The effect of heat on nitrocelluloses and nitrocellulose powders is to lower the viscosity of their acetone solutions, measured by the number of seconds required for 25 c.c. of solution to flow through a tube of 2 mm. bore 20 cm. long. Thus a collodion cotton declined from 69·3 to 57·7, after heating at 80° C. for seven hours twenty-five minutes; a guncotton from 210 to 99 under similar treatment; a smokeless blank from 36 to 21 after five hours at 110° C.; and a sporting powder from 94·8 to 33·3 after twelve hours at 110° C. O. E. M.

Physical and Chemical Properties of the Petroleums of the San Joaquin Valley of California. I. C. Allen and W. A. Jacobs. (American Bureau of Mines, 1911, Bull. 19, pp. 60).—This pamphlet deals with the collection of samples and their physical and chemical examination. An electrically-heated still, suitable for difficult distillations, is figured and described, and full details are given of its mode of operation and devices employed in connection with it. Owing to trouble with frothing samples, a closed form of flash tester could not be used, and an open Pensky-Martens cup screened from air-currents was employed. Viscosity was determined in an Engler viscosimeter at 20° C. and calorific value in a Berthelot combustion bomb (Dinsmore-Atwater model). To prevent bumping a "boiling stone" of porous porcelain or pumice weighing about 0·5 grm. is found to be most useful, even with heavy oils that boil at 325° C. under a pressure of 20 mm. A large number of samples are tabulated with the analyses of their fractions. H. F. E. H.

Colorimetric Estimation of Salicylic Acid and Copper. F. Schott. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1911, **22**, 727-728.)—Jorissen's reaction, as described by Shermann and Gross (ANALYST, 1911, **36**, 463), may be used for the colorimetric estimation of salicyclic acid and, conversely, for the estimation of small quantities of copper. In the case of salicylic acid, a definite quantity of the solution is placed in a test-tube, and in a set of exactly similar tubes are placed quantities of 0, 0·2, 0·4, 0·6, 0·8, 1·0, etc., c.c. of a salicylic acid solution which contains 100 mgrms. of the acid per litre. To each tube are now added 2 c.c. of Fehling's copper solution diluted previously with nine times its volume of water, 5 drops of a 2 per cent. potassium nitrite solution, and 5 drops of 10 per cent. acetic acid. After the volumes of the mixtures in the test-tubes have been diluted to a volume of 5 c.c., the tubes are heated in a boiling water-bath for forty-five minutes, cooled, and the coloration yielded by the solution under examination compared with those given by the quantities of salicylic acid in the other test-tubes. Salicylic acid may be estimated directly in milk by means of this method. Twenty-five c.c. of the milk are treated with 10 c.c. of Fehling's copper solution and the mixture is nearly neutralised with $\frac{N}{1}$ sodium hydroxide solution; after filtration, 15 c.c. of the filtrate are mixed with 5 drops of 10 per cent. potassium nitrite solution and the same quantity of 10 per cent. acetic acid. The coloration obtained on heating the mixture is then compared with standards prepared with milk containing known quantities of salicyclic acid. The colour of the milk serum remains unaltered in the absence of salicylic acid, but the reaction is readily obtained when the quantity of the latter amounts to 10 mgrm. or more per litre.

For the estimation of copper, comparison solutions containing 0, 0·1, 0·2, 0·4, etc., c.c. of a copper sulphate solution containing 0·3927 grm. of the crystallised salt per litre (equivalent to 100 mgrms. of copper) are employed. To each tube is added 0·3 c.c. of a 0·5 per cent. salicylic acid solution (in dilute alcohol) together with the above-mentioned qualities of nitrite and acetic acid, and the estimation is then carried out as described in the case of salicylic acid. Sucrose, dextrose, lactose, and invert sugar do not interfere with the reaction, but free mineral acids, tartaric acid, citric acid, and more than mere traces of iron should not be present in the solution under examination. The coloration is yielded by as little as 0·01 mgrm. of copper.

W. P. S.

Use of the Reagent "Tetramethyl Base." R. J. Carney. (*J. Amer. Chem. Soc.*, 1912, **34**, 32-35).—Tetramethyldiaminodi-phenylmethane $(CH_3)_4N_2(C_6H_4)_2CH_2$ in acetic acid solution was used by Trillat (*Compt. rend.*, 1903, **136**, 1205-1207) for the detection of traces of lead and manganese. The author, who finds many advantages in substituting citric acid for acetic, dissolves 2·5 grms. of the base in 10 c.c. of water containing 10 grms. of citric acid, and dilutes to 500 c.c. The base itself is prepared as follows: A mixture of 30 grms. of dimethylaniline, 10 grms. of formaldehyde, 200 c.c. of water, and 10 c.c. of sulphuric acid is warmed on the water-bath for one hour. After cooling, the mixture is made alkaline with excess of caustic soda, and the excess of dimethylaniline driven off with steam. The brownish product is cooled, filtered, and washed with water, and then recrystallised once from alcohol. The base is recommended as a new test for gold; with very dilute solutions, the reagent gives a beautiful purple colour, soon changing to blue, and then fading; the blue colour reappears on warming. The reaction is not interfered with by platinum, palladium, or other elements, and is more distinct than "purple of Cassius." Free mineral acid must be absent, so solutions should be neutralised and made slightly acid with acetic or citric acids. The test shows 0·01 mgrm. per 50 c.c. in a solution containing nothing but gold. H. F. E. H.

INORGANIC ANALYSIS.

Rapid Estimation of Carbon Monoxide. L. A. Levy. (*J. Soc. Chem. Ind.*, 1911, **30**, 1437-1439.)—The author has devised a colorimetric method for this estimation, accurate to about 0·3 per cent., which is regarded as sufficiently near for technical purposes. The method is based on that of Gautier (*Comptes rend.*, 1898, **126**, 793), in which carbon monoxide is selectively oxidised to carbon dioxide by means of heated iodine pentoxide. The author then aspirates the oxidised gas through a known volume of standard baryta solution coloured with phenolphthaleïn. The solution becomes colourless when it is completely neutralised by the carbon dioxide, the colour change thus corresponding to a fixed volume of carbon monoxide, which can be measured, and the percentage of the latter estimated. Certain precautions are necessary in carrying out the process. Unsaturated hydrocarbons are oxidised by iodine pentoxide, and must therefore be removed before the oxidation. The inhibitory action of traces of ethylene on the oxidation of carbon monoxide by the iodine pentoxide at 60° to 100° C. is not noticeable if the oxidation be effected at 170° C. The gas is bubbled through a strong solution of bromine in potassium bromide at a rate not greater than 2 litres per hour, and bromine vapour is then removed by potassium hydroxide solution (1 in 2), which also serves to remove any carbon dioxide in the original gas. After this treatment the gas is dried by passing over phosphorus pentoxide in a tube 4 inches long and 1 inch in diameter. The gas is oxidised in a U-tube containing iodine pentoxide mixed with ignited asbestos to render the column pervious to the passage of gas, and the liberated iodine is caught in a connected U-tube full of copper turnings, with which the iodine combines. This oxidation apparatus is contained in an air-oven maintained at 160° to 180° C. The oxidised gas now passes to the baryta absorption coil, a special form of which is employed in order to obtain complete absorption of carbon dioxide. The baryta solution is of such strength that it is exactly neutralised by the passage of 20 c.c. of carbon dioxide measured at 60° F. and 30 inches pressure. A three-way tap is interposed between the oxidation-tube and the baryta decolorisation vessel, so that the gas may be by-passed until the test is commenced; 100 c.c. of gas completely displaced the residual gas in the apparatus. If the volume of water flowing out of the aspirator $=\mathrm{V}$, which is the volume of gas passing, then V c.c. contain 20 c.c. of carbon dioxide, and the percentage is $\frac{2000}{\mathrm{V}}$, which can be directly read off on a specially graduated aspirator vessel. The results agree to within about 0·3 per cent. with analysis made with accurate forms of gas-analysis apparatus. The results with weaker baryta solution, in the case of gases containing only 1 to 2 per cent. of carbon dioxide, are not quite so good. Better results are obtained by using strong baryta solution with large volumes of gas, and titrating back the excess of alkali with oxalic acid. This method is useful in the analysis of fumes from stoves, mine air, and air from lime-kilns, etc. The apparatus is made in portable form by A. Wright and Co., Westminster. A. R. T.

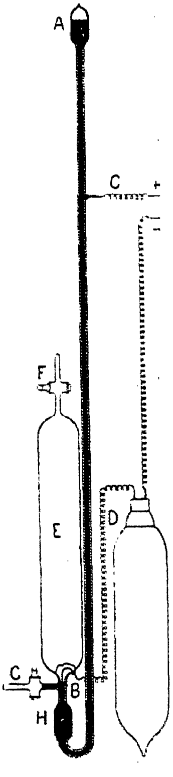
Rapid Estimation of Manganese in Ferro-Tungsten. P. Slawik. (*Chem. Zeit.*, 1912, **36**, 106.)—A mixture of 1 grm. of the finely-divided sample with 10 grms. of sodium peroxide is heated in a porcelain crucible for two or three minutes at a dull red heat, cooled, and extracted with water, acidulated cautiously with hydrochloric acid, boiled fifteen to twenty minutes with a large excess of the acid, boiled up with a slight excess of zinc oxide, and titrated with permanganate. As a check, the same sample was decomposed with sodium hydroxide and potassium nitrate in a nickel crucible, the melt dissolved in water, the manganese precipitated with sodium peroxide, filtered off, ignited, dissolved in hydrochloric acid, diluted, and, after addition of zinc oxide in slight excess, titrated hot with permanganate. Results showed a maximum error for the first method of 0·02 per cent. on an alloy containing 0·47 per cent. manganese as determined by the second. O. E. M.

Separation of Phosphomolybdates from Silicomolybdates. P. Mēlikoff. (*Comptes rend.*, 1911, **153**, 1478.)—Ammonium molybdate precipitates silicic acid as well as phosphoric acid. A mixture of equal volumes of 30 per cent. hydrogen peroxide and 8 per cent. ammonium molybdate in nitric acid dissolves out the phosphomolybdate from the precipitate, leaving the silicomolybdate. The reaction may be followed under the microscope. O. E. M.

Geochemical Interpretation of Water Analysis. C. Palmer. (U.S.A. Geological Survey, 1911, Bull. 479, pp. 31)—The interpretation of the chemical character of a water from the results of analysis is necessarily uncertain and unsatisfactory if it is based merely on the amounts of the radicles determined; a form of statement which discloses their true relations and proportions is required, and this the author, following Stabler, calls their proportional reaction capacity. The reaction capacities of the radicles of dissolved salts are the quotients obtained by dividing the weight of each radicle by its equivalent combining weight. The "reaction coefficient" is the chemical reacting power of a unit weight of a radicle, or the ratio of the reaction capacity of 1 part of that radicle to the reaction capacity of 8 parts of oxygen. Thus, calcium has an atomic weight of 40, an equivalent weight of 20, a reaction coefficient of $\frac{1}{20}$ or 0·05. The product of the "reaction coefficient" and the amount of a radicle is called the "reacting value" of that amount of the radicle, and is really equal to "mgrm. equivalents of hydrogen." When water analyses are so expressed, many operations such as the calculation of the amounts of remedial agents required to produce desired changes are much facilitated. In a particular water the reacting values of the alkali metals was 0·264, and that of the sulphates and chlorides 0·188. The excess of alkalinity (0·076) multiplied by 53 (the combining weight of sodium carbonate) is equal to 4·02, which represents the parts of sodium carbonate per million of water. It is advisable that the reacting value of a water be expressed independently of its particular concentration so as to facilitate comparison of different waters which vary in their total saline content. This is done by stating the reacting value of each radicle as a percentage of the concentration value, and so obtaining a "character formula," which not only shows the radicles found, but clearly distinguishes slight differences in the proportions of these radicles present in any waters that are to be compared. The following five properties of a water may be distinguished: (1) Primary salinity due to salts of alkalis and strong acids; (2) secondary salinity due to salts of alkaline earths and strong acids; (3) acidity or excess of strong acid if any; (4) permanent alkalinity due to alkali metals; and (5) temporary alkalinity due to alkaline earths. Carbonic acid is not regarded as capable of producing acidity, and silica and alumina are classed separately as colloids. An extensive series of analyses of American river waters is given, and the results discussed in relation to the geology of the river basins. H. F. E. H.

APPARATUS, ETC.

Thermo-Regulators. W. R. Bousfield. (*Chem. News*, 1912, **105**, 13-14.)—The figure shows an air-thermostat, capable of being used for water by slight changes of detail. This form was designed to regulate the heat of an electric radiator, worked direct from the main, carrying an alternating current at 240 volts. A, B, are the upper and lower surfaces of a mercury column in a barometer-tube, part of the column being in series with the radiator and the main current, which passes in and out of the mercury by platinum wires 1 mm. thick, sealed in the glass walls of the tube. The current enters at C, a point low enough to be always immersed in mercury. The circuit is closed by contact with the platinum wire D at B. The connected bulb E is filled with hydrogen through F, a cock, C, serving to regulate the amount of mercury for the desired temperature, and enabling E to be thoroughly washed out with hydrogen. Overheating of the thermostat expands the gas, and causes the mercury surface B to be forced away from the platinum wire, cutting off the current. The reverse process takes place when the temperature falls below the mean. The mean pressure in E must be so chosen that the mercury in A normally occupies half the bulb. The mercury in H allows of the filling of A in case of overheating, and prevents air-bubbles passing the bend at the bottom and spoiling the vacuum in A. If the mean pressure in E is about equal to atmospheric pressure, as it should be, then the tube will be of the length of the ordinary barometer-tube, and possible leakage of hydrogen through defective taps is avoided. The use of hydrogen in E is necessary, since it forms no compound with mercury, and the sparking at B does not result in oxidation nor deterioration of the surface of the mercury.



A modified form of a Lowry gas regulator is also described, which is unaffected by gas and atmospheric pressure variations, and is sensitive to 0·01° C. A. R. T.

Filtration with Alundum Plates. R. C. Benner and W. H. Ross. (*J. Amer. Chem. Soc.*, 1912, **34**, 51.)—Filtration of large volumes of liquids containing very fine precipitates by means of asbestos fibre and the Witte plate is sometimes inconvenient, and it is claimed that there is an advantage in the use of "alundum" (fused aluminium oxide) discs made by the Norton Company of Worcester, Mass., which are to be had in several grades with pores of different sizes. They fit into a glass funnel by means of an ordinary flat rubber band, and their use makes possible the stirring of the precipitate while on the plate. H. F. E. H.

GOVERNMENT REPORT.

Milk and Cream Regulations (Draft).—The under-mentioned Draft of Regulations has been forwarded to the Society by the Local Government Board. The statutory notice of the proposal to make regulations under the Public Health (Regulations as to Food) Act, 1907, was inserted in the *London Gazette* of February 20, 1912:

To the Several Local Authorities in England and Wales for the Time being authorised to appoint an Analyst for the Purposes of the Sale of Food and Drugs Acts, 1875 *to* 1907*;—To Officers of Customs and Excise;—To the Principal Chemist of the Government Laboratories;—To Medical Officers of Health;—To Public Analysts; —To Dairymen, and to Wholesale and Retail Dealers in Milk and Cream;—and to all Others whom it may concern.*

Whereas by Section 1 of the Public Health (Regulations as to Food) Act, 1907, it is enacted as follows:

"1. The power of making regulations under the Public Health Act, 1896, and the enactments mentioned in that Act, shall include the power of making regulations authorising measures to be taken for the prevention of danger arising to public health from the importation, preparation, storage, and distribution of articles of food or drink (other than drugs or water) intended for sale for human consumption, and, without prejudice to the generality of the powers so conferred, the regulations may—

"(*a*) Provide for the examination and taking of samples of any such articles;

"(*b*) Apply, as respects any matters to be dealt with by the regulations, any provision in any Act of Parliament dealing with the like matters, with the necessary modifications and adaptations;

"(*c*) Provide for the recovery of any charges authorised to be made by the regulations for the purposes of the regulations or any services performed thereunder;

"2. For the purposes of regulations made under this Act, articles commonly used for the food or drink of man shall be deemed to be intended for sale for human consumption unless the contrary is proved. . . ."

And whereas we, the Local Government Board, are empowered by regulations made under the Public Health Act, 1896, and the enactments mentioned in that Act, to provide for the regulations being enforced and executed by the Officers of Customs and Excise, as well as by other Authorities and Officers, and subsection 2 (*a*) of Section 1 of the Public Health Act, 1896, requires that the regulations shall be subject to the consent, so far as they apply to the Officers of Customs and Excise, of the Commissioners of Customs and Excise;

And whereas in the exercise of Our powers under the Public Health (Regulations as to Food) Act, 1907, We, by the Public Health (First Series: Unsound Food) Regulations, 1908, made Regulations in relation to articles of food;

And whereas, for the prevention of danger arising to public health, it is expedient that such Regulations as are hereinafter set forth be made in relation to Milk and Cream;

And whereas the Commissioners of Customs and Excise have signified their consent to the said Regulations, so far as they apply to the Officers of Customs and Excise:

Now therefore, We, the Local Government Board, by this Our Order, and in the exercise of the powers conferred upon Us by the Public Health Act, 1875, the Public Health (London) Act, 1891, the Public Health Act, 1896, and the Public Health (Regulations as to Food) Act, 1907, and of every other power enabling Us in that behalf, do make the following Regulations, that is to say:

PART I.

ARTICLE I.—In these Regulations, unless the contrary intention appears—

(*a*) The expression "preservative substance" means any substance, preparation, or solution which when added to milk or cream is capable of retarding the onset of sourness or decomposition, or is capable of neutralising acidity (sourness) in milk or cream, and the expression "thickening substance means sucrate of lime, gelatine, starch paste, or any other substance which, when added to cream, is capable of increasing its thickness:

Provided that neither cane nor beet sugar shall be regarded as a preservative or as a thickening substance;

(*b*) The expression "milk" includes separated, skimmed, condensed, and dried milk;

(*c*) The expression "cream" means that portion of milk rich in milk fat which has risen to the surface of milk on standing and has then been removed, or which has been separated from milk by centrifugal force;

(*d*) The expression "preserved cream" means cream containing 40 per cent. or more by weight of milk fat, to which has been added—

(i.) boric acid, borax or a mixture of those preservative substances, or

(ii.) hydrogen peroxide, in amount not exceeding 0·1 per cent. by weight;

(*e*) The expression "seller" includes any person who exposes or offers for sale, or has in his possession for the purpose of sale;

(*f*) The expression "foreign" used in relation to milk, cream, or preserved cream means brought from a place situate elsewhere than in the United Kingdom, the Channel Islands, or the Isle of Man;

(*g*) The expression "Local Authority" means any local authority authorised to appoint an analyst for the purposes of the Sale of Food and Drugs Acts, 1875 to 1907, and the expression "public analyst" means an analyst so appointed;

(*h*) The expression "Unsound Food Regulations" means the Public Health (First Series: Unsound Food) Regulations, 1908;

(*i*) Other expressions have the same meaning, *mutatis mutandis*, as in the Unsound Food Regulations.

ARTICLE II.—Subject as provided in sub-division (1) of Article V. hereof these Regulations shall come into operation on the First day of June, One thousand nine hundred and twelve.

PART II.

ARTICLE III.—(1) No person shall add, or order or permit any other person to add, any preservative substance to milk intended for sale for human consumption.

(2) No person shall sell, or expose or offer for sale, or have in his possession for the purpose of sale, any milk to which any preservative substance has been added in contravention of the provisions of sub-division (1) of this Article.

ARTICLE IV.—(1) No person shall add, or order or permit any other person to add—

(*a*) any thickening substance to cream or preserved cream;

(*b*) any preservative substance to cream containing less than 40 per cent. by weight of milk fat;

(*c*) to cream containing 40 per cent. or more by weight of milk fat any preservative substance other than—

(i.) boric acid, borax, or a mixture of those preservative substances, or

(ii.) hydrogen peroxide, in amount not exceeding 0·1 per cent. by weight;

in any case in which the cream is intended for sale for human consumption.

(2) No person shall sell, or expose or offer for sale, or have in his possession for the purpose of sale, any cream to which any thickening substance or any preservative substance has been added in contravention of the provisions of sub-division (1) of this Article.

ARTICLE V.—(1) Every seller of preserved cream shall, in every invoice, bill, advertisement, trade list, or other document which is used in connection with the sale of preserved cream for human consumption, describe that article as—

(*a*) preserved cream (boracised), or

(*b*) preserved cream (peroxidised)

as the case may require, and in no such document shall any words be contained which might imply that the preserved cream is cream to which a preservative substance has not been added.

The provision in this sub-division of this Article shall come into operation on the First day of January, One thousand nine hundred and thirteen.

(2) No seller of preserved cream shall deposit for sale in any place, or dispatch or deliver to any purchaser, or to any other person, any receptacle containing preserved cream intended for human consumption unless the receptacle is labelled in the manner prescribed in the Schedule to these Regulations, and unless, in the case of preserved cream containing boric acid, borax, or a mixture of those preservative substances, the amount of those substances calculated as boric acid (H_3BO_3) is accurately stated as not exceeding the limit specified on the label in the manner prescribed in the said Schedule:

Provided that if in any public refreshment room, restaurant, shop, or other public premises preserved cream is delivered to a purchaser or other person for consumption on the premises, the receptacle containing the preserved cream shall not be required to be labelled in accordance with the foregoing provisions if there is placed in a conspicuous position in every room on the premises in which customers are served with refreshments a notice, printed in large and easily legible type, indicating that the cream supplied for consumption on the premises is preserved cream, or if a statement to that effect is conspicuously made on every bill of fare exhibited to customers, or if by some other adequate means similar intimation is publicly given.

Article VI.—The Local Authority shall enforce and execute the Regulations in this Part of this Order, and for this purpose shall authorise the making of inquiries and the taking of any other steps which may seem to them to be necessary for securing the due observance of the Regulations in their District:

Provided that before the Local Authority institute proceedings against any person for a contravention of any of the Regulations in this Part of this Order the Local Authority shall afford him an opportunity of furnishing an explanation in writing or otherwise as they may appoint, and shall duly consider any such explanation and all the circumstances of the case.

Article VII.—Any of the officers named in Section 13 of the Sale of Food and Drugs Act, 1875, may under the direction of the Local Authority appointing him procure for examination, in accordance with the provisions of Section 14 of that Act so far as the same may be applicable, samples of milk or cream or preserved cream, or of any article resembling milk or cream, or of any substance which appears to be intended for addition to milk or cream; and the owner or occupier of any premises on which there is deposited milk or cream or preserved cream intended for sale, or for preparation for sale, for human consumption, or the person having the custody thereof, shall afford to the officer all reasonable facilities for entering the said premises for the purpose of taking samples or making inquiries or for any other purpose of the Regulations in this Part of this Order.

Part III.

Article VIII.—No person shall import into England or Wales—

(*a*) any foreign milk to which any preservative substance has been added;

(*b*) any foreign cream to which any thickening substance has been added;

(*c*) any foreign cream containing less than 40 per cent. by weight of milk fat to which any preservative substance has been added;

(*d*) any foreign cream containing 40 per cent. or more by weight of milk fat to which has been added any preservative substance other than—

(i.) boric acid, borax or a mixture of those preservative substances; or

(ii.) hydrogen peroxide in amount not exceeding 0·1 per cent. by weight;

(*e*) any foreign preserved cream which is not contained in a vessel or receptacle duly labelled in the manner prescribed in the Schedule to these Regulations.

ARTICLE IX.—(1) The Officers of Customs and Excise shall enforce and execute the Regulations in this Part of this Order and for this purpose shall, in accordance with directions given by the Treasury after consultation with Us, take samples of consignments of imported milk or cream or articles resembling milk or cream.

(2) When any Officer of Customs and Excise takes a sample in pursuance of sub-division (1) of this Article he shall divide it into not less than three parts, and send one part to the importer and one part to the Principal Chemist of the Government Laboratories, and retain one part for future comparison.

(3) In any proceeding under this Part of this Order the certificate of the Principal Chemist of the Government Laboratories of the result of the analysis shall be sufficient evidence of the facts therein stated unless the defendant require that the person who made the analysis be called as a witness, and the defendant shall not be entitled to require the person who made the analysis to be called as a witness unless he shall, at least three clear days before the return day, give notice to the prosecutor that he requires his attendance and deposit with the prosecutor a sum sufficient to cover the reasonable costs and expenses of his attendance, which costs and expenses shall be paid by the defendant in the event of his conviction.

(4) If in any case the Officer of Customs and Excise is of opinion that an offence has been committed under this Part of this Order, he shall communicate to Us for Our information the name of the importer and such other information as he possesses or may obtain as to the destination of the consignment.

PART IV.

ARTICLE X.—(1) If a difference arises in relation to any subject matter of, or to anything done under, these Regulations, the difference may, on the application of all the parties affected, be referred to Us for determination.

(2) It shall be at Our option to determine any such difference as arbitrators or otherwise; and, if We elect to determine the difference as arbitrators, the provisions of the Regulation of Railways Act, 1868, respecting arbitrations by the Board of Trade, and the enactments amending those provisions, shall apply as if they were re-enacted in these Regulations, and in terms made applicable to Us, and to the determination of the difference.

(3) Where We elect to determine any such difference otherwise than as arbitrators, We may by Our Order determine the difference, and Our determination shall be final and conclusive.

(4) Every Order made by Us in pursuance of this Article shall have effect as if the Order were enacted in these Regulations.

Article XI.—All powers given by these Regulations shall be deemed to be in addition to, and not in derogation of, any other powers conferred by Regulations under the Public Health (Regulations as to Food) Act, 1907; and those other powers may be exercised in the same manner as if these Regulations had not been made.

Article XII.—These Regulations may be cited as "The Public Health (Milk and Cream) Regulations, 1912."

SCHEDULE.

Regulations with respect to the Labelling of Preserved Cream.

1. Every receptacle containing preserved cream shall be labelled by the attachment thereto of an adhesive label, in this Schedule referred to as the "declaratory label."

2. Every declaratory label shall be in the form and contain the information indicated in Label I. or Label II. set out in this Schedule, as the case may require. Such information shall be printed in black type, of not less size than that shown in the said Label I. or Label II., upon a white ground in the centre of the declaratory label, and nothing else shall be printed on the declaratory label; except that in every case in which Label I. is used the maximum amount per cent. of boric acid (H_3BO_3) contained in the preserved cream shall be stated in figures on the declaratory label.

Label I.

PRESERVED CREAM
CONTAINING
BORIC ACID
NOT EXCEEDING
PER CENT.

Label II.

PRESERVED CREAM

PEROXIDISED

3. The size of the declaratory label shall be determined as follows:

Capacity of Receptacle.	Size of Label.		
	Inches.		Inches.
Less than ¼ pint	1	by	2⅜
¼ pint or more, but not exceeding ½ pint	2	by	3⅜
Exceeding ½ pint	3	by	5

4. The declaratory label shall be so attached to the receptacle that the whole of the label shall be visible and clearly legible, and the declaratory label shall not be overlapped by any other label or otherwise obscured.

5. The declaratory label shall not be affixed either over the mouth of the receptacle or beneath the receptacle.

6. Where on any receptacle containing preserved cream or on any wrapper or package in which such receptacle is enclosed, there appears any reference by label (other than the declaratory label) or otherwise to preserved cream contained therein, the preserved cream shall in every case be described as "preserved cream," the words "preserved" and "cream" being set out in letters of the same size.

7. No receptacle containing preserved cream shall bear or shall have attached on any label a trade description within the meaning of the Merchandise Marks Act, 1887, which shall be false or in any way likely to mislead a purchaser as to the presence or utility of the preservative substance, or as to the declaratory label, or as to the Regulations.

NOTICE.—The Public Health Act, 1896, provides by subsection (3) of Section 1 that if any person wilfully neglects or refuses to obey or carry out, or obstructs the execution of, any regulation made under any of the enactments mentioned in that Act, he shall be liable to a penalty not exceeding one hundred pounds, and, in the case of a continuing offence, to a further penalty not exceeding fifty pounds for every day during which the offence continues.

The power of making regulations under the Public Health Act, 1896, and the enactments mentioned in that Act is enlarged by the Public Health (Regulations as to Food) Act, 1907.

REVIEWS.

THE TECHNOLOGY OF BREAD-MAKING: CHEMISTRY AND ANALYSIS OF MATERIALS USED IN BREAD-MAKING AND CONFECTIONERY. By WILLIAM JAGO and WILLIAM C. JAGO. Simpkin, Marshall, Hamilton, Kent and Co. 8vo., pp. 908. London, 1911. Price 21s. net.

The present volume is a development of the authors' former works on the same subject which appeared in 1886 and 1895, and the general mode of treatment is, in consequence, to some extent governed by the previous publications. Much space has been devoted to quite elementary considerations, such as the description of the balance and method of weighing (six pages) the principal chemical elements and their inorganic compounds, the microscope, polarisation of light, etc. The reader, whoever he may be, will probably prefer to refresh his memory on the first principles of physics and chemistry from appropriate textbooks. Without wishing to be unduly critical, we think it unfortunate that the opportunity was not taken of eliminating such unnecessary weighting from a work which is obviously intended for the practitioner rather than the student.

Mr. Jago has also devoted a considerable amount of space to recording his own researches, hitherto unpublished, on flour and fermentation. It is doubtful whether such a course is a wise one. Certainly it is not in the authors' own interests from the point of view of priority. Moreover, it is extremely annoying to investigators, as textbooks are not the recognised medium for publication of original work.

In a book of this size certain defects are unavoidable, and the reader will notice such expressions as "when a little of the substance called yeast," "sugar of milk," and "Kjeldahlise." Again, in some cases authors' names are mentioned without the accompanying reference. The account of the action of diastase on starch is only brought down to 1899, and the work of all Continental and some English workers on this subject is ignored. In consequence of this, the information relating to the dextrins of high molecular weight, which occupy an important rôle in bread-making, is quite out of date. In the list of enzymes the statement is made that invertase converts sucrose into glucose. If another edition of this book be published, the authors should carefully revise the more purely chemical and biochemical portions.

The chapter dealing with the manufacture of yeasts shows much care in its compilation, the authors having obtained some of their information first hand by visiting a well-known yeast factory in Holland. It need hardly be said that in up-to-date factories full advantage is taken of the practical bearings of Hansen's researches, and fermentation is started with pure cultures. Formulæ and full particulars are also given for the preparation of patent or bakers' home-made yeasts, Scotch flour-balms, and Parisian balms.

The important question of the strength of flour is discussed, and the work of the authors Humphries, Biffen, Wood, and Baker and Hulton is discussed at some length. Strength is defined as the measure of the capacity of the flour for producing a bold, large-volumed, well-risen loaf. In the authors' opinion there is no satisfactory method of numerically registering strength except by a baking test, when the actual volume or girth of the loaf may be measured. They consider that the strength of a flour may be deduced from the character and quality of the gluten. But this is rather begging the question, for no methods are available of expressing quantitatively the quality of a gluten. Wood has shown that certain salts exercise a marked influence on the character of gluten, and that the proteins of gluten, in the absence of electrolytes, are collectively neither ductile or tenacious; later he has stated that the determination of water-soluble phosphate gives a certain amount of information as to the character of the gluten in a flour. Wood's work, although of interest, is of a pioneer nature, and as regards the measurement of strength of flour does not carry us far. In fact, as has been pointed out by Baker and Hulton, it is not possible that the estimation of one constituent or the determination of one physical property will enable the chemist to affix a baking value to a flour, when this value is the resultant of several factors.

The authors still attach importance to gluten determinations. They consider that the weight of wet gluten is a measure of the amount of that constituent of flour which by its physical character determines the quality and nature of the resultant dough and bread.

A considerable amount of statistical information is given concerning the weights and chemical composition of typical British and foreign wheats. Different flours and milling products, and the general relationship which exists between water-absorbing power, gluten, moisture, and colour of flours, are discussed at some length.

In view of recent legislation, and reports to the Local Government Board on the bleaching of flour, the views of the authors will be read with interest. Owing to the development of milling processes, there has been a marked increase in the amount of patent flour obtainable from the wheat; but, as would be expected, this leads to a slight darkening with milling impurities. The opinion is expressed that to bleach this flour by a harmless process cannot be regarded as an adulteration, nor is such flour misbranded when called "patent flour." There will always be a difference of opinion among experts as to what is a harmless or harmful process, and in this connection it should be remembered that the United States Board of Food Inspection has decided that flour bleached with nitrogen peroxide is an adulterated product. The authors' arguments on the matter of bleaching are not convincing. The public have no means of detecting a bleached flour, and so long as bleaching is resorted to in order to improve the appearance of certain grades of flour and make it resemble a more highly priced article, misrepresentation to the advantage of the retailer is bound to ensue.

In the section on bread-making the different recipes and processes in the United Kingdom are briefly described, and also, in some detail, the diseases and faults of breads.

The nutritive value of bread is dealt with at some length, and for those who can read between the lines it will be apparent how far from disinterested was the recent Press agitation in favour of "Standard Bread."

The authors describe their methods for the estimation in flour of gluten, water-absorbing capacity, colour consistency, and other characteristics. This portion of the book will be of interest to those chemists who occasionally have to examine flours. The analysis of bread receives some attention, and the detection of various adulterations and additions.

The literature on flour and bread has been up to the present in a chaotic state, and, since the authors have made a genuine and successful attempt to present to their readers the best information available, the book should deservedly have a wide circulation. Mr. Jago has made this subject peculiarly his own, and it is not too much to say that the present volume contains the best of all that is worth knowing of flour and bread.

MODERN MICROSCOPY. By M. I. CROSS and MARTIN J. COLE. Baillière, Tindall and Cox. London. Pp. 318. Price 6s. net.

This is the fourth edition of a well-known work. In spite of its moderate dimensions, it not only deals with the design, construction and practical use of the microscope, and, to a less extent, with the principles therein involved, but also aims at furnishing a brief account of the methods of microscopical preparation employed in almost every branch of science in which the instrument is used.

The first of the three parts into which the book is divided treats of the microscope and its accessories; and the advice given as to the choice of an instrument is practical and sound, and is supported by clear statements of the reasons on which such advice is based.

The theoretical considerations underlying the construction and use of both instrument and accessories are dealt with, as far as is possible, without the use of mathematics; but the book is, and is intended to be, essentially practical, and theory is mainly referred to when necessary to give the worker an intelligent comprehension of the operations he has to undertake. Within these limits this part of the book is excellent, and to the amateur, for whom it is mainly intended, will do much to help him to understand the more elaborate treatises.

Part II. describes the various processes employed for the hardening, preserving, and embedding of animal and vegetable organisms and tissues, and the methods used for cutting, or grinding, and mounting sections of every class of material, and for making almost every kind of microscopic preparation. Coming, as it does, from the pen of Mr. Martin Cole, whose skill and experience in these matters are so well known, it is, as would be expected, thoroughly practical and efficient.

Part III. contains seven chapters, each by a separate author, on the following subjects: The Use of the Petrological Microscope; Rotifera; Fresh-Water Mites *Hydrachnidæ*); *Foraminifera*; Mosses and Liverworts; Nature Study; and, finally, the Microscopy of Foods.

This last chapter, to which many readers of this journal would naturally turn, is very unsatisfactory, and it is plain that the author of it is not familiar with the common routine work of the public analyst. In the short space at his disposal it would, of course, be quite impossible to deal adequately with such a subject; but he repeatedly goes out of his way to refer vaguely to chemical processes with which he is obviously far from conversant, and which have no connection with the microscope whatever, although to the uninitiated this might not be apparent from the text. Not only is much irrelevant matter introduced, but in very many cases the statements are incorrect or misleading. This is perhaps the more to be wondered at because the writer gives a short list of works to which readers are referred for information, and to some of which he acknowledges his indebtedness. The twenty-four photomicrographs, with which the chapter is illustrated, are in most cases extremely satisfactory; but Fig. 94 has surely been misnamed *Penicillium;* it should surely be *Aspergillus.*

Apart from this chapter, which should be entirely rewritten, the book may safely be recommended, as it deals in small space and in a thoroughly practical manner with a very wide range of microscopical technique.

C. H. Cribb.

THE INSTITUTE OF CHEMISTRY OF GREAT BRITAIN AND IRELAND.

IMPORTANT NOTICE.

THE Council of the Institute of Chemistry of Great Britain and Ireland have had under consideration the particulars of proposed appointments of Public Analysts for the Metropolitan Boroughs of Lambeth and Wandsworth.

In each of these cases the following terms are set forth:

"3. The Officer will be required to examine and report upon 2,000 samples, formal and informal, or such number up to the said 2,000 as may be submitted by or on behalf of the Council in every year. For the purpose of this clause, a year shall be held to commence on the 1st January and end on the 31st December."

"4. The Officer will be required, at his own cost, and in such place as the Council may approve, to provide and maintain his own Laboratory, together with all such apparatus, chemicals, and assistance as are necessary to enable him adequately and completely to execute the duties of the office. The Officer will also be required to provide, at his own cost, and to the satisfaction of the Council and the approval of the Local Government Board, a competent Deputy to act during any absence from duty of the Officer through sickness, holiday, or other cause."

"5. In addition to the certificate of analysis directed by the Sale of Food and Drugs Acts to be given to the person submitting a sample, the Officer will be required, at the same time as he gives the Statutory certificate, to transmit direct to the Medical Officer of Health a duplicate copy of every such certificate."

"6. The fixed remuneration to be paid by the Council in respect of the said 2,000 samples, or such number up to 2,000 as may be submitted in any year, will be £500 per annum, and will be payable quarterly on the 31st March, 30th June, 30th September, and 31st December in every year."

The terms in the case of Wandsworth contain a further clause:

"7. The fee of one guinea will be paid by the Council for each analysis of water and one guinea for each attendance of the Officer at the police court when required by the Council."

The Council have also considered an announcement regarding the proposed appointment of an Analyst to the County of Antrim, under the following conditions:

"The Analyst will be paid a salary of £150 per annum, with first-class travelling expenses through the County when he is required as a witness in any case of prosecution."

"He is to make analyses of all samples submitted to him by the Inspectors appointed under the Food and Drugs Acts, and to analyse samples under the Fertilisers and Feeding Stuffs Act, 1906, for farmers and others resident in the County, at a fee of 5s. for each analysis, payable by the person sending the sample."

"Three months' notice on either side to terminate the engagement."

In explanation of the above, the Registrar has received the following letter from the Deputy Secretary to the Antrim County Council:

"In reply to yours of the 19th inst., I beg to inform you that the salary of £150 per annum to be paid to the County Analyst for County Antrim is for his services in making analyses of samples taken under the Sale of Food and Drugs Acts. In addition to this salary he is to be paid a fee of 5s. for each analysis of samples under the Fertilisers and Feeding Stuffs Act, 1906. This fee to be paid by the farmers, and other persons resident in the County, sending the samples."

"There is no limit to the number of samples likely to be submitted to the Analyst, so far as I am aware."

The number of samples per annum usually submitted is over 800. During the quarter ending September 30th, 1911, 270 samples were submitted for analysis.

The Council of the Institute are of opinion that the remuneration and conditions offered for the three appointments referred to above are not compatible with the adequate and complete execution of the duties of these offices, and that it is contrary to the public interest that appointments should be made on such terms.

The Council of the Institute view with the strongest disapproval the application for and acceptance of any of these appointments on the terms and conditions stated. They advise any Member who shall have made application for any of these appointments to withdraw the same; and they advise Members of the Institute to refrain from giving testimonials in support of any candidate applying for them.

By order of the Council of the Institute of Chemistry of Great Britain and Ireland.

RICHARD B. PILCHER,
Registrar and Secretary.

1*st March*, 1912.

The Resolution of the Council to publish this notice was reported to the Annual General Meeting of the Institute and approved.

Tl

THE ANALYST.

OBITUARY.

We deeply regret to have to record the deaths of Mr. Arthur E. Ekins and Mr. John Pattinson, former Vice-Presidents of the Society. Obituary notices will appear in the next number of the Journal.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

The Monthly Meeting of the Society was held on Wednesday evening, March 6, in the Chemical Society's Rooms, Burlington House. The President, Mr. L. Archbutt, F.I.C., occupied the chair.

The minutes of the previous Ordinary Meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. M. E. Balston, M.A., H. A. Caulkin, B.Sc., F.I.C., and C. R. Wilkins, B.Sc., were read for the second time, and certificates in favour of Messrs. Reginald Freeman Easton, 38, Edith Road, West Kensington, W., assistant to Mr. G. Cecil Jones, F.I.C., and Leonard Goodban, A.I.C., 43, Addison Gardens, W., assistant to Mr. Frederick Davis, were read for the first time.

Miss M. Gazdar, B.Sc., A.I.C., and Mr. H. Hawley, M.Sc., were elected members of the Society.

The following papers were read: "Standards for Malt Vinegar," by A. Chaston Chapman, F.I.C.; "The Estimation of Ammonia in Carbonated Waters," by G. D. Elsdon, B.Sc., and Norman Evers, B.Sc.; "A Note on a New Preservative for Milk, Cream, etc.," by George A. Stokes; "The Phosphomolybdate Estimation of Phosphoric Acid in Soils," by S. J. M. Auld, D.Sc., Ph.D., F.I.C.; and "A Method of Estimating Calcium Carbonate in Soils," by Herbert S. Shrewsbury, F.I.C.

NOTES ON THE DETERMINATION OF BUTTER FAT AND COCOANUT OIL IN MARGARINE.

By F. W. F. ARNAUD, F.I.C., and H. HAWLEY, M.Sc.

(*Read at the Meeting, February* 7, 1912.)

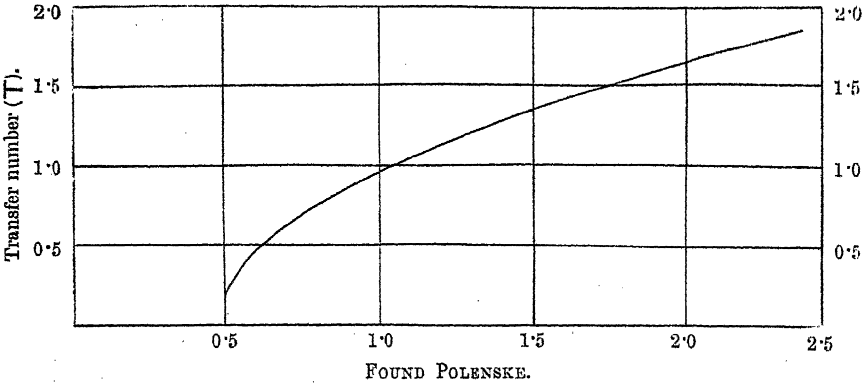
The method suggested by Cribb and Richards (Analyst, 1911, **36**, 327) for calculating from the Reichert and Polenske figures the percentage of cocoanut oil and butter fat in margarine mixtures yields excellent results with comparatively large proportions of cocoanut oil, but with quantities under 20 per cent. (the Polenske being below 2·5) the correction applied to the Reichert and Polenske figures is too great.

With the aid of the following formulæ and of the subjoined curve, deduced from the analysis of a variety of mixtures, the corrected Polenske figure may be obtained and the percentage of cocoanut oil calculated:

$$P = (P' - P'') - \frac{R}{10} + T.$$

P = corrected Polenske figure.
P′ = found Polenske figure.
P″ = Polenske figure of margarine fat free from cocoanut oil and butter (about 0·4).
T = correction ascertained from curve.

$$\text{Percentage of cocoanut oil} = \frac{100P}{17{\cdot}6}.$$



The butter fat is then found by the following method:

$$R = (R' - R'') - \text{Reichert due to cocoanut oil} - T.$$

R = corrected Reichert-Meissl figure.
R′ = found Reichert-Meissl figure.
R″ = Reichert-Meissl figure of margarine free from butter and cocoanut oil (about 0·6).
T = correction ascertained from curve.

$$\text{Percentage of butter fat} = \frac{100R}{25}.$$

The percentage of butter fat in any margarine mixture may be confirmed by the Kirschner process, for which purpose the following formula is recommended:

$$K = (K' - 0{\cdot}5) - \frac{P}{10}, \text{ in which}$$

K = corrected Kirschner figure.
K' = found Kirschner figure.
$0{\cdot}5$ = Kirschner figure of butter-free margarine.
P = found Polenske.

$$\text{Percentage of butter fat} = \frac{100\,K}{23}.$$

DISCUSSION.

Mr. C. H. CRIBB said that Mr. Richards and he had referred in their paper to the question of an allowance for the Reichert and Polenske figures of margarine fat in mixtures, but in the mixtures then dealt with there was never less than 20 per cent. of cocoanut oil and 20 per cent. of butter, so that the correction would be very small, and it seemed scarcely worth while to make it; but when the proportion of margarine might be as high as 90 per cent. it became necessary to take the correction into account.

Mr. E. R. BOLTON said that due regard must be had to the composition of the margarine. Margarine nowadays often contained notable quantities of lard, and, although lard itself had a very low Reichert-Meissl value, it exercised, when mixed with other fats, a curious altering effect on the volatile fatty acids.

* * * * *

STANDARDS FOR MALT VINEGAR.

By A. CHASTON CHAPMAN, F.I.C.

(*Read at the Meeting, March* 6, 1912.)

DESPITE the numerous attempts which have been made to define malt vinegar and to lay down analytical limits for its composition, the present state of affairs in regard to that condiment can scarcely be described as satisfactory. It is clearly a much simpler matter to say what malt vinegar should be in terms of the materials used or the methods adopted in its production than to lay down chemical standards of composition. The latest pronouncement in this country appears to be contained in a letter addressed by the Assistant-Secretary of the Local Government Board to the Secretary of the London and Country Vinegar Brewers' Association. In this it is stated that malt vinegar "is derived wholly from malted barley or wholly from cereals, the starch of which has been saccharified by the diastase of malt." Under the general definition of "vinegar," moreover, it is to be "a liquid derived wholly from alcoholic and acetous fermentations; it shall contain not less than 4 grammes of acetic acid (CH_3COOH) in 100 cubic centimetres of vinegar; it shall not contain arsenic in amounts exceeding 0·0143 milligramme in 100 cubic centimetres of vinegar, nor sulphuric or other mineral acid, lead, or copper; nor shall it contain any foreign substance or colouring matter except caramel." On June 26, 1906, the United States Department of Agriculture issued a circular (No. 19) giving definitions of various kinds of vinegar. In this circular malt vinegar is defined as "a product made by the alcoholic and subsequent acetous fermentations, without distillation, of an infusion of barley malt or cereals, whose starch has been converted by malt, is dextro-rotatory, and contains, in one hundred (100) cubic centimetres (20° C.), not less than four (4) grammes of acetic acid, not less than two (2) grammes of solids, and not less than two-tenths (0·2) gramme of ash; and the water-soluble ash from one hundred (100) cubic centimetres (20° C.) of the vinegar contains not less than nine (9) milligrammes of phosphoric acid (P_2O_5), and requires not less than four (4) cubic centimetres of decinormal acid to neutralise its alkalinity."

Some time ago a certain firm of vinegar manufacturers, finding that their vinegar, although made strictly in accordance with the requirements of the United States Department of Agriculture—that is to say, wholly from barley malt and cereals, without the use of any sugar whatever—did not comply with the analytical requirements of the Department, asked me, if I could, to explain the apparent discrepancy. On referring to the above definition, it will be seen that malt vinegar must be, among other things, dextro-rotatory; and presumably any vinegar which did not comply with the definition in this respect would not be admitted into the United States under the description of "malt vinegar." Now, it so happened that, whilst the vinegar manufactured by the firm in question sometimes had a dextro-rotatory action on polarised light, it was very much more frequently appreciably lævo-rotatory. Thus, twelve samples which I examined, and which represented in the aggregate almost the whole of the vinegar at that time in stock, were all lævo-rotatory, the rotations varying from $-0·56°$ to $-0·76°$ when examined in a tube 200 mm. long, using sodium light. Inasmuch as it was absolutely certain that no sugar of any description had been used in the manufacture of this vinegar, it became necessary to explain this lævo-rotation. It was clear that certain lævo-rotatory constituents had been extracted from the grain during the manufacture of the vinegar, and a moment's consideration sufficed to show that these constituents could only be the proteins or certain of the products of their hydrolysis, such as the proteoses, peptones, and amino-acids. It may be pointed out here that the vinegar in question contained an average of 0·085 per cent. of nitrogen, equivalent to 0·53 per cent. of proteins. It is, of course, very well known that the naturally-occurring proteins are almost invariably strongly lævo-rotatory, and the same applies to many of the products of their hydrolysis, particularly the proteoses and peptones, the specific rotatory powers of these substances for sodium light varying from $-50°$ to $-80°$ in a 200 mm. tube, using sodium light. Asparagine, which occurs in malt wort, is slightly lævo-rotatory, and certain other of the amino-acids and amides are slightly dextro-rotatory. The important point, however, is that the more complex products of hydrolysis are those which are most strongly lævo-rotatory. It is clear that, if it were possible so thoroughly to ferment away the carbohydrate constituents of malt wort as to leave practically nothing undecomposed, the protein matters present might quite well cause the resulting wash to exhibit a lævo-rotatory action, and my first experiments were directed to ascertaining whether such was the case. It is, of course, the practice of vinegar manufacturers to carry out the fermentations of their worts in the presence of diastase, since by this means the malto-dextrins and other comparatively stable carbohydrates are converted into fermentable substances, and so the maximum amount of alcohol, and subsequently of acetic acid, is obtained. In the experiments described below I have therefore carried out the fermentations of the worts in question in the presence of active diastase—that is to say, the worts were not boiled prior to the introduction of the yeast. In the first place, two worts having the same sp. gr. (1070°) were prepared from the same malt, and were pitched with a small quantity of ordinary distillers' yeast, the temperature being kept within the ordinary limits of practice. The fermentations were started on December 4, and five days later the sp. gr. of each had fallen below 1000°. The following results show the optical activities in a 200 mm. tube, using sodium light, of these worts on three different dates:

	No. 1.	No. 2.
December 9	−0·40°	−0·08°
,, 11	−1·00°	−0·70°
,, 13	−1·00°	−0·80°

Two further experiments were then made with worts of rather lower sp. gr. (1050°), and employing the yeast actually used in the vinegar factory in question in place of the distillers' yeast used in the preceding experiment. The following results were obtained:

	No. 1.	No. 2.
December 11	+0·54°	—
,, 13	+0·04°	+0·20°
,, 14	−0·44°	−0·04°

It will be scarcely necessary to point out that these worts were not examined polarimetrically until their density showed that almost the whole of the carbohydrate matter had disappeared, and for that reason no considerable *plus* rotations are shown. These results show very clearly that, with a sufficiently perfect fermentation, worts prepared from malt alone are capable of yielding liquids which are appreciably lævo-rotatory.

In the next place, experiments were directed to proving that the lævo-rotation of these worts was in fact due to the presence of proteins and their products of hydrolysis. If such were the case, it should be possible, by the removal of these substances, to convert a lævo-rotatory liquid into either an inactive or a dextro-rotatory one. It is well known that, by the combined use, under proper conditions, of aqueous solutions of mercuric acetate and phosphotungstic acid, both the proteins and the majority of the products of their hydrolysis may be removed from organic liquids without effecting any change in the carbohydrates present. The mercuric acetate solution used in the following experiments consisted of a saturated aqueous solution of the salt; the phosphotungstic acid solution consisted of a 25 per cent. solution of the substance in water without the addition of mineral acid. In the first place, the mercuric acetate and the phosphotungstic solutions were added to some fermented malt wort made in the laboratory, and having a rotation in a 200 mm. tube of −0·45°. After filtering and making the requisite correction for the dilution due to the volume of the reagents employed, the liquid was found to have a rotation of +0·46°. Similar experiments were then made with five samples of lævo-rotatory vinegar, with the following results, the numbers under (*a*) representing the rotation of the vinegar prior to the addition of the reagents, and those under (*b*) the rotation after filtration:

	(*a*)	(*b*)
No. 1	−0·63°	+0·02°
„ 2	−0·60°	inactive
„ 3	−0·65°	+0·08°
„ 4	−0·63°	+0·13°
„ 5	−0·72°	+0·06°

These results entirely bear out those obtained with the malt wort itself, and show that the lævo-rotation of this vinegar is, in fact, due to the presence of proteins and the products of their hydrolysis. During the process of fermentation the amino-acids, and to a less extent the proteoses and peptones, will have been utilised by the yeast for its nutrition, and the residual nitrogen in the vinegar must consist largely of proteins and of their more complex hydrolytic products—that is to say, of those substances which exhibit the greatest degree of lævo-rotation. I may perhaps add that I have made experiments with the mercuric acetate and phosphotungstic acid solutions in the presence of a small quantity of lævulose, and have found that when used under proper conditions these reagents bring about no change whatever in the rotation of that carbohydrate. This is borne out by experiments which have recently been made by Neuberg and Ishida (*Biochem. Zeitsch.*, 1911, **37**, 142-169), who call attention to the errors which may result in the polarimetric estimation of sugar in natural products owing to the presence of lævo-rotatory proteins and amino-acids. These authors have also made use of mercuric acetate and phosphotungstic acid, and have recorded a great many results to show that these reagents have no effect on the rotation of the carbohydrates present. The above results show very clearly that a genuine malt vinegar—that is to say, a vinegar prepared entirely from malt and cereals whose starch has been converted by diastase—need not necessarily be dextro-rotatory, but may be either lævo-rotatory or optically inactive. As further showing the fallacy of insisting on dextro-rotation as an indication of genuineness, it is only necessary to point out that the unfermentable matter in many samples of commercial invert sugar is optically inactive, and that even if a considerable proportion of invert sugar were used in the manufacture of the vinegar, the latter would not necessarily be lævo-rotatory. It would appear, therefore, that unless the United States Department of Agriculture modify their existing regulation, considerable injustice may be done, not only to the home producer, but also to vinegar manufacturers in other countries, whose malt vinegar may be optically inactive or slightly lævo-rotatory, and who may wish to introduce it into the United States. Whilst many samples of malt vinegar are undoubtedly dextro-rotatory, to insist upon this analytical requirement would be tantamount to excluding from the United States the vinegar of every manufacturer who is successful in very thoroughly fermenting away the carbohydrate constituents of his worts, and would practically amount to putting a premium on bad working, to say nothing of tempting dishonest manufacturers to make their vinegar comply with the requirements by the appropriate additions. Perhaps the simplest way of manufacturing a malt vinegar to insure its satisfying the United States authorities in respect of its rotation would be to employ in its manufacture a proportion of commercial glucose.

The requirements of the United States Department of Agriculture in respect of the proportion of soluble phosphoric acid in the ash of malt vinegar affords a further example of the inadvisability of putting forward standards for manufactured products, the composition of which must in the nature of things depend somewhat considerably on the precise methods adopted in their manufacture. The amount of phosphoric acid passing from the grain into the wort, as also that left in the soluble condition when the resulting vinegar is incinerated, must depend very largely on the mineral composition of the water used for mashing. Although this is sufficiently obvious, it may perhaps be of interest to record the following experiments which illustrate this point. Two different malts were taken, and were mashed (*a*) with distilled water, (*b*) with water containing about 20 grains per gallon of total dissolved solid matter, and (*c*) with a very hard water containing more than 100 grains per gallon of calcium sulphate. The mashes were made under precisely the same conditions of time and temperature, and were, in fact, treated in the same way throughout. At the end of the mashing period of one and a quarter hours the mashes were filtered, and the total phosphoric acid determined in the worts in the usual way.

MALT A.	Phosphoric Acid (P_2O_5).
Distilled water	46·56 grains per gallon.
Water containing 20 grains of total dissolved solid matter ...	42·44 ,, ,,
Very hard water	30·44 ,, ,,

MALT B.	Phosphoric Acid (P_2O_5).
Distilled water	44·77 grains per gallon.
Water containing 20 grains of total dissolved solid matter ...	37·61 ,, ,,
Very hard water	26·88 ,, ,,

I may add that in the preparation of the above worts the same proportions of malt and water were used in all cases. I have at different times examined several samples of genuine malt vinegar made with very hard water, and have found that when ignited they yielded ashes which contained almost the whole of the phosphoric acid in the insoluble condition—that is to say, as tribasic calcium phosphate. On extracting these ashes with water, the resulting solutions were practically free from phosphoric acid, and were almost neutral. I think I have shown that the United States definition of malt vinegar requires amendment in at least two respects, and have incidentally provided yet another example of the dangers of setting up official standards for the composition of manufactured foodstuffs.

My best thanks are due to my assistant, Mr. R. L. Collett, for help in connection with this investigation.

A METHOD OF ESTIMATING CALCIUM CARBONATE IN SOILS.

By HERBERT S. SHREWSBURY, F.I.C.

(*Read at the Meeting, March* 6, 1912.)

Methods of estimating calcium carbonate in soils depending on the measurement of carbon dioxide evolved from the carbonates by absorption or otherwise have not been found very satisfactory; the modified method proposed by F. S. Marr (*J. Agricultural Science*, 1909, **3**, 155) appears to give good results, but is somewhat lengthy, and entails rather special apparatus and skilful manipulation for its successful application.

An alternative method which I have devised depends upon the extraction of the calcium carbonate from the soil in $\frac{N}{4}$ acetic acid, the conversion of the calcium acetate so formed into calcium oxide and its solution in $\frac{N}{10}$ acetic acid, and the titration of the excess of acid required by the lime with $\frac{N}{10}$ potash or soda, using phenolphthaleïn as an indicator.

Ten grms. of finely divided air-dried soil are placed in a dry wide-mouthed flask or bottle, and 100 c.c. of approximately $\frac{N}{4}$ acetic acid are added. For a period of ten minutes the flask is shaken with a rotary movement every time the bulk of the soil settles, which occurs about every thirty seconds. The soil is then allowed to settle for the last time, and the liquid contents of the flask decanted through a dry filter. Schleicher and Schüll's filter cones answer the purpose admirably. A control experiment is made with another 10 grms. of soil, using distilled water as the extracting solvent. Twenty-five c.c. of each filtrate are evaporated to dryness in a platinum dish, and ignited at a bright red heat for thirty minutes, the residues when cool being treated with 10 c.c. of $\frac{N}{10}$ acetic acid (or more if necessary). Solution is effected in a few minutes, particularly if the residues are gently rubbed with a glass rod tipped with a small rubber bung.

The excess of acid is then titrated with $\frac{N}{10}$ soda or potash, using phenolphthaleïn as indicator. The volume obtained from the control is now subtracted from that obtained from the acid extraction of the soil, and the result multiplied by 0·2. The product gives the percentage of calcium carbonate in the soil.

Notes on the Process.—The quantities given will answer for soils containing up to 5 per cent. of calcium carbonate, which covers the usual range. For larger percentages proportionate amounts of soil are taken. The time and method of extraction were based on experiments made with pure calcium carbonate and $\frac{N}{4}$ acetic acid.

Some soils appear to retain a portion of the calcium acetate, presumably by reason of a greater concentration of the solution occurring in immediate contact with the soil particles. The occasional error due to a soil of this type does not appear to be large enough to warrant a complete washing of the soil, an operation which is lengthy and tedious.

The purpose of the control is to measure alkaline carbonates and alkaline organic salts, soluble organic calcium salts, calcium nitrate, or any bodies which are soluble in water, and which on ignition leave an alkaline residue soluble in $\frac{N}{10}$ acetic acid. One-tenth c.c. of $\frac{N}{10}$ acid was the maximum obtained in this titration for three soils that were examined. $\frac{N}{10}$ acetic acid is chosen for the solution of the residues because it does not dissolve ignited iron oxide, whilst easily attacking calcium oxide.

It is preferable to measure the calcium oxide by titration rather than to weigh it or estimate it by conversion into oxalates and comparison of the turbid liquid with standards, since the first method excludes other salts of calcium than the carbonate, with the possible exception of organic calcium salts insoluble in water but soluble in $\frac{N}{4}$ acetic acid. It is desirable to make qualitative tests on the same volumes of the acetic acid extract of the soil for the presence of calcium and magnesium, chlorides and sulphates.

Frequently the last three are only present in traces.

If the amount of magnesium is comparatively large, it may be quickly estimated by the method given by Thresh ("Examination of Water and Water-Supplies," p. 238), depending on the comparison of the precipitate obtained with sodium hydrogen phosphate (after removal of calcium with ammonium hydrate and ammonium oxalate), when shaken up in a certain volume of water, with standards prepared in the same way. The magnesium estimated would of course include any salt of magnesium soluble in $\frac{N}{4}$ acetic acid, but in most soils the error introduced would be insignificant.

The following table sets out the results of test experiments, made with the process on soils prepared with known percentages of calcium carbonate. The sample of precipitated chalk used for this purpose was analysed, and found to contain practically 100 per cent. of calcium carbonate:

Sample of Soil.	Per Cent. Calcium Carbonate in Soil.			
	Originally Present.	Added.	Total.	Found by Process.
A. Surface soil from soft ferruginous shale ...	0·07	0·05	0·12	0·13
B. Heavy clay subsoil previously treated with hot concentrated hydrochloric acid for twelve hours, washed, and dried in steam-oven	Nil	0·50	0·50	0·50
C. Clay subsoil	0·29	0·50	0·79	0·61
D. Clay subsoil	0·23	4·76	4·99	4·86

GOVERNMENT LABORATORY,
TRINIDAD, B.W.I.

THE PHOSPHOMOLYBDATE ESTIMATION OF PHOSPHORIC ACID IN SOILS.

By S. J. M. AULD, D.Sc. (Lond.), Ph.D., F.I.C.

(*Read at the Meeting, March* 6, 1912.)

The necessity of estimating very small quantities of phosphoric acid during the chemical analysis of soils has lead to the suggestion of many methods for the direct utilisation of the bulky phosphomolybdate precipitate, instead of finally precipitating its ammoniacal solution with magnesia mixture.

The difficulties attending these methods are concerned chiefly with the variation in composition of the yellow ammonium phosphomolybdate precipitate, the constitution of which has been the subject of much investigation. Under standard methods of precipitation, however, any variation in composition is practically confined to the amount of ammonia in combination and to the quantity of water of crystallisation; this, of course, apart from the possible co-precipitation of molybdic acid, admixture with other ammonium salts or incomplete separation (in soil analysis) from silica, etc. The ratio of $P_2O_5 : MoO_3$ was originally stated by Debray and others to be 1 : 20, but was definitely shown by Finkener (*Ber.*, 1878, **11**, 1638) and Gibbs (*Amer. Chem. J.*, 1882, **3**, 317) to be $P_2O_5 : MoO_3 = 1 : 24$. This has been confirmed more recently by Levi and Spelta (*Gazz. Chim. Ital.*, 1903, **33**, 207). Gibbs gives the formula of the yellow precipitate as

$$(NH_4)_3PO_4{\cdot}12MoO_3 + (NH_4)_2HPO_4{\cdot}12MoO_3 + 8H_2O;$$

whilst Finkener describes the precipitate, washed with ammonium nitrate solution and carefully heated in a crucible until the ammonium nitrate is volatilised, as

$$(9 - x)(NH_4)_2O{\cdot}xH_2O{\cdot}3P_2O_5{\cdot}72MoO_3,$$

where x generally equals 1. Carnot (*Bull. Soc. Chim.* 1893, **9**, 343) regards the reprecipitated compound as

$$3(NH_4)_2O{\cdot}P_2O_5{\cdot}24MoO_3{\cdot}3H_2O,$$

and Hundeshagen (*Zeit. f. Anal. Chem.*, 1889, **28**, 141) states that the precipitate dried at 130° C. is always

$$(NH_4)_3PO_4{\cdot}12MoO_3,$$

independent of the content of mineral acids, phosphoric and molybdic acids, or ammonium salts. The ratio $NH_4 : P_2O_5$ is thus variously given as 5 : 1, 16 : 3, and 6 : 1. This may possibly be due to the fact, shown by Levi and Spelta (*loc. cit.*) that phosphomolybdic acid contains twenty-seven replaceable hydrogen atoms, five of which behave differently from the remaining twenty-two. The estimation of phosphoric acid by Carnot's method (*loc. cit.*), by weighing the reprecipitated compound after drying at 100° C., which is still extensively used and recommended in certain textbooks, should therefore be rejected on the grounds of insufficient evidence of composition; besides which, the coefficient recommended by him—viz., 0·0373—is calculated on the *fully hydrated* precipitate of the formula given above. On the other hand, the factor 0·043 recommended by the Committee of the Association of Official Agricultural Chemists of the United States has been recognised as inaccurate (*cf.* Wiley's "Agricultural Analysis, i. 423). To test the possible removal of water of hydration during drying, and the composition of the residual precipitate, an extended series of analyses by the Carnot method were carried out, using standard solutions of purified sodium phosphate to check the results, which were also controlled by dissolving the precipitates in ammonia solution and precipitating with magnesia mixture. Previous to drying, the precipitates were thoroughly washed with a 1 per cent solution of nitric acid.

TABLE I.

Series.	Volume of $\frac{N}{5}$ Na_2HPO_4 Solution.	Weight of P_2O_5.	Precipitate dried at 100° C.		Precipitate dried at 105° to 110° C.	
			Average Weight.	Factor.	Average Weight.	Factor.
	C.C.	Grms.	Grms.		Grms.	
1	20	0·0946	2·5165	0·0376	2·5045	0·0378
2	15	0·0710	1·8761	0·0378	1·8732	0·0381
3	10	0·0473	1·2671	0·0375	1·2443	0·0381
4	5	0·0236	0·6300	0·0376	0·6185	0·0383

Although carried out with care, a number of the estimations gave only approximate results, and these were not included in the above table. The method was certainly not completely satisfactory, and if used should probably be calculated from the coefficient 0·0378, the theoretical value for the anhydrous salt. This, however, probably does not represent the true state of affairs, and it will be noticed that heating for some time at 105° to 110° C. gives a residue containing a percentage of phosphoric acid incompatible with Hundeshagen's asserted stability of the ammonium salt, assuming that his simple formula correctly represents its composition. This tends to confirm the statement of Dehérain ("Chim. Agricole," p. 449) that decomposition may ensue if the yellow precipitate is heated above 90° C. He recommends the factor 0·0376.

It was chiefly, however, for the purpose of examining the more generally adopted procedure of gravimetrically estimating the P_2O_5 in soils that this work was started. The operation, first suggested by Hehner (ANALYST, 1879, 4, 23), consists of dissolving the ammonium phosphomolybdate precipitate in dilute ammonia, evaporating the ammoniacal solution, and weighing the residue after drying or gentle ignition. The factors employed for calculating the percentage of phosphoric acid vary somewhat according to different authors and works of reference, but, from their order of magnitude, apparently frequently depend on an assumed stability of the combined ammonia on heating at moderate temperatures:

Mode of Treatment.	Factor.	Reference.
Heat gently to volatilise the ammonium nitrate	0·0374	Finkener (*loc. cit.*).
Ignite gently over an Argand burner	0·0379	Hall ("The Soil," p. 146).
Repeated evaporation to dryness with small quantities of water ...	0·0350	Hehner (*loc. cit.*, p. 27).
Heat to dark blue colour	0·0396	Wood ("Pract. Agric. Chem.," p. 17).

The difference in the factors becomes of importance when one is forced to estimate very small quantities of P_2O_5, as, for example, in the estimation of available or "citric soluble" phosphoric acid in soil. In this case there is difficulty in increasing the amount of material used, and the weight of the final residue may not amount to more than 0·3 to 0·4 grm. During the heating, the residues generally take on a more or less blue colour—sometimes to a very considerable extent—and this cannot be controlled to any particular stage coincident with the complete removal of the extraneous ammonium salts. Hehner avoided this by washing the precipitate with dilute alcohol, dissolving in ammonia, and weighing the residue after repeated evaporation to dryness with small quantities of water.

The formation of the blue colour generally obtained would also indicate a partial decomposition of the phosphomolybdate, and suggest *prima facie* that the residue should be obtained either wholly yellow or wholly blue. That one is not so likely to obtain a uniform product at all by dissolution of the yellow precipitate in ammonia may be gathered from a consideration of the reactions involved.

According to Levi and Spelta (*loc. cit.*), ammonia resolves ammonium phosphomolybdate into ammonium phosphate and ammonium molybdate. Certainly, repeated evaporation of the ammoniacal solution with water gives acid molybdate and ammonium phosphate. But the reaction is probably not quite so simple as might be expressed by the equation

$$x(NH_4)_2O{\cdot}P_2O_5{\cdot}24MoO_3 + 2(27-x)NH_4OH = 24(NH_4)_2O{\cdot}MoO_3 + \\ 2(NH_4)_3PO_4 + (27-x)H_2O,$$

and may, at any rate partially, involve the formation of ammonium phosphopentamolybdate:

$$x(NH_4)_2O{\cdot}P_2O_5{\cdot}24MoO_3 + 2(22-x)NH_4OH = 19(NH_4)_2O{\cdot}MoO_3 + \\ 3(NH_4)_2O{\cdot}P_2O_5{\cdot}5MoO_3 + (22-x)H_2O.$$

This would serve as an explanation of the separation from the ammonia solution by Gibbs (*loc. cit.*), under certain conditions, of Debray's duodecaphosphomolybdate, since the pentaphosphomolybdate salts in certain circumstances split off phosphoric acid:

$$4(5MoO_3{\cdot}P_2O_5) + 9H_2O = 20MoO_3{\cdot}P_2O_5 + 6H_3PO_4.$$

It is difficult to see, therefore, how a satisfactory product for weighing can be obtained by heating the residue at 100° C. or by partial ignition, since ammonium phosphate readily loses ammonia on heating, and the molybdate is partially reduced with the formation of blue molybdic oxide (Mo$_3$O$_8$). There would also appear a possible danger, by overheating, of loss of phosphoric acid. By the ordinary method used in the analytical laboratories of the South-Eastern Agricultural College, the residue is heated over an Argand burner for some time, and weighed in a partially blue state. Taking at random the residue in five phosphoric acid estimations in soils, and further heating, till uniformly blue, over a medium-sized Bunsen flame, different percentage losses were obtained, although the blue residues after moderately strong heating for another half-hour in no case lost any further weight.

TABLE II.

Soil.	Weight of Residue; partially Blue.	Weight of Residue; wholly Blue.	Loss on Heating.
	Grms.	Grms.	Per Cent.
1	0·0770	0·0710	7·5
2	0·1595	0·1535	3·7
3	0·0981	0·0909	7·1
4	0·1452	0·1390	4·1
5	0·0679	0·0650	4·4

The effect of heating until uniformly blue and of constant weight was consequently tried with precipitates dissolved in ammonia obtained from standard phosphate solutions, and also with soil extracts, in order to determine the constancy of the P$_2$O$_5$ content. The results are given in Tables III. and IV.

TABLE III.

Solutions of $\frac{N}{5}$ Sodium Phosphate.

This series of soils was simply one of many tested during the ordinary routine analytical work, and the residues in Column 3 give the actual weights taken for calculation. The difficulty of testing the soil content sufficiently accurately by estimation as magnesium pyrophosphate may be responsible for the high factor obtained, but the experience gained in these numerous analyses rather points to a difficulty of preventing the decomposition of the yellow compound where the amount is small, and the gradual attainment of a more uniform weight and factor on heating. From this point of view the figures in Tables III. and IV. are very suggestive, the rather bluer "yellow" residues from the smaller phosphoric acid content of the soils giving higher, but more concordant, factors than those from the yellower residues of Table III. It must be remembered, also, that the residues in Column 3 of Table IV. were obtained by Mr. R. H. Carter, the College analyst, in the ordinary course of practice, and in the case of the higher factors for P. 1 and Q.B. the residues were much more blue than the others.

The experiments would therefore seem to show that residues containing, on the average, 3·891 per cent. of phosphoric acid are generally obtained by the method described by Hall, as against the 3·794 actually laid down. The factors obtained by heating the ammoniacal solution residues to complete blueness are more concordant than those obtained in practice from the yellow residues, and average 0·0393; but, in harmony with the non-uniformity of the residue, as shown above, the results vary somewhat.

Much better results were obtained by heating the yellow ammonium phosphomolybdate precipitate direct until it is of a blue colour. This method is described by Wood (*loc. cit.*). He gives the blue residue the same formula—viz., $P_2O_5 \cdot 24MoO_3$—as that obtained by heating the residue after dissolution in ammonia, and uses the same coefficient for calculating the results—viz., 0·0396.

Owing to the necessity of freeing the yellow precipitate from silica or other contamination, the procedure described below was eventually adopted.

Method Recommended.—The yellow precipitate obtained in the ordinary way is dissolved in dilute ammonia, and the filtered solution reprecipitated by the addition of excess of nitric acid (1 part of acid to 2 parts of water). A further 5 c.c. of ammonium molybdate solution are also added, and the mixture is allowed to stand in a warm place for some time, as in the first precipitation. The precipitate thus obtained is of a fine consistency, and may be completely filtered with ease and rapidity through a Gooch crucible. It is then washed thoroughly with 1 per cent. nitric acid, dried in the oven, and ignited until of a uniform dark blue colour and of constant weight. During ignition the base of the Gooch should be protected by a cap or by placing it inside another crucible.

A quicker method, useful for students, and nearly as accurate, consists of reprecipitating the ammonia solution with nitric acid in a porcelain dish, washing out most of the ammonium nitrate by decantation, and, after drying on the water-bath, igniting until uniformly blue. Very little phosphoric acid remains in solution after addition of the nitric acid.

The results obtained by the method are given below:

TABLE V.

Experiment.	Weight of P_2O_5 taken.	"Yellow" Residue.		Blue Residue.	
		Weight.	Factor.	Weight.	Factor.
	Grms.	Grms.		Grms.	
1	0·0473	1·2391	0·0382	1·2015	0·0395
2	0·0473	—	—	1·2010	0·0395
3	0·0236	—	—	0·5970	0·0396
4	0·0236	0·6250	0·0379	0·5975	0·0396
5	0·0710	—	—	1·7925	0·0396
6	0·0946	2·4705	0·0383	2·3800	0·0397
7	0·0236	0·6255	0·0380	0·5961	0·0396
8	0·0236	0·6230	0·0379	0·6011	0·0394

The factors from the yellow resides vary much as before, but by careful manipulation very constant results were obtained with the blue residues, the average being 0·0396.

It is interesting to find that the coefficient obtained does not correspond to the phosphomolybdic acid ($P_2O_5 \cdot 24MoO_3$), which contains 3·94 per cent. of P_2O_5, but to a partial reduction corresponding to the formula $P_2O_5 \cdot Mo_3O_8 \cdot 21MoO_3$.

SUMMARY OF RESULTS.

1. Owing to the difficulty of controlling the amount of ammonium salts present, and the possible variation of the amount of combined ammonia, methods of weighing the phosphomolybdate precipitate direct should be avoided. If used, Carnot's method should be employed, using the factor 0·0378.

2. If the precipitate is dissolved in ammonia, the difficulty of removing ammonium salts without, in practice, decomposing the residue to an indefinite extent renders it desirable to weigh the residue in the uniformly blue condition. In

the ordinary method of heating till partially blue, the factor used should be 0·0389; if heated until quite blue, 0·0393.

3. Since ammonia splits up the ordinary phosphomolybdate precipitate on solution, and the P_2O_5 content of the residue may be subject to variation, it is best to reprecipitate the ammoniacal solution with nitric acid, filter through a Gooch crucible, wash, and ignite the residue until dark blue in colour and of constant weight. Factor = 0·0396.

4. As a quicker method of carrying out the operation, the reprecipitated phosphomolybdate may be washed by decantation, evaporated to dryness on the water-bath, and the residue ignited direct, using the same coefficient for calculating the result.

The author wishes to thank Mr. F. Knowles for carrying out some of the analyses quoted above.

CHEMICAL DEPARTMENT,
SOUTH-EASTERN AGRICULTURAL COLLEGE, WYE.

DISCUSSION.

Dr. DYER said that ever since Hehner read his paper in 1879, he had adopted Hehner's modification of the molybdic acid process for the determination of such small quantities of phosphoric acid as were contained in soil. If, after the ammoniacal solution was evaporated down, the residue was again evaporated two or three times with water, as Hehner had suggested, a precipitate was obtained which could be rapidly dried in the water-oven to a constant weight. If the evaporation with water were omitted, the residue had to be kept in the water-oven for a much longer time.

The PRESIDENT said that he used the molybdic acid method for the determination of phosphorus, chiefly in the case of steel and iron. The composition of the compound was perfectly definite, provided it was precipitated under definite conditions, which conditions, of course, must be duly learnt. Having obtained the precipitate under those definite conditions, he thought it immaterial by what method it was weighed. He had never found any difficulty in obtaining correct results by drying the precipitate in a porcelain crucible at 100° C. in the water-oven, the precipitate being rinsed from the filter-paper into the crucible and dried and weighed. Latterly, however, he had adopted the more rapid method of Handy—namely, dissolving the precipitate from the filter with a standard solution of caustic soda and titrating back the excess of soda with standard nitric acid solution. When it was desired to check the results, a larger quantity of steel was taken, and the larger molybdate precipitate was redissolved, and the phosphorus precipitated with magnesia mixture and weighed as magnesium pyrophosphate. The results commonly agreed within a point or two in the third decimal place, which showed that the composition of the molybdate precipitate was quite definite, and also that its reaction with caustic soda was definite, so that probably its reaction with ammonia would be equally definite.

Dr. AULD, in reply, said that the estimation of phosphoric acid in soil called for a nearer approach to absolute accuracy than many other chemical estimations, because in the conversion of the results, say, into pounds per acre, any error that might exist was very largely multiplied. He therefore could not agree that it was not desirable to get as near to scientific exactitude as possible. It was only recently that his attention had been directed to Hehner's method, and he had never seen it used—perhaps because the washing of the precipitate with alcohol and its repeated evaporation with water were regarded as troublesome—and from that point of view it was an advantage to be able to weigh the precipitate at once without further manipulation. He agreed that the composition of the precipitate was, practically speaking, constant, but with very small quantities* the error due to the use of an inexact factor became relatively large. He had found titration to give good results, but in order to keep the experimental error of reading within proper limits about 12 c.c. of liquid must be used in an ordinary burette, and with soils the precipitate was usually too small to allow of this unless the quantity worked upon was inconveniently large.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Micro-Chemical Detection of Certain Alkaloids. A. Grutterink. (*Zeitsch. anal. Chem.*, 1912, **51**, 175-234.)—The reactions between alkaloids and many other substances are described, and particular information is recorded as to the crystalline compounds which are formed as the result of these reactions. In many cases the crystals are characteristic, and may be obtained from very small quantities of the alkaloids. In the original paper the reactions are recorded in tabular form, and those relating to the alkaloids of the strychnine, cocaine, quinine, and calumba groups receive special attention. Many of the natural and synthetic bases may be identified microscopically, the following organic acids yielding characteristic compounds or crystals: *m*-nitrobenzoic acid (with strychnine); *p*-nitrobenzoic acid (with strychnine and tropacocaine); dinitrobenzoic acid (with hydrastine, novocaine, brucine, and strychnine); trinitrobenzoic acid (with novocaine, tropacocaine, strychnine, brucine, and conine); dinitro-anisic acid (with hydrastamide); dihydroxybenzoic acid (with cinchonine); trihydroxybenzoic acid (with quinidine); opianic acid (with brucine); meconic acid (with quinidine); mellitic acid (with quinidine and cinchonidine); naphthalenesulphonic acid (with cocaine and strychnine); *p*-nitrophenylpropiolic acid (with hydrastinine, hydrastine, strychnine, tropacocaine, cinchonidine, nicotine, and hydrastamide). Potassium permanganate is also a very useful reagent for the micro-chemical detection of hydrastinine, hydrastine, tropacocaine, and cotarnine. W. P. S.

* Such as were obtained in estimating the "citric soluble" phosphoric acid in soil, and in which the weight of residue might not be more than 0·03 grm.

Process of Extracting Alkaloids from Syrups. E. Kohn-Abrest. (*Bull. Soc. Chim.*, 1912, **11**, 73-75.)—When a syrup containing alkaloids is treated with alcohol and solid potassium carbonate, the alcohol, in causing the dehydration of the potassium salt, simultaneously precipitates the sugar, whilst the alcohol forms a supernatant layer containing the whole of the alkaloids present. Syrups of sp. gr. 1·15 to 1·20 should be shaken with about four times their volume of absolute alcohol and about their own weight of potassium carbonate, the shaking being repeated several times, and the mixture then left for twelve hours. In the case of more concentrated syrups it is preferable to use 95 per cent. alcohol to insure complete elimination of sugar from the alcoholic layer. After standing for a sufficient time, the alcoholic extract is decanted, filtered, and distilled, and the residue taken up with a little absolute alcohol and again filtered. The fresh residue is dissolved in 10 to 15 c.c. of boiling chloroform, the filtered solution evaporated, the residue dissolved in hydrochloric acid, the solution evaporated to dryness, and the hydrochloride of the alkaloid crystallised. The method has given excellent results with syrups containing morphine, codeine, quinine, strychnine, and atropine. Thus, 20 grms. of a syrup containing 0·040 grm. of morphine hydrochloride gave a residue of 0·15 grm., which, after purification as described, yielded 0·040 grm. of crystals consisting entirely of morphine hydrochloride. C. A. M.

Estimation of Glycyrrhizic Acid in Liquorice Juice. H. Cormimbœuf. (*Ann. Chim. anal.*, 1912, **17**, 47-50.)—In the following method the errors caused by the solubility of glycyrrhizic acid in water (about 0·5 per cent.) are eliminated: Two grms. of the sample are treated with 50 c.c. of hot water, the solution filtered through a tared filter, and the insoluble organic matter washed with 50 c.c. of hot water, dried, and weighed. The filtrate is treated with 5 c.c. of N-sulphuric acid and allowed to stand for about twelve hours, after which the supernatant liquid is decanted, and the precipitated glycyrrhizic acid washed with as little water as possible until the washings are no longer acid. The precipitate is now dissolved in ammonia solution, and the resulting solution will contain the bulk of the glycyrrhizic acid. The filtrate and the washings are then evaporated nearly to dryness, the black viscous residue is mixed with successive portions of 10, 10, and 5 c.c. of water, and the liquids filtered after each treatment. The fresh quantity of glycyrrhizic acid thus separated is dissolved in ammonia solution and added to the main solution, the whole being then evaporated to dryness, and the residue of ammonium glycyrrhizate dried at 100° C. until constant in weight. The gummy substances may be estimated by evaporating the last filtrate to dryness, drying the residue at 100° C. until constant in weight, and deducting 0·330 grm. for the ammonium sulphate corresponding to the 5 c.c. of N-sulphuric acid originally added. As thus separated the gummy substances should be a transparent yellow mass, which, when dissolved and treated with an acid, should not yield more than a trace of glycyrrhizic acid. In various estimations the amount of glycyrrhizic acid retained by the gums did not exceed 0·010 grm., corresponding to a negligible error of not more than 0·5 per cent. in the amount of ammonium glycyrrhizate in the sample. (*Cf.* ANALYST, 1911, **36**, 409, 410, 497.) C. A. M.

Bitter Resins of Hops in Worts and Beers and their Volumetric Estimation. D. Neumann. (*Wochensch. Brau.*, 1912, **29**, 97-99.)—In a previous note (ANALYST, 1912, 92) the author described how the resins could be extracted from wort or beer by means of ether without the production of troublesome emulsions. The beer is shaken, in small portions at a time, with five times its volume of ether, the same ether being used for each successive portion of wort or beer until the entire sample has been treated. Each extraction should be performed in a shaking machine for at least fifteen minutes. The ethereal extract is concentrated to a volume of 15 to 20 c.c.; it is treated with 40 to 50 c.c. of benzene, and transferred to a separating funnel, in which it is washed with water until the washings are neutral. Too vigorous shaking at this stage is to be avoided. Finally, the ethereal benzene solution of the resins is titrated with $\frac{N}{10}$ alcoholic potassium hydroxide according to the usual method of hop analysis. The error, due to the carbon dioxide of the air, using phenolphthaleïn, amounts to about 0·1 c.c. of $\frac{N}{10}$ potash, or 0·004 grm. of bitter resin. Performed in conjunction with a blank test, this method appears to give very satisfactory results when applied to unhopped worts, to which known quantities of standardised hop-extract were added. But when the worts were boiled for two hours under a reflux condenser with the hop resins, a considerable deficiency, corresponding to about 35 per cent. of the original resin, was found on analysis. This deficiency is not due to loss of resin by volatilisation or precipitation, but evidently corresponds to a constitutional change in the resin itself. Experiments with the purified crystalline α-resin of hops showed that this substance, after boiling with wort, undergoes a change, whereby a portion of it becomes soluble in water without losing its bitter properties, and is removed in the washing process. The author has applied his method to the analysis of ordinary beers (1 litre taken for extraction), and found that it gave concordant results with beers of the same manufacture, and that it showed clearly the effect of variations in the proportions of hops used in brewing. J. F. B.

Examination of Meal. E. Kohn. (*Chem. Zeit.*, 1912, **36**, 121-123.)—In the microscopical examination of meals for the detection of foreign seeds, the author prepares the sample in the following manner: 0·5 grm. of the meal is shaken in a test-tube with 10 c.c. of ether, and the mixture is poured out into a wide, shallow porcelain dish. The characteristic seed-hairs for the identification of the meal constituents can easily be floated off from the surface of the ether in the test-tube, whilst yellow-coloured bran particles and foreign impurities can be separated by tilting the dish so as to spread the liquid in a thin layer as the ether evaporates. Alternatively, the ethereal-meal suspension may be poured on to filter-paper and allowed to spread out.

A method for the differentiation of various meals may be based on the variable rates of the attack on the starch granules by diastase. Two grms. of starch or meal are weighed out into a 300 c.c. Erlenmeyer flask, mixed with 100 c.c. of water, 0·4 grm. of Merck's diastase, and 1 c.c. of $\frac{N}{10}$ hydrochloric acid. The mixture is digested at the optimum temperature (50° to 52° C.) for a given time—*e.g.*, four hours. The liquid is filtered, and the amount of dissolved solids or sugar is determined with the pyknometer, or preferably by Fehling's solution. The figures so obtained are compared with those established with standard meals. Rye starch or meal gives the highest values, bean flour the lowest; wheat flour shows higher values than barley. The values vary slightly for different grades of the same flour; mixtures show intermediate values.

J. F. B.

Estimation of Potassium Nitrate in Meats. J. Tillmans and A. Splittgerber. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 49-56.)—When the quantity of potassium nitrate in a sample of meat does not exceed 1·5 per cent., it may be accurately estimated by Noll's brucine-sulphuric acid method, or by the diphenylamine-sulphuric acid method. In order to obtain a solution to which the reagents may be applied, the following procedure is recommended: Fifty grms. of the finely-divided meat are immersed in about 500 c.c. of water for three hours, with occasional shaking; the aqueous portion is then decanted through a filter and diluted to a volume of 1 litre. Fifty c.c. of this solution are now treated with 50 c.c. of a mixture consisting of equal volumes of 5 per cent. mercuric chloride solution and 2 per cent. hydrochloric acid, and, after filtration, the nitrate is estimated in a definite volume of the filtrate by means of the methods mentioned; the comparison solutions employed should contain definite quantities of potassium nitrate, and, in the case of the diphenylamine method, sodium chloride must be added to these solutions as well as to the meat solution (*cf.* ANALYST, 1911, **36**, 67). The brucine-sulphuric acid method will be found to be the more convenient for single estimations, and the diphenylamine method preferable when a series have to be made. In cases where the amount of potassium nitrate present in the meat exceeds 1·5 per cent., Schloesing's method should be employed. The results of a considerable number of analyses are given, which show that the methods are trustworthy. The preparation of the diphenylamine reagent has been described previously (*loc. cit.*), and the brucine reagent is made by moistening 0·25 grm. of brucine with water, and then dissolving it in 100 c.c. of concentrated sulphuric acid.

W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Estimation of Dextrose in Urine and Blood. B. Oppler. (*Zeitsch. physiol. Chem.*, 1911, **75**, 71-134; through *Chem. Zentralbl.*, 1912, I., 380-381.)—For the estimation of dextrose at concentrations below the limits at which the qualitative tests are sensitive, the urine is decolorised by the addition of crystallised phosphotungstic acid, protected from the light. After standing for twelve hours, the liquid is filtered, and the filtrate treated with neutral lead acetate; after a further twelve hours in the dark it is again filtered, and the lead is removed by hydrogen sulphide. Urines thus treated in most cases no longer contain any perceptible quantity of lævo-rotatory substances; at the same time, substances which interfere with the cupric reducing reaction are removed. The dextrose can then be estimated by polarisation, or cupric reduction, before and after fermentation by yeast. Healthy urine contains, however, cupric reducing, optically inactive substances, which are removable by yeast, to an amount equivalent to 0·04 per cent. of dextrose. In the urine of mental patients dextrose was found in the majority of cases, but mostly in small amounts. Such urine frequently shows an abnormally high lævo-rotation, equivalent to as much as 0·97 per cent. of glucose. The application of the above method of purification to blood showed that the colouring, lævo-rotatory, and interfering matters of the serum behaved very much in the same way as those present in urine, and the methods applicable for the estimation of sugar in urine are likewise suitable in the case of blood. J. F. B.

Estimation of Sugar in Blood. D. Takahashi. (*Biochem. Zeitsch.*, 1911, **37**, 30-33.)—Results of estimations of sugar in dogs' blood by various methods are recorded; the methods described by Bertrand and by Kumagawa and Suto yielded results which agreed with one another and with those obtained by the polarimetric method. The total amount of sugar found to be present varied from 0·12 to 0·18 per cent. when these methods were employed, whilst Bang's method gave results which were about 0·03 per cent. higher. No sugar was found after fermentation.

W. P. S.

Are the Alkalinity and Peroxydase of Milk Identical? W. D. Kooper. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 1-13.)—The alkalinity value of milk (as measured by the quantity of acid required to change the violet coloration to green when 100 c.c. of milk are treated with a mixture containing *p*-phenylenediamine hydrochloride, guaiacum, and hydrogen peroxide, the alkalinity value being expressed in c.c. of $\frac{N}{10}$ acid) is not a constant quantity, varying from 106 to 112, with an average of 110. The value is higher for colostrum, but decreases as the lactation period proceeds; for fresh goats' milk it generally lies above 120. The addition of water to milk raises the value, whilst the acidity of the milk is diminished, and the decrease in the acidity is greater in the case of old milk than with fresh milk; on the contrary, the increase in the alkalinity is smaller. These and other results of an investigation carried out by the author led him to the opinion that the property possessed by milk of being capable of producing a coloration with the above-mentioned reagent is due to the action of inorganic compounds contained in the milk. These compounds appear to be various phosphates of the alkalis and alkali-earths. W. P. S.

Separation of Rennin and Pepsin by Means of the Electric Current. W. E. Burge. (*Amer. J. Physiol.*, 1912, **29**, 330-334; through *Chem. Zentralbl.*, 1912, I., 687.)—When an electric current of 10 milliampères was passed through a solution containing rennin and pepsin for twenty-four hours, the liquid completely lost its property of digesting fibrin, whereas the activity of the rennin, as displayed by its power of coagulating fresh milk, remained unchanged. J. F. B.

Estimation of the Acidity of Urine. L. Grimbert and J. Morel. (*Comptes rend.*, 1912, **154**, 378-380.)—In titrating the acidity of urine, with phenolphthaleïn as indicator, apparent neutrality is obtained when the monosodium phosphate has been converted into disodium phosphate, but the *absolute* acidity would correspond to the formation of trisodium phosphate. If the conversion of the monosodium salt into the disodium salt be regarded as indicating the *real* acidity, account must still be taken of the influence of ammonium and calcium salts upon the results of the titration. The first source of error may be obviated by titrating the ammonia by Ronchèse's formaldehyde method, and making a correction from the result obtained; and the second by adding to the urine a small quantity of powdered potassium oxalate to remove the calcium salts. If, then, the proportion of phosphoric acid in the urine $\left(=\frac{P_2O_5}{2}\right)$ be calculated into that of the corresponding monosodium salt, the acidity of the latter towards phenolphthaleïn will represent the phosphatic acidity, p, of the urine. On the other hand, if R represent the real acidity as estimated by direct titration, it is possible to calculate: (1) the organic acidity, a; (2) the absolute acidity, A, and the amounts of monosodium and disodium phosphate in the urine. If the phosphatic acidity is inferior to the real acidity, disodium phosphate cannot be present, but there will be organic acidity. Since $a = R - p$, and $A = 2p + a$, the proportion of monosodium phosphate will be equivalent to $p \times 3{\cdot}680$. Again, if the phosphatic acidity is superior to the real acidity, there can be no organic acidity, but the total phosphatic acidity must be distributed between the acidity due to the monosodium phosphate ($= m$), and that due to the disodium phosphate, d. The calculations would then be as follows: $m = R$, $d = p - R$, $A = 2R + d$, whence—

$$NaH_2PO_4 = R \times 3{\cdot}680, \text{ and}$$
$$Na_2HPO_4 = d \times 4{\cdot}356.$$

C. A. M.

ORGANIC ANALYSIS.

Alkaloidal Assay of Calabar Beans. A. H. Salway. (*Amer. J. Pharm.*, 1912, **84**, 49-51.)—The United States Pharmacopœia method for this assay was found by the author to give very low results, and the following modification is suggested: Twenty grms. of powdered beans (No. 60 powder) are well shaken with 200 c.c. of ether, 10 c.c. of an aqueous solution of sodium carbonate (10 per cent.) are added, and the mixture shaken vigorously at intervals for four hours. The powder is allowed to settle, after which 100 c.c. of the ethereal liquid are transferred to a separator and sufficient $\frac{N}{10}$ sulphuric acid added to make it distinctly acid. After thorough shaking, the acid layer is drawn off, and the operation repeated twice, using 10 c.c. of $\frac{N}{10}$ sulphuric acid each time. The combined acid extracts are made alkaline with sodium carbonate solution (10 per cent.), and the liquid extracted successively with 10 quantities of 20 c.c. each of ether. After washing the whole ethereal extract with 5 c.c. of water, the ether is distilled, the alkaloidal residue dissolved in 5 c.c. of $\frac{N}{10}$ sulphuric acid, and the excess of the latter titrated with $\frac{N}{50}$ alkali, using iodeosin as indicator.

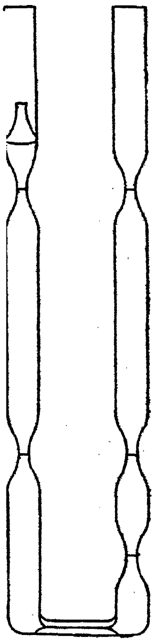
A. R. T.

Application of Methyl-Red to the Colorimetric Estimation of Hydrogen Ion Concentrations. S. Palitzsch. (*Biochem. Zeitsch.*, 1911, **37**, 131-138.)—Methyl-red (*p*-dimethylaminoazobenzene-*o*-carboxylic acid) is particularly suitable for use as an indicator in the measurement of hydrogen ion concentrations between the zones $p_H = 4{\cdot}2$ and $p_H = 6{\cdot}3$, the change of colour being from violet-red to yellow.

A table of corrections is given, these corrections (which are only small) being applied in case proteins and salts are present. W. P. S.

Detection of Pine Oil in Turpentine Oil. C. Piest. (*Chem. Zeit.*, 1912, **36**, 198.)—A mixture of 5 c.c. of the turpentine oil and 5 c.c. of acetic anhydride is shaken with 10 drops of concentrated hydrochloric acid, and allowed to cool, after which an additional 10 drops of hydrochloric acid are added, and the mixture again shaken. Under these conditions pure turpentine oil remains transparent and light yellow, whilst pine oil becomes black. This test will give a distinct coloration in the presence of 10 per cent. of pine oil, whilst even 5 per cent. causes a slight darkening of the liquid. In the case of old turpentine oil the sample should be distilled, and the test applied to the distillate. Purified pine oil also gives a dark coloration, though not to so marked an extent as ordinary pine oil. C. A. M.

Viscosity of Fish Oils. G. F. White. (*J. Ind. Eng. Chem.*, 1912, **4**, 106-110.)—For determining the viscosity of moderately viscous liquids such as fish oils, the author has devised a viscosimeter very similar to that previously described by him for less viscous liquids (*Biochem. Zeitsch.*, 1911, **37**, 482), but with a shorter capillary and with the volumes of the limbs considerably less. The method of standardising the instrument was similar to that described in detail in the earlier paper, but water could not be used as the time of flow would have been too short. Therefore, the viscosity of a sample of Menhaden oil was determined in the earlier form of apparatus which had been standardised with water, the temperature being 50° C. to reduce the time necessary for measurement. The viscosity was found to be 0·1518 in the left limb and 0·1514 in the right limb. The new viscosimeter was next calibrated with this oil and the following constants obtained for the instrument:



Length of capillary (approximate) ...	1·7 cm.
Volume of left limb	2·1310 c.c.
Volume of right limb	2·0748 c.c.
Pressure correction, left limb	1·23 cm.
Pressure correction, right limb	1·20 cm.
Ratio of r^4 to l	0·00004577. 0·00004582.

In use the liquid is forced through the capillary under a pressure of 100 to 180 cm. The kinetic energy correction $\frac{vd}{8\pi tl}$ in the formula $\eta = \frac{\pi r^4 pt}{8vl} - \frac{vd}{8\pi tl}$ is low, this being necessary if the work is to be of a high order of accuracy. This correction was always less than 0·5 per cent. of the total viscosity. In the above equation η is the viscosity, r and l are the radius and length of the capillary, v is the volume of the liquid of density d, p is the pressure, and t is the time of flow.

With this instrument the viscosity of the following oils in absolute measure (c.g.s. units) was determined at 30°, 50°, 70°, and 90° C.:

When, after heating to 90° C., these oils were cooled to 30° C. and their viscosity redetermined at that temperature, this was found to have been unaffected by the heating. The fluidities of the oils are not linear functions of the temperature, indicating that there is some association at the lower temperature (*cf.* Bingham, *Zeitsch. Phys. Chem.*, 1909, **66**, 1). G. C. J.

"Pergamyn" and Imitation Parchment Papers. W. Herzberg. (*Mitt. K. Materialprufungsamt*, 1911, **29**, 464-467; through *Chem. Zentralbl.*, 1912, I. 688.) —"Pergamyn," "greaseproof," or imitation parchment papers owe their special qualities to the mechanical treatment followed in their manufacture and not to any addition of an external substance, such as paraffin wax. Genuine parchment papers possess somewhat similar characters owing to a chemical treatment, a modification of the fibres by the action of sulphuric acid. Customs officials are not always in a position to recognise these distinctions, and pergamyn papers and the like are sometimes charged as impregnated or waxed papers, sometimes as genuine parchment papers.

Test for Paraffin Wax.—The paper is extracted with ether, the ethereal extract is saponified with alcoholic potash, the dried residue after saponification is extracted with ether, and the ethereal extract is dissolved in hot acetic anhydride. If paraffin wax is present, it separates out on cooling. It is generally sufficient to observe whether the paper loses its lustre and transparency after extraction with ether; pergamyn papers remain unaltered.

Test for Genuine Parchment Papers.—A portion of the paper is boiled with a 2 or 3 per cent. solution of sodium hydroxide whilst stirring. Imitation parchment papers fall to pieces under this treatment, whilst genuine, chemically modified parchment papers retain their form. J. F. B.

Unification of Reducing Sugar Methods (A Correction for Lactose). P. H. Walker.

(*J. Amer. Chem. Soc.*, 1912, **34**, 202-209.)—Attention has been called to arithmetical errors in the tables originally published for lactose (*J. Amer. Chem. Soc.*, 1907, **29**, 541). Table IV. giving the amount of sugar for each mgrm. of cuprous oxide has been wrongly calculated and does not agree with the experimental results of Table III., which is correct. The same error has been reproduced in the U. S. Bulletin, No. 107, Bureau of Chemistry, Official and Provisional Methods of Analysis, pp. 243-251, which has been in use for several years. In the formula—

$$y = a + bx + cx^2,$$

where y = cuprous oxide and x = reducing sugar, the true values in the case of lactose are $a = 4{\cdot}1759$, $b = 1{\cdot}48697$, $c = -0{,}00009$. The lactose used was the crystallised hydrate $C_{12}H_{22}O_{11} + \frac{1}{2}H_2O$. J. F. B.

Estimation of Sugars in Natural Products. C. Neuberg and M. Ishida.

(*Biochem. Zeitsch.*, 1912, **37**, 141-169.)—It is shown that by treating sugar solutions with 50 per cent. mercuric acetate solution followed by precipitation with 25 per cent. phosphotungstic acid solution, all optically active proteins, their derivatives (amino-acids, etc.), and other substances are removed, whilst the sugars remain in solution and can be estimated polarimetrically. The process is particularly applicable to the analysis of mixtures of sugar with amino-acids, molasses, etc., and results of experiments are recorded showing that the method is trustworthy. The amino-sugar, *d*-glycosamine, may be estimated in the presence of amino-acids by means of this method, as it is not precipitated by the reagents mentioned. A method is described for preparing the phosphotungstic acid reagent; 200 grms. of crystallised sodium tungstate are dissolved in hot water, 5 grms. of solid phosphoric acid are added, and the clear solution is mixed first with 60 c.c. of dilute sulphuric acid, and then with 58 grms. of concentrated sulphuric acid, the solution being cooled during the addition of the acid. The solution is next evaporated on a water-bath to a volume of 290 c.c., cooled in an ice-chest, the crystals of sodium sulphate are separated, and the residual solution is diluted with an equal volume of water. W. P. S.

INORGANIC ANALYSIS.

Detection of Bromine by Fluoresceïn. H. Baubigny.

(*Bull. Soc. Chim.*, 1912, **11**, 13.)—The author's test (*Comptes rend.*, 1897, **125**, 654) has been stated by Pribram, and later by Labat, to be inconclusive as applied to the detection of bromine in animal organs, on the ground that chlorine or iodine would give the same reaction. This is denied: the chlorine compound of fluoresceïn is almost colourless, and iodine should be converted into iodate by oxidation with permanganate, as indicated in the original paper. C. E. M.

Estimation of Alkalis in Silicates by Fusion with Calcium Chloride. E. Mäkinen. (*Zeitsch. anorg. Chem*, 1912, **74**, 74-78.)—Instead of the calcium carbonate and ammonium chloride of the Lawrence Smith method (*Ann. Chem. u. Pharm.*, 1871, **159**, 82), anhydrous calcium chloride is recommended. The calcium chloride should be prepared in the laboratory, as the purest commercial salt may contain as much as 0·02 grm. of alkali chloride in 7 grms., the amount of flux recommended for use with 0·5 grm. of the silicate. Intimate admixture of the silicate with the flux is unnecessary, as the latter, unlike the mixture of Lawrence Smith, really melts. The crucible is supported on asbestos millboard, so that its upper portion and the cover may remain relatively cool and so serve to prevent volatilisation of alkali chloride. The crucible is heated gently at first until the calcium chloride is fused, but is then raised to a full red heat by means of a Teclu burner. The use of a blowpipe-flame leads to volatilisation of alkali. After twenty-five to thirty minutes fusion the flame is withdrawn, the crucible cooled suddenly, and the analysis completed in the usual manner, except that the use of ammonium carbonate in place of ammonium oxalate is recommended for removing the last traces of calcium. Ammonium carbonate is said to separate the last traces of calcium as well as oxalate, and is preferred because of the high temperature which is necessary to expel oxalic acid from the residue of alkali chlorides. When the results obtained differ from those yielded by the Lawrence Smith method, they are higher, and the author thinks they should be preferred. G. C. J.

Estimation of Ferrous Iron in Silicate Rocks. M. Dittrich and A. Leonhard. (*Zeitsch. anorg. Chem.*, 1912, **74**, 21-32.)—The paper contains a detailed description of the experiments which led Dittrich to publish the statement (Analyst, 1911, **36**, 602) that the uncertain end-point in the titration of ferrous iron in certain rocks, after decomposition by means of hydrofluoric acid, was due to the presence in those rocks of Ti_2O_3, and not to the presence of manganese. The following method of conducting the estimation of ferrous iron avoids any difficulty due to the presence of Ti_2O_3. From 0·8 to 1 grm. of the not too finely powdered sample is mixed with 0·5 grm. quartz sand (Analyst, 1911, **36**, 372) and 2 c.c. sulphuric acid, and decomposed by means of 8 c.c. of hydrofluoric acid. The crucible is placed on a boiling water-bath and covered with an inverted funnel, which is sufficient to prevent any appreciable oxidation during the few minutes required for decomposition of the rock. The contents of the crucible are poured, without previous cooling, into a mixture of 100 c.c. water, 10 grms. precipitated silica, 20 grms. potassium sulphate, and 2 c.c. sulphuric acid, and the mixture is titrated at once with permanganate. G. C. J.

Estimation of Chromium and its Separation from Vanadium Steels. J. R. Cain. (*J. Ind. Eng. Chem.*, 1912, **4**, 17-19.)—After drawing attention to the difficulties which attend the estimation of chromium in chrome-vanadium steels, the author recommends the following method, which depends on the fact established by him (Analyst, 1911, **36**, 475) that chromium can be precipitated completely by boiling the nearly neutralised (ferrous) solution with barium carbonate, and on the observation of Noyes and Bray (*Technology Quarterly*, 1908, **21**, 14), that chromate may be separated from vanadate by precipitation as lead chromate if certain precautions are observed.

The drillings, which should preferably contain not more than 0·06 or 0·07 grm. of chromium, are placed in a 300 c.c. Erlenmeyer flask and dissolved in fuming hydrochloric acid of which about 10 c.c. is taken for each grm. of steel. The solution is diluted to 100 or 150 c.c. with hot water and nearly neutralised with saturated sodium carbonate solution. A slight excess of an emulsion of barium carbonate is added and the mixture boiled vigorously for ten or fifteen minutes with small additions of barium carbonate every two or three minutes, the flask being kept covered to exclude air as completely as possible. The excess of barium carbonate used should not be more than 2 grms. or there may be difficulty in extracting the chromium by a single fusion. The precipitate is allowed to settle and is then filtered off and washed twice with hot water, these operations being conducted as quickly as possible. The filter and precipitate are transferred to a platinum crucible, the paper is burned away, 2 grms. sodium carbonate and about 0·25 grm. potassium nitrate are mixed in, and the mixture is maintained in a state of fusion for twenty minutes. The product of the fusion is digested with boiling water and the solution filtered. Hydrogen peroxide (1 or 2 c.c. of a 3 per cent. solution) is added to destroy any nitrite, and the solution is boiled for five minutes to decompose the excess of peroxide. The solution is cooled and transferred to a separator, rendered slightly acid with nitric acid and vigorously shaken to expel carbon dioxide. It is then transferred to a beaker, just neutralised with sodium hydroxide, and then made acid by addition of 2 c.c. nitric acid (1 : 1) for each 100 c.c. of solution. Lead nitrate (20 c.c. of a 20 per cent. solution) is added to the cold solution with vigorous stirring, and the lead chromate is filtered off on asbestos and washed three or four times with cold water. The asbestos mat is transferred to a beaker or flask and the lead chromate decomposed with hot hydrochloric acid (1 : 4). The solution is cooled, made up to 150 or 200 c.c., and titrated against $\frac{N}{10}$ ferrous sulphate with ferricyanide as an outside indicator. The amount of sodium carbonate permissible in the fusion is limited by the fact that for a successful separation of chromium from vanadium not too much sodium nitrate should be present (Noyes and Bray, *loc. cit.*), and it is this necessity for restricting the amount of sodium carbonate which makes it advisable to take for analysis not more of the sample than corresponds to 6 or 7 cgrms. of chromium. Larger amounts are not readily extracted by 2 grms. of sodium carbonate, especially if too great an excess of barium is present. The shaking of the solution to eliminate carbon dioxide determines the subsequent formation of a precipitate which settles and filters well, and equally cogent grounds underlie other directions as to manipulative detail. Test numbers, obtained with solutions of a vanadium and chromium free steel to which known amounts of bichromate and vanadate were added, show maximum errors of ± 0·0004 grm. with from 0·02 to 0·3 grm. chromium present. The filtrates from the barium carbonate precipitation were tested for chromium with negative results in every case, and in only a few cases was any trace of vanadium found in the chromium solution after titration, and in those cases the amount was negligibly small. On the other hand, it is well to examine the insoluble matter from the fusion by fusing it again with sodium carbonate and potassium nitrate. With much chromium in the original weight of drillings, a yellow-coloured solution may result. If so, the chromium in it may be estimated with sufficient exactness colorimetrically. G. C. J.

Analysis of Higher Oxides of Lead. A. Chwala and E. Colle. (*Gazz. Chim. Ital.*, 1911, **41**, 551-579.)—From the results of an experimental study of the different methods proposed for the analysis of lead peroxide the author recommends the following modification of Lux's method (*Zeit. anal. Chem.*, **19**, 153) as the most convenient and reliable: From 1 to 2 grms. of the sample are treated with 100 c.c. of $\frac{N}{1}$ nitric acid and 25 c.c. of $\frac{N}{2}$ oxalic acid solution, and the liquid boiled for ten to fifteen minutes, until solution is complete. The excess of oxalic acid is then titrated with standard permanganate solution, and the amount of lead peroxide calculated from the result—

$$PbO_2 + C_2H_2O_4 = PbO + H_2O + 2CO_2$$

The duration of the boiling with nitric acid and the concentration of that acid have considerable influence upon the results. The results of experiments have shown that the differences between the results given by the oxalic acid method and the iodometric methods are entirely due to the occurrence of secondary reactions in the latter, leading to the formation of lead iodide and methyl acetate, so that part of the iodine escapes titration—

$$Pb(CH_3COO)_2 + 2I = CH_3COOCH_3 + PbI_2 + CO_2$$

In some instances the error thus produced may be considerable, and, in any case, should always be taken into account in iodometric estimations of oxidising substances in the presence of weak acids and heavy metals. Various samples of commercial lead peroxide analysed by the foregoing method contained from 43·5 to 95·56 per cent. of lead peroxide. C. A. M.

Bismuthate Method for Manganese. D. J. Demorest. (*J. Ind. Eng. Chem.*, 1912, **4**, 19.)—The following modification of the bismuthate method is recommended for use with chrome and chrome-vanadium steels. The drillings are dissolved in nitric acid (sp. gr. 1·1), boiled to expel nitrous fumes, and potassium bismuthate is added until permanganic acid or manganese dioxide persists on boiling. Potassium nitrite is added to dissolve the manganese dioxide, and the solution is boiled to expel nitrous fumes, after which it is cooled and the manganese oxidised by bismuthate in the cold as usual. The solution is then filtered rapidly through asbestos on glass wool and titrated with a standard solution of sodium arsenite, made by dissolving 2·25 grms. of arsenious acid in a hot solution of sodium carbonate and diluting to 2·5 litres. The test numbers, obtained in presence of three or four times as much chromium or vanadium as manganese, are good, the worst being 0·671 per cent. found with 0·666 present. G. C. J.

Determination of the Density of Minerals by Means of Rohrbach Solution of Standard Refractive Index. H. E. Merwin. (*Amer. J. Science, Silliman*, 1911 [4], **32**, 425; through *Chem. Zentralbl.*, 1912, I., 524.)—The density of a solution contained in the cell of a refractometer is adjusted until a fragment of the mineral under examination is just suspended in it; its refractive index is determined, and from this its density, and hence the density of the sample, is found. For Rohrbach (barium mercury iodide) solution, the relation between D (density) and n (refractive index), at 20° C., is as follows:

D =	3·449	3·396	3·246	3·180	3·046	2·980
n =	1·7686	1·7950	1·7312	1·7195	1·6944	1·6823
D =	2·748	2·649	2·648	2·367	2·163	2·067
n =	1·6391	1·6207	1·6205	1·5685	1·5320	1·5148

For densities between 2·25 and 3·40 it may be expressed, with a maximum error of ± 0·002, by the empirical formula:

$$D^{20} = 5{\cdot}39\,(n - 1{\cdot}5467) + 2{\cdot}25 = 5{\cdot}39n - 6{\cdot}0865.$$

For variations from 20° exceeding 3° a correction of ± 0·001 per ± 2° is necessary. For densities between 2·0 and 2·25, $D = 5{\cdot}7n - 6{\cdot}567$; and between 3·4 and 3·5, $D = 5{\cdot}52n - 6{\cdot}313$. For approximations, the mineral is brought to suspension, and n then determined on a drop of the liquid. O. E. M.

Estimation of Nitrates in Sewage Effluents. H. Silvester.

(*J. Soc. Chem. Ind.*, 1912, **31**, 95-96.)—Effluents derived from sewage containing waste gas liquor may contain thiocyanates, and in presence of thiocyanates the phenol-sulphonic acid method for the estimation of nitrates is not trustworthy. The zinc-copper couple method is recommended as the best for sewage effluents. In using this method it is convenient to have an approximate idea of the amount of nitrate present, and for this purpose the diphenylamine test serves well. To 2 c.c. of the effluent a few drops of the diphenylamine reagent and 10 c.c. of sulphuric acid (free from nitrate) are added. The intensity of the blue coloration which results enables the analyst to form a rough estimate of the amount of nitrate present.

G. C. J.

Detection of Nitrates in Presence of Nitrites. H. K. Sen and B. B. Dey.

(*Zeitsch. anorg. Chem.*, 1912, **74**, 52-54.)—When nitrites are destroyed by means of urea, as in Piccini's method for the detection of nitrate in presence of nitrite, small quantities of nitrate are invariably formed by the decomposition of nitrous acid into water, nitric oxide, and nitric acid. It is shown that the reaction of hydrazine sulphate with nitrites (ANALYST, 1911, **36**, 468) is unattended by the formation of even such traces of nitrate as may be detected by the diphenylamine reaction, and hydrazine sulphate is therefore recommended for the preliminary destruction of nitrite when it is wished to test for nitrate in a liquid containing nitrites.

G. C. J.

Note by Abstractor.—Stutzer and Goy (ANALYST, 1911, **36**, 524) have stated that the decomposition of nitrite by hydrazine sulphate is never complete.

Estimation of Phosphoric Acid by von Lorenz's Method. H. Neubauer and F. Lücker.

(*Zeitsch. anal. Chem.*, 1912, **51**, 161-175.)—The following procedure is recommended in estimating phosphoric acid by this method, the principal modification introduced being that acetone is employed instead of alcohol and ether for washing the phosphomolybdate precipitate. The reagents required are: (1) *Molybdic acid reagent.* One hundred and fifty grms. of ammonium molybdate are dissolved in 400 c.c. of boiling water, and the solution, when cold, is added gradually to a solution of 50 grms. of ammonium sulphate in 450 c.c. of nitric acid of sp. gr. 1·4; the whole is then diluted to a volume of 1 litre, filtered, and stored in a dark place. (2) *Nitric acid containing sulphuric acid.* Thirty c.c. of sulphuric acid of sp. gr. 1·84 are added to 1 litre of nitric acid of sp. gr. 1·20. (3) Nitric acid of sp. gr. 1·20. (4) A 2 per cent ammonium nitrate solution. (5) Neutral acetone. A quantity of from 10 to 15 c.c. of the phosphoric acid solution under examination (for instance, the solutions obtained in the analysis of fertilisers for total and citric acid soluble phosphoric acid) is diluted to a volume of 50 c.c.; should sulphates not be present, the dilution is made with the nitric acid containing sulphuric acid, otherwise with the dilute nitric acid. The mixture is then heated nearly to boiling, and 50 c.c. of the molybdate reagent are added, the whole being stirred for five minutes. After the lapse of from two to eighteen hours (the longer period is necessary if less than 3 mgrms. of phosphoric be present), the precipitate is collected in a Gooch crucible, washed with the 2 per cent. ammonium nitrate solution about four times, and then twice with acetone. The crucible is now placed for at least thirty minutes in a vessel in which the pressure has been reduced below 150 mm., and then weighed. The precipitate thus obtained contains 3·295 per cent. of phosphoric anhydride (P_2O_5). It is shown that the acetone removes the ammonium nitrate completely from the precipitate and filter, and results of estimations are recorded which show that the method is accurate. W. P. S.

Determination of the Penetration of Salts in Treated Wood. (*Forest Service Circular*, 190, *U.S. Dept. of Agriculture;* through *Chem. Trade Journal*, 1912, **50**, 12.)—If zinc chloride is the preservative, a representative disk of the wood is dipped first, for not more than ten seconds, into 1 per cent. potassium ferrocyanide, and then, after removal of the excess with filter paper, into 10 per cent. uranium acetate; it is then allowed to dry. The untreated portion will now be dark red, the treated portion somewhat lighter than the natural wood. The method allows 0·2 pound per cubic foot to be detected. Copper and iron salts are determined by the dark-red and deep blue coloration, respectively, of the treated zone on immersion in potassium ferrocyanide solution; mercuric chloride by the blackening in hydrogen sulphide solution. O. E. M.

Rapid Method for Determination of Sulphur in Roasted Blende. C. C. Nitchie. (*J. Ind. Eng. Chem.* 1912, 4, 30-32.)—For determining whether a particular car-load of roasted blende is sufficiently roasted to be suitable for use in the spelter furnaces, or whether it should be returned to the kiln for additional roasting, a rapid method is essential. The following method is recommended as rapid, and sufficiently exact for the purpose. The sample is ground no more finely than is necessary to get a 1-grm. sample which shall be fairly representative; finer grinding prolongs the time necessary for the subsequent roasting of the ore. One grm. of the sample is weighed out into a boat, which is placed in a silica combustion-tube previously heated to 1000° C., and a current of air, freed from carbon dioxide, is led through the tube and through an absorption apparatus containing standard caustic alkali. A fume of zinc oxide, formed by reduction of zinc oxide by zinc sulphide, volatilisation of the zinc, and its subsequent oxidation in the air-current, passes through the absorption apparatus, only negligible traces being dissolved by the alkali solution. Experiment has shown that the roasting may be discontinued when this fume is no longer seen in the absorption apparatus. The only sulphur then remaining with the roasted ore is that combined as calcium sulphate. The whole of the "false" sulphur—sulphur which should have been eliminated in the kiln, but which remained as sulphide or sulphate of zinc or lead in the sample—will have passed into the absorption apparatus, mostly as sulphur dioxide with some trioxide. The excess of alkali hydroxide is titrated with standard acid, using phenolphthaleïn as indicator, and the sulphur in 1 grm. of the sample is calculated from the alkali neutralised by the gases resulting from roasting the ore. The roasting process usually occupies only about six minutes. The maximum error of the method is −0·1 per cent. on the ore, which is quite near enough for the purpose, the percentage of "false" sulphur in roasted blende being of the order of 1 per cent. Without modification the method is not sufficiently exact for application to unroasted blende.

G. C. J.

Rapid Volumetric Method for Estimation of Free Sulphur. C. Davis and J. L. Foucar. (*J. Soc. Chem. Ind.*, 1912, **31**, 100.)—The method depends on the quantitative conversion of the sulphur into thiocyanate by digestion with an alcoholic solution of sodium cyanide, and the subsequent titration of the thiocyanate. One grm. of the finely ground (60 mesh) spent oxide or other material is dried for an hour in the steam oven and then transferred, with 1·5 grm. sodium cyanide and 50 c.c. absolute alcohol, to a 250 c.c. flask. The contents of the flask are boiled under a reflux condenser for two hours, and the alcohol is then completely removed by distillation. The residue is dissolved in 100 c.c. of hot water, and the solution, when cool, made up to 250 c.c. To 25 c.c. of this solution, 75 c.c. of water and 5 c.c. of a saturated solution of iron alum are added and the mixture heated, with constant stirring, to 95° C., filtered, and the filter washed until free from thiocyanate. To the cool filtrate, 5 c.c. of nitric acid and enough water to bring the bulk up to about 500 c.c. are added, and the mixture is titrated with $\frac{N}{20}$ silver nitrate until the red colour of ferric thiocyanate disappears, or excess of silver nitrate may be added, and the solution titrated back with $\frac{N}{20}$ thiocyanate. Should the sample contain thiocyanate, as is most likely in the case of spent oxide, a blank test must be conducted, the thiocyanate being extracted with water. Test numbers obtained on applying the method to sulphur crystals agree well with those obtained by oxidising the sulphur and weighing as barium sulphate. The test numbers for spent oxides are from 0·3 to 0·4 per cent. lower than those obtained by oxidation of the carbon bisulphide extract, but the latter method includes as free sulphur the sulphur of any compound soluble in carbon bisulphide.

G. C. J.

Estimation of Sulphur in Illuminating Gas. J. Niermeyer. (*J. f. Gasbeleuchtung*, 1911, **54**, 1078-1079; through *Chem. Zentralbl.*, 1912, I., 375-376.)—According to Dennstedt and Ahrens, the ratio between sulphur dioxide and sulphur trioxide in the products of combustion of illuminating gas shows only small variations: 92 to 94 per cent. of the total sulphur exists as the dioxide and 6 to 8 per cent. as the trioxide. On this observation the author has based a simple method for the estimation of sulphur. A known volume of gas is burnt, the sulphur dioxide is estimated in the products, the quantity of sulphur found is increased by 6 to 8 per cent. and calculated per cub. m. of gas. The sulphur dioxide is absorbed in $\frac{N}{100}$ iodine solution, to which an excess of potassium iodide has been added to reduce the volatility of the iodine. The glass tube of a Drehschmidt sulphur-estimation apparatus is used, and the thin, downwardly inclined portion of the tube is utilised as a cooler for the products of combustion, which are then aspirated through the washing vessel containing the iodine. The gas-consumption is adjusted at 70 to 80 litres per hour; 10 c.c. of $\frac{N}{100}$ iodine solution, 10 c.c. of 10 per cent. potassium iodide solution, a few drops of starch solution, and 50 c.c. of water are placed in the washing vessel, and a current of air is aspirated. The burner is then placed under the glass tube, and, when the iodine solution is decolorised, the volume of gas burnt is read off on the meter. The quantity of iodine used represents 1·6 mgrm. of sulphur; this is divided by the number of litres of gas burnt, and the result is increased by 6 per cent., giving mgrms. of total sulphur per litre. J. F. B.

Estimation of Sulphur in Nitrocellulose. C. Kullgren. (*Zeitsch. ges. Schiess- und Sprengstoffwesen*, 1912, **7**, 89.)—About 0·75 grm. of the substance, denitrated by heating for thirty minutes on the water-bath with 10 c.c. hydrochloric acid, is dried in a large porcelain boat. It is then burnt in a stream of oxygen by the method of Barlow (*J. Amer. Chem. Soc.*, 1904, **26**, 341), the sulphur being absorbed as sulphuric acid in water or alkali. Hydrogen peroxide is added to the solution to ensure conversion of any sulphur dioxide to sulphuric acid, which is then precipitated with barium chloride solution. The results showed satisfactory agreement.

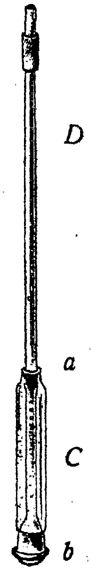
O. E. M.

Estimation of Sulphuric Acid. K. K. Järvinen. (*Ann. acad. scient. Fennicæ*, 1911, Serie A.2. Nr. 16; through *Chem. Zentralbl.*, 1912, I., 526.)—By the method given, about ·0025 grm.-molecule of sulphuric acid is titrated with a maximum accuracy of 0·2 per cent. The following ions may be present: sodium, potassium (magnesium), ammonium, in almost unlimited quantity; calcium, aluminium, manganese, zinc, iron, to the extent of 4 equivalents; copper, 1; chloride, 8; nitrate and borate, 4; phosphate, 2; oxalate, 1. Strontium, lead, chromium, and chromate ions must be absent. The solution, containing ·002 to ·003 grm.-molecule sulphate in 40 to 50 c.c., is neutralised if necessary until about 1 to 3 equivalents (= 2·5 to 7·5 c.c. 2 N) hydrochloric acid are left free; 3 equivalents are only required if 2 of phosphoric acid or 1 of oxalic acid are present. Ferric salts, 1 to 4 equivalents, are reduced by boiling with ½ to 2 equivalents of hydroxylamine. The solution is boiled up and slowly precipitated with about 40 c.c. (1 to 5 equivalents) of hot benzidine hydrochloride solution ($\frac{N}{5}+\frac{N}{10}$ HCl). The liquid is now evaporated to one-half, cooled, filtered, the precipitate washed with water containing benzidine sulphate, transferred to the original flask, and titrated hot with $\frac{N}{5}$ sodium hydroxide free from carbon dioxide, and phenolphthaleïn. The result is usually not more than 0·1 to 0·2 per cent. high. O. E. M.

Rapid Method of Estimating Zinc. K. Voigt. (*Zeitsch. angew. Chem.*, 1912, **25**, 205-206.)—V. Hassreidter has stated (*Zeitsch. angew. Chem.*, 1911, **24**, 2471) that the author's method (Analyst, 1912, 35) is open to objection on the ground that zinc may be underestimated owing to the re-formation of zinc silicate in presence of hydrated silica. The author points to the test numbers in his earlier paper for proof of the accuracy of the method, and adds that many of those test numbers were obtained in presence of 30 to 40 times as much "soluble" silica as zinc. He also points out that Hassreidter's experiments were not conducted in accordance with his directions, since Hassreidter used the smallest possible excess of ammonia, as he wished finally to complete the analysis by titration with sodium sulphide, which is rendered difficult or impossible by excess of ammonia. The large excess of ammonia directed to be used by the author prevents the zinc passing into the precipitate as silicate. A still larger excess is without influence on the results, but serves no useful purpose (*cf.* Analyst, 1912, 35). G. C. J.

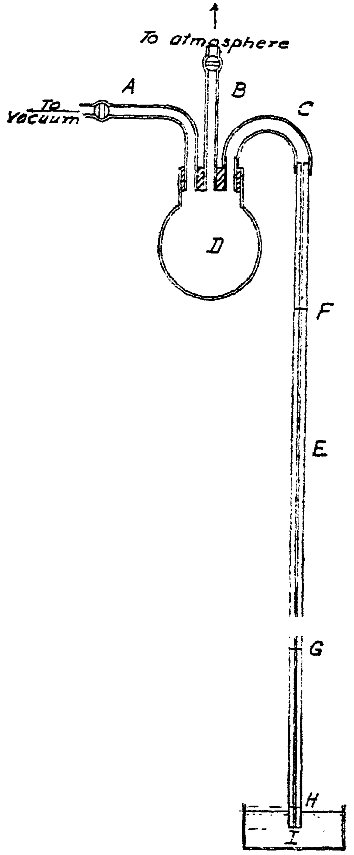
APPARATUS, ETC.

Automatic Pressure Pipette. W. Skinder. (*Chem. Zeit.*, 1912, **30**, 166).—The apparatus shown in the illustration is useful in cases where it is desired to bring two solutions to the same temperature before they are allowed to react with one another. It consists of a hollow rod, *D*, and a mantle, *C*, which are joined together by means of two ground-in joints. A small opening is provided at *a*, and another at *b*, which passes through both the hollow rod and the mantle. The apparatus is filled by raising the rod and immersing the mantle in the fluid; on withdrawing the apparatus from the fluid, it closes automatically. The hollow rod is then rinsed out with water, and the apparatus is placed in a vessel containing another fluid, and when the desired temperature is attained the contents of the apparatus are discharged by means of a pressure-bulb fitted to the upper end of *D*, the pressure produced raising the mantle, and allowing its contents to mix with the other fluid. W. P. S.



Device for Preventing the Bumping of Boiling Liquids. E. Pieszczek. (*Chem. Zeit.*, 1912, **36**, 198.)—A glass tube, 6 to 8 cm. long and 3 to 5 mm. in diameter, is drawn to a point at one end, into which is then fused a length of platinum wire to serve as a handle. The tube is immersed with its open end downwards, in a nearly vertical position, in the liquid. On heating the latter, bubbles of enclosed air escape from the tube, and all bumping is prevented, even in the case of liquids containing barium sulphate, or those covered with a layer of fatty acids. The air is never completely expelled from the small tube. C. A. M.

Method of Measuring Absolute Viscosity. H. P. Gurney. (*J. Amer. Chem. Soc.*, 1912, **34**, 24-28.)—The desirability of expressing the viscosity of liquids in absolute units is urged, and the apparatus figured is suggested for the purpose, for which the author claims extreme accuracy, simple and rapid manipulation, ease of working, shortness of time required for calibration, and the capacity for being used with opaque liquids and very small volumes. *F*, *H* is a capillary tube of suitable dimensions, graduated at *F*, *G*, and *H*, fixed vertically, and jacketed if necessary. The liquid to be tested is poured into *I* until it rises in the capillary to *H*, *B* being open to the atmosphere. *B* being then closed, *A* is opened, and the liquid drawn up above *F*. Atmospheric pressure is then restored, and the time required by the liquid to fall from *F* to *G* is taken by means of a stop-watch. Increased accuracy is attainable by repeating and averaging results. The density of the liquid may be obtained by any suitable method, and the radius of the capillary from the length and weight of a thread of mercury. A mathematical discussion of the results obtainable follows, from which the author deduces a very simple expression for the calculation of the viscosity. Thus, for a capillary tube of 1 metre in length, and bore of radius 0·03475 cm., of which the distance from *F* to *G* is 57·08 cm., and from *G* to *I* 21·37 cm.,



$$\mu = 0{\cdot}00247\gamma T,$$

where γ = the density of the liquid, and T = the time of flow from *F* to *G* in seconds, the radius of the dish *I* being 4·4 cm. H. F. E. H.

"Luminator" Treatment of Water. H. B. Lake. (*J. Soc. Chem. Ind.*, 1912, **31**, 57.)—It has been claimed (*J. Soc. Chem. Ind.*, 1910, **30**, 933) that the passage of a hard water over aluminium plates reduces its temporary hardness, and causes the deposit of its mineral matter, on boiling, as a sludge and not as a scale; the apparatus should be arranged north and south, exposed to direct light, and be given a weekly rest. The author has submitted water passed through either an aluminium chute or an aluminium tube, under the conditions stated, to soap-tests for total and permanent hardness, and to mineral analysis, comparing the residues obtained by evaporation of treated and untreated water. The differences were small. With one of the two waters treated there appeared to be a tendency towards the conversion of calcium salts from permanent to temporary hardness; with the other this was reversed. The treatment was without effect on the conversion of carbonates of lime and magnesia to sulphates, in hard water, by aluminium sulphate. O. E. M.

GOVERNMENT REPORT.

Report to the Local Government Board on Analyses and Methods of Detection of Certain Proprietary Substances sold as Preservatives for Milk, Cream, etc. G. Monier-Williams. (*Food Reports*, 1912, No. **17**, 1-7.)—A new preservative, sold under the name of "mystin," for preserving milk and cream, has recently been advertised as possessing the advantage that its presence cannot be detected by analysis. An analysis of the preparation showed that it had the following composition: Sodium nitrite, 9·85; formaldehyde, 0·30; water, 89·85 per cent.; the smell of the preparation indicated the presence of some essential oil, probably peppermint oil. The directions given prescribe the addition of 3 ounces of the preparation to 17 imperial gallons of milk. It was found that milk treated with this proportion of "mystin" failed to give the Hehner reaction for formaldehyde. This action of the nitrite in inhibiting the reaction appears to be due to the action of the nitrous acid with the tryptophane which is present among the products of hydrolysis of casein, rendering the tryptophane incapable of condensing with formaldehyde. If, however, the nitrous acid in the acidified milk be destroyed by some such substance as urea, the milk treated with "mystin" readily yields a coloration with Hehner's test. Five c.c. of the milk should be treated with 0·05 grm. of urea and 1 c.c. of $\frac{N}{1}$ sulphuric acid, the mixture heated for two minutes in a boiling water-bath, then cooled, and tested in the usual way. The quantity of formaldehyde may be estimated by the method described by Shrewsbury and Knapp (ANALYST, 1909, **34**, 12), after the milk has been treated with urea. In view of the possibility that "mystin" may have already come into extensive use among milk vendors, it would appear to be advisable to include the Griess-Ilosvay test for nitrites among the routine tests applied to milk and cream samples; milk containing "mystin" gives a pink coloration almost immediately with this test, and if a positive reaction is obtained, formaldehyde should be looked for by the method given above. It is pointed out that a quart of milk (treated with the proportion of "mystin" directed) would contain 2 grains of sodium nitrite, which is the maximum pharmacopœial dose of this salt. Sodium nitrite is a dangerous drug, with a powerful action on the heart, and the risk of using any preparation containing a comparatively large amount of sodium nitrite is universally recognised.

Reference is made to certain other preservatives for milk, cream, and margarine, to which the attention of the Board has recently been drawn. One of these, sold under the name of "accoine," consisted of an aqueous solution containing 13·97 per cent. of sodium benzoate, and 1·94 per cent. of sodium carbonate. It is claimed also for this preparation that it cannot be detected by analysis, but the presence of benzoic acid in milk and cream may be detected by the test described by Richmond (ANALYST, 1907, **32**, 151). Another substance, sold as a preservative for margarine, was found to consist almost entirely of sodium fluoride, whilst a cream preservative examined consisted of a mixture of sodium meta-bisulphite and sodium sulphate.

REVIEWS.

FOOD AND DRUGS. VOL. I.: THE ANALYSIS OF FOOD AND DRUGS. By E. J. PARRY, B.Sc. (Lond.), F.I.C. 1911. Pp. 715. London: Scott, Greenwood and Son. Price 21s. net.

The number of English textbooks on the analysis of foods and drugs is so limited that the appearance of a fresh claimant for space on our shelves need not, perhaps, excite surprise. The time has come, however, when single works covering such a wide range cannot be written by one individual from his own personal experience and knowledge, and the place of such encyclopædic enterprises as this must soon be taken by monographs on special subjects, or groups of subjects, by those who have made them their life's study.

The volume before us necessarily resembles in many points its predecessors, but, without any increase in bulk, it probably exceeds in range any of its rivals, owing chiefly to the omission of matters of historical and theoretical interest and of descriptions of apparatus, and, perhaps still more, to the inclusion of only "live" methods of analysis.

The book is written with a strict eye to utility, and if for the sake of brevity and convenience the style has suffered, something may be forgiven.

It is divided into two parts containing twelve chapters. Part I. treats of Food and Drinks, beginning with Tea, Coffee, and Cocoa, and ending with a chapter by Professor Greenish, on what is somewhat unhappily called "Microscopical Analysis," in which the apparatus, reagents, and general methods for preparing substances for microscopical examination are dealt with shortly and clearly. All the ordinary foods are referred to, and, in addition, some articles about which most of the general textbooks have little or nothing to say—*e.g.*, Macaroni and Italian pastes, meat extracts, and flesh foods, with a section on the properties of ptomaines, and the methods employed for their detection.

Part II. is devoted to Drugs, and is in some ways the most valuable part of the book, inasmuch as a great deal of information, which has hitherto only been available in isolated papers scattered through various journals, is here brought together for the first time. In addition to this, much of the ground covered comes within what may be considered as Mr. Parry's own special province, on which he is able to give authoritative and first-hand information. In the five chapters into which it is divided, the author adopts a system of classification which is novel, and though not without advantages is not, in our opinion, very logical or convenient, as it herds together the most unlike substances, and at the same time separates the preparations from the substances from which they are made. The first of these chapters is a perfect Noah's ark, for in it we find crude drugs—other than those containing active principles capable of estimation—gums, balsams, and resins cheek by jowl with roots, such as liquorice and male fern, animal derivatives such as musk and pepsin, organic preparations such as spirit of nitrous ether and the tinctures, liquors, and spirits of he Pharmacopœia, some of the substances from which these latter are derived being found in this and some in the next chapter.

Subsequent chapters deal with "Drugs containing Alkaloids, etc.," "The Essential Oils of the British Pharmacopœia," "The Fixed Oils, Fats, and Waxes of the British Pharmacopœia," "The Chemicals of the Pharmacopœia." In the case of the latter more than one-third of the space is taken up with the tests for arsenic and lead. The only chemicals treated at any length are saccharin, salicylic acid, camphor, and chloroform, the rest being dealt with in tabular form, the melting-point, boiling-point, solubility, and limits for arsenic and lead, being usually given, with a statement, in some cases, of the likely adulterants. Practically, the tables are an abstract of the British Pharmacopœia descriptions and requirements, with occasional criticisms. The most valuable portions of the second part of the book are the chapters on the drugs containing alkaloids and on the essential oils, which are commendably full and embody much of the author's personal experience.

While the work as a whole may be highly commended, it suffers considerably from haste in production and insufficient revision. The wording is, as a rule, clear and concise, but in the matter of style leaves a good deal to be desired.

In the case of the chapters dealing with foods, uniformity of treatment, especially as regards the headings of the paragraphs, might have been carried a good deal further, and a more systematic division of the chapters into sections and subsections, with appropriate headlines would have made for ease of reference, and would have prevented the author from omitting some by no means unimportant matters. The articles on individual foods are certainly broken up into paragraphs with descriptive headings, but the plan adopted differs in the case of almost all of them—for instance, under cheese we find "the adulteration of cheese," under tea "the adulterants of tea," but under butter and milk no corresponding headline appears, although there is "calculation of adulteration" in the case of milk. The difficult question of food standards is not very satisfactorily dealt with, for the word in this sense does not occur in the index, and although well-selected tables of analytical data are given for the articles dealt with, and definite suggestions are frequently made as to the basis on which to calculate the percentage of adulteration, it is necessary in many cases to read the whole article through in order to find it. In other parts of the book the word "standard" is somewhat loosely used, as in one place it is applied to the definitions and descriptions of substances given in the British Pharmacopœia, while in another, a table showing the range of variation of the analytical constants of the British Pharmacopœia tinctures is headed "Standards for Tinctures," etc. A more important point is the omission to refer, except in one or two instances, to the numerous standards and definitions of articles of food drawn up by the United States Department of Agriculture, which, though not binding in this country and by no means universally accepted here, nevertheless carry a good deal of weight. Certain other omissions should also be mentioned here. No reference is made to the reports issued by the Local Government Board on Vinegar (1908), on Baking Powders, and on the Bleaching of Flour (1911). (As these were issued about a year ago there is some excuse for them not appearing, although the book as a whole has been brought very well up to date.) The Report of the Departmental Committee on Preservatives and Colouring matters only receives a passing mention. In connection with the analytical methods, there are a few similar omissions of processes to which reference might reasonably be expected, but they must be regarded, in the case of a book of such wide range, rather as departures from the ideal than as serious blemishes.

There are also a number of printer's errors which a more careful revision would have avoided. Fortunately, most of them do not alter the sense—*e.g.*, "Hanwill" for "Hamill," "Avi-Lallement" for "Ave-Lallement," "Badouin" for "Baudouin," "*Capsicum fastigatum*" and "*C. putescens*" instead of "*fastigiatum*" and "*frutescens.*" More unfortunate is the reference to the rotation of "1 mg. of quartz." The definition of specific rotation has also suffered in some way at the printer's hands—in fact, the whole of the section dealing with the Polarimeter is hardly up to the author's usual standard of lucidity.

Speaking generally, and it is impossible to criticise in detail a book which is almost an encyclopædia, the work of compilation has been excellently done, the selection of methods and of tables of analysis—always a difficult task—has been most judicious, very few obsolete processes are included, and the best, as well as the newest, work is referred to. The microscopical examination of the vegetable foods and drugs is dealt with briefly but clearly, and in a really useful manner; the illustrations are clear, and will be as helpful as illustrations in the absence of actual specimens are ever likely to be. Mr. Parry is to be congratulated on having so satisfactorily accomplished such a colossal task. C. H. CRIBB.

FOOD AND DRUGS. By E. J. PARRY, B.Sc. (Lond.), F.I.C. Vol. ii.: The Sale of Food and Drugs Acts, 1875-1907. Pp. 181. London: Scott, Greenwood and Son. 1911. Price 7s. 6d. net.

In view of the existence of other recently published works, Mr. Parry's task in dealing with the Sale of Food and Drugs Acts from a legal standpoint cannot have been easy. But he has wisely endeavoured to break fresh ground by giving the reader the benefit of his personal views on many points, and several of his suggestions and submissions have both originality and force. Especially good are Mr. Parry's observations on the British Pharmacopœia in relation to the Sale of Food and Drugs Acts. For the purpose of this discussion the drugs of the B.P. are classified in five groups, and the effect of High Court decisions in such cases as Hudson *v.* Bridge is stated with admirable clearness and accuracy. Cogent arguments are adduced in support of the contention that convictions under the Sale of Food and Drugs Acts for the sale of distilled water containing traces of impurities are wrong, on the ground that distilled water is not a drug. Mr. Parry thinks that any conviction for the sale of golden syrup containing glucose would be upheld by the High Court; that there need be no soda in a "whisky and soda" sold at a refreshment bar; and that if a sample of pills, tablets, or capsules, be taken by an inspector under the Sale of Food and Drugs Acts, it is necessary, under the decisions in the cases of Mason *v.* Cowdary and Smith *v.* Savage, that each pill, tablet, or capsule be divided into three parts. These and other personal opinions are always interesting, and, even if erroneous, add to the value of the work. The ordinary lawyer is too cautious thus to volunteer his views.

It is interesting to note that Mr. Parry is among those who hold that the Public Health (Regulations as to Food) Act, 1907, clothes the Local Government Board with wide powers to make binding regulations and "standards" with respect to articles of food, to prohibit preservatives, and so forth. Over eight pages in the body of the work are occupied by the text of the regulations of the Institute of Chemistry for the analytical qualification.

The author makes a good point, which is not perhaps universally understood—namely, that a private purchaser desiring to act as a prosecutor under the Sale of Food and Drugs Acts can rely on the evidence of any analyst, and need not necessarily make use of the power given him by Section 12 of the Act of 1875 to have his sample analysed by the public analyst for the district. Mr. Parry includes in this book six specimen certificates, against which he suggests no technical objection could be sustained. This is probably true; but the specimen certificate for diluted spirits is needlessly involved, and would convey singularly little meaning to an ordinary bench of magistrates. Much better, surely, is the form of certificate adopted by several well-known public analysts as follows:

". . . . . . parts as under:

Whisky, 25 degrees under proof … …	78
Added water … … … … …	22
	100

"This opinion is based on the fact that the sample was 41·5 degrees under proof. To whisky of 25 degrees under proof, the above-mentioned proportion of water must be added to reduce it to 41·5 degrees under proof. Genuine whisky should not be more than 25 degrees under proof."

Mr. Parry states that any person desiring to appeal to the High Court by way of special case "must apply for a case to be stated within three days of the Justice's decision." This is not so. He must apply within seven days, and the case must be stated within three months. And surely some sort of information ought to have been given as to the formal steps which have to be taken in lodging such an appeal. Another unsatisfactory statement is that where proceedings are taken under the Merchandise Marks Act "it is sometimes necessary to institute proceedings in the High Court, as in the case of limited companies." Is it ever necessary to institute proceedings in the High Court except in the case of a limited company refusing to be dealt with summarily?

The index is a little scanty, and the editing of the work slovenly in the extreme. *Res ipse loquitur* sets the teeth on edge. The date of the last edition of the British Pharmacopœia is twice given as 1908. The case of Parker *v.* Alder, reported in Law Reports, 1899 (1 Q. B., 20) is twice cited as Parker *v.* Adler (1 Q. B., 20) 1898. The case of Fortune *v.* Hanson is quoted at p. 44, but the only reference there given is "(1 Q. B., 202)." Such a reference is of course utterly valueless without a reference to the year in which the report appeared. At p. 5 the year comes first in each reference to volumes of the Law Reports; in the whole of the rest of the book this proper and sensible practice does not obtain. Mr. Parry has made remarkably little use of the ordinary typographical resources which can be made of such assistance in legal textbooks—a fact which detracts enormously from the practical value of the work. There are few subheadings and little variation in the fount of type used. Thus, at p. 79, under Section 18 of the Sale of Food and Drugs Act, 1875, is set out the schedule giving the form for the analyst's certificate. This is printed in exactly the same way as Mr. Parry's comments (which follow it), and there is nothing to indicate where the schedule ends. Indeed, no one who was not already familiar with the schedule would know whether the last sentence in the schedule is statutory or whether it is an observation on the part of Mr. Parry. In one instance, however, there is too much variation. The prefatory words to Acts of Parliament (Be it enacted . . . etc.) are printed sometimes in ordinary type and sometimes in heavy black type, without any apparent reason for the distinction. Many proper names are misspelt, Macfadden, Londsdale, Meddlings, and Hillard being examples. There is an irritating absence of uniformity in the references to the reports of the Inspectors of Food to the Local Government Board, and at p. 11, dealing with the same subject, Mr. Parry writes of "these recommendations by the Local Government Board *committees*." The Pharmacy Act of 1868 is wrongly cited as the Sale of Poisons and Pharmacy Act, 1868. In the most recent edition of another text-book this unfortunate statute was cited as the Sale of Provisions and Pharmacy Act, 1868.

On the whole it may be said that while this second volume contains much that is sound, original, and interesting, it bears evidence of careless preparation, and is hardly likely to be regarded by those who have to conduct cases under the Sale of Food and Drugs Acts, as a book to be taken into the Police Court as a matter of course.

R. A. ROBINSON.

MILK AND THE PUBLIC HEALTH. W. G. SAVAGE, B.Sc., M.D. Macmillan and Co., Ltd., London. 1912. Pp. xviii + 459. Price 10s. net.

The author in his preface states that this volume is entirely concerned with milk in its relationship to the general health of the community. In Part I. he makes an endeavour to give a summary of our scientific knowledge, and of the facts with which the patient labours of many investigators have endowed us, as to the bacterial contamination of milk and its relationship to disease; in Part II. the practical bacteriological examination of milk is described in some detail, while in Part III. the administrative side of the subject is dealt with.

It is recognised that our present knowledge of the subject is far from complete, and though great strides have been made within a very few years, the chief fault of the book is the failure to grasp the fact that great advances in the technical handling of milk have also taken place in recent years; for instance, the question of preservatives is discussed quite fully, and tests are given for the leading substances that have been used; yet, although he has been obliged to go back to 1899 for any statistics as to their prevalence, the author has not realised that their use in milk has practically ceased, owing to the realisation by the technical man of the fact that it is better, and even cheaper, to keep milk by refrigerating than by drugs. The question of refrigeration is dismissed in less than a page, and no mention whatever is made of the small refrigerating plants designed specally for use with milk which are now so generally employed; there are also other reforms taking place from within the dairy industry —such as the extending use of an efficient pattern of milk churn and the provision of washing accommodation—which the author ignores.

Apart from the want of technical knowledge, and an equally excusable weakness in some of the chemical portions, the author has presented an excellent *résumé* of our present knowledge. The practical bacteriological section is less satisfactory, not through any shortcoming of the author, except possibly that he is too anxious to give all the information, and is, therefore, not sufficiently dogmatic. This will best be illustrated by a criticism of the detection of *B. coli* and allied organisms; the method is, broadly, MacConkey's, as the milk is added to lactose bile salt broth, and if acid and gas fermentation is produced, the solution is plated out on lactose bile salt neutral red agar (not MacConkey's most recent formula), which is preferred to the other media which have been proposed. What the characters of *B. coli* are is not strictly defined, though it would appear that the author considers as this all organisms which grow as red colonies on the bile salt lactose neutral red agar, and which do not liquefy gelatine, which give acid and clot in milk, ferment lactose, and which produce indol; whether even the indol production is essential is doubtful, as it is stated that the relative significance of the strains that produce indol, and those which do not, has yet to be accurately determined. It is true that the differentiation of the various species by the fermentation of sugars is discussed very fully, but the final words of this discussion are "the practical value of these tests has yet to be demonstrated."

It would have been far better, from a practical point of view, had the author selected a particular technique, described it in detail, and said, autocratically, the particular organisms identified by this method may be considered for practical purposes as *B. coli*; it is important to describe the method fully, as modifications in detail often produce large differences in the result; thus, while it is mentioned that better tests for indol are now available, no mention whatever of the *p*-methylaminobenzaldehyde method is given, though this is very much more sensitive and reliable than the old nitrite method.

In conclusion, this book is written by a bacteriologist for bacteriologists, and for the trained man who can use it with discrimination the work is full of valuable information; but the analyst whose knowledge of bacteriology is not extensive had better leave it alone.

H. DROOP RICHMOND.

CHAUX, CIMENTS, PLÂTRES. By E. LEDUC and G. CHENU. (Manuels Pratiques d'Analyses Chimiques), Paris and Liège. Ch. Béranger. 1912. Price 6 francs.

This little volume forms one of a series designed for the use of public analysts, and deals with the chemical, physical, and mechanical methods of controlling the quality of lime, cement, and plaster. The analytical methods described are almost all familiar, and little notice is taken of recent improvements in cement analysis, but the directions are clearly given and would in most cases lead to satisfactory results. Exception may, however, be taken to certain points. It is unfortunate that the misleading sugar test for "free lime" should be retained, it having long been known that the proportion of lime extracted from a cement by means of a sugar solution has no practical or theoretical significance. The methods proposed for the detection of blast-furnace slag in Portland cement are also unsatisfactory, the separation by means of methylene iodide being only applicable to coarsely-ground cements, and failing almost completely with the modern very finely ground product. Fresenius' method, based on the difference of reducing power towards permanganate, is not mentioned. Some confusion may be caused by the use in one place of Michaelis' "hydraulic modulus," and in another of a "hydraulic index" which is the reciprocal of the former, and this confusion is increased by "inférieur" being printed instead of "supérieur" at the foot of p. 95. The methods of making the usual tests of fineness, constancy of volume, tensile strength, permeability, etc., are clearly described and illustrated, the authors generally following Le Chatelier, and there are some useful tables of results obtained from cements of French manufacture. The appendix contains a full account of the French specifications for various classes of material, as well as those relating to Portland cement laid down by the Governments of Prussia, Egypt, Argentine, and Switzerland, and the American Society for Testing Materials, but the British Standard Specification is not included.

The book should be useful to French public analysts, and to others who have frequent occasion to examine products of French manufacture. C. H. Desch.

* * * * *

INSTITUTE OF CHEMISTRY.

The Thirty-fourth Annual General Meeting of the Institute of Chemistry was held on March 1 at 30, Bloomsbury Square, Dr. George Beilby, F.R.S., the President, occupying the chair.

After the routine business had been transacted, the Retiring President delivered his address. He showed that, during his period of office (1909-1912), the Institute had increased by 102 members and 86 students, while the number of candidates for examination during the same period had increased by about twenty. The scheme for raising a fund for new buildings for the Institute had made substantial progress, and had reached the sum of over £8,500 of the £15,000 considered necessary for the erection of a simple but dignified building suitable for carrying on the work of the Institute. Speaking of the prospects of the profession of chemistry, he believed that there was plenty of room for men of the right stamp, both in educational and industrial work. The Institute had been able to secure appointments for many young members of the profession, and, indeed, lately it had been difficult to find candidates for appointments offering quite good commencing salaries and fair prospects. Touching on the difficulties which confront public analysts and private practitioners, he referred to the attempts made on the part of certain local authorities to lower the status of the professional chemist by offering appointments at ridiculous remuneration. The Institute had decided to take a new and somewhat drastic step by issuing a notice (ANALYST, 1912, 119) to Fellows and Associates, advising them not to apply for appointments advertised by the Metropolitan boroughs of Lambeth and Wandsworth, both of which at the present time seek to appoint a public analyst who will be required to provide a laboratory, duly equipped, and a deputy, and to examine possibly as many as 2,000 samples, for £500 per annum; while the County of Antrim seek to appoint a public analyst to examine an indefinite number of samples—almost certainly over 800 a year—at a salary of £150. The more enlightened municipal bodies realise that the proper administration of important Statutes, such as the Sale of Food and Drugs Act, cannot be expected unless they succeed in attracting to their appointments men of competence and integrity, and, moreover, men who can hold their own as responsible representative officers of their authorities. The Act is as much a Statute against fraud as in the interests of public health, and it must be clearly understood that the public analyst is in no way subject to the control of the Medical Officer of Health. It was a false notion that medical men were capable of controlling chemical laboratories. Very few of them possessed anything approaching a competent knowledge of chemistry in any one of its branches, and it was astonishing to find Government authorities in some of our overseas dominions requiring doctors of medicine to supervise qualified professional chemists engaged in laboratories mainly devoted to the analysis of metals and ores. DR. BEILBY referred to important changes which were being made in educational appointments, particularly the Chairs of Chemistry at the Royal College of Science, Dublin, Oxford University, and University College, London, indicating how men who had achieved great things were making way for the younger generation of chemists, to whom we look to maintain the honour of the British school of chemistry, to which their predecessors had contributed so much. During the past year the Council had inaugurated a new scheme of lectures, mainly intended to help registered students and the younger members, such lectures being given by acknowledged experts in various branches, and illustrating the actual work of practice as distinct from purely academic training.

A ballot having been taken, Dr. George Beilby, F.R.S., Professor Percy F. Frankland, F.R.S., Mr. David Howard, and Sir William Tilden, F.R.S., were declared elected as censors.

The following were elected officers and Council:

President.—Raphael Meldola, D.Sc., LL.D., F.R.S.

Vice-Presidents.—George Thomas Beilby, LL.D., F.R.S.; Frank Clowes, D.Sc.; George McGowan, Ph.D.; Sir Alexander Pedler, C.I.E., F.R.S.; John Millar Thomson, LL.D., F.R.S.; Sir William Augustus Tilden, D.Sc., LL.D., F.R.S.

Hon. Treasurer.—Alfred Gordon Salamon, A.R.S.M.

Members of Council.—Francis William Frederick Arnaud; Edward John Bevan; Bertram Blount; Arthur George Bloxam; James Connah, B.Sc.; William Salvador Curphey; Cyril Dickinson, B.Sc.; James Johnston Dobbie, Ph.D., LL.D., F.R.S.;

William Porter Dreaper; Martin Onslow Forster, D.Sc., F.R.S.; John Alfred Foster; Sir Richard Garton; Frank William Harbord, A.R.S.M.; Otto Hehner; Gordon Wickham Monier-Williams, B.A., Ph.D.; William Henry Perkin, LL.D., Ph.D., F.R.S.; Thomas Slater Price, D.Sc., Ph.D.; Charles Proctor; Sir Boverton Redwood, Bart., D.Sc.; Henry Droop Richmond; Clarence Arthur Seyler, B.Sc.; Alfred Smetham; Thomas Stenhouse, jun., B.Sc., A.R.S.M.; Oliver Trigger; Edward William Voelcker, A.R.S.M.; John White; Sydney Young, D.Sc., F.R.S.

MAY, 1912. Vol. XXXVII., No. 434.

THE ANALYST.

OBITUARY.

ARTHUR EDWARD EKINS, J.P., F.I.C.

Arthur Edward Ekins, whose death on March 12 was briefly recorded in our last number, was one of the early members of the Society of Public Analysts. He was the son of a farmer in the Fen country, was born in the Isle of Ely in 1852, and educated at St. Ives Grammar School and at Melbourn, Cambridge. He was originally trained for pharmacy, and in 1876 established a pharmaceutical business at St. Albans. In conjunction with this he carried on an analytical practice, chiefly in connection with agricultural matters, as Analyst to the Herts Agricultural Society. On the death of Charles Heisch, the County Analyst, in 1892, Mr. Ekins was appointed Public Analyst for the County under the Sale of Food and Drugs Act, shortly after which he retired from his pharmacy in order to devote himself more fully to his professional duties, as well as to the municipal work of the Corporation of St. Albans, in which he had always taken an active part. He occupied the position of Mayor of the City in the year of King Edward's Coronation, and it is recorded that during his mayoralty he attended in his official capacity no fewer than 600 meetings.

In addition to working constantly on the various committees of the Corporation (including the Library Committee, the Assessment Committee, and the Pensions Committee), he laboured assiduously as a Magistrate, Poor Law Guardian, Overseer, Churchwarden, and Manager and Treasurer of the local Christ Church School. He also held the position of Chairman of the local County Council School Managers, of the Joint Committee of the Sisters' Hospital and of the St. Albans Building Society. He took a prominent part in the masonic life of the county, in which he held honours as a Provincial Grand Officer.

All these forms of civic and social activity left him but little time for active contribution to the advancement of chemical knowledge by original work, but he did his work as County Analyst conscientiously and effectively, his duties extending to the annual examination of a considerable number of water samples and sewage farm effluents, in addition to his routine work under the Sale of Food and Drugs Act. It was very rarely that Mr. Ekins missed his attendance at the monthly meetings of the Society of Public Analysts or at the social gatherings connected with them. He served the Society not only as a member of Council, but as Vice-President, in which capacities his assiduous attendance at both Council and Committee meetings was rendered the more useful by reason of the sound judgment and business ability which he always brought to bear on the matters under discussion. He had, moreover, a high sense of professional honour, which gained for him the respect and esteem of his colleagues, while his geniality and kindheartedness equally won their personal affection.

BERNARD DYER.

JOHN PATTINSON, J.P., F.I.C.

JOHN PATTINSON was born at Alston, in Cumberland, on February 13, 1828. His schooldays were spent in his native town, and, as a youth, he was brought to Newcastle by his distant relative Hugh Lee Pattinson, well known as the inventor of the Pattinson process for desilverising lead. Hugh Lee Pattinson was a proprietor of the Felling Chemical Works, and there John Pattinson received his early chemical training. He remained there for ten years, and then went to Middlesbrough, under another north-country leader of industry, Isaac Lowthian Bell. He thus obtained a first-hand knowledge of the processes involved in the alkali manufacture, and in the iron and steel manufacture of the time. In 1858 he returned to Newcastle, and took over the practice of analytical and consulting chemist of William Crowder, in the Side, out of which the present firm of J. and H. S. Pattinson has developed. In 1868, along with other devotees of chemical science in the town and district, he took part in the foundation of the Newcastle Chemical Society; he was treasurer of that Society until the date of its absorption into the Society of Chemical Industry in 1882, president in 1874-5, and contributed to it papers on the determination of peroxide of manganese, on the quality of the small coal used on the Tyne, on the determination of arsenic in copper, and on other subjects. When the British Association met in Newcastle in 1863, he read a paper on the pyrites used on the Tyne. His practice dealt largely with iron and manganese ores, and in 1879 he read a paper (*J. Chem. Soc.*, 1879, 365) on the determination of manganese, describing a volumetric method which, with slight modifications (described in *J. Soc. Chem. Ind.*, 1891, **10**, 333), is still widely used, and is probably the most accurate method known. Several other papers and notes appear under his name, alone, or in association with his son the late Dr. H. S. Pattinson or with Dr. Dunn, in the Society of Chemical Industry's *Journal*. He was one of the earliest of Public Analysts; he was appointed Gas and Water Examiner for Newcastle in 1863 or earlier, Food Analyst in 1871, and later became, under the Food and Drugs Acts, Public Analyst for the town, for the county of Northumberland, and for other boroughs in the district. He had been a Vice-President of the Chemical Society, and Vice-President of this Society; was an original Fellow of the Institute of Chemistry, which he had served as member of Council and as Censor; and an original member of the Iron and Steel Institute. He was an enthusiastic musician, was a Vice-President of the Newcastle Literary and Philosophical Society, a justice of the peace, and greatly interested in social and philanthropic matters. He kept up all his interests, professional and other, to the last; and after only a few days' illness he died on March 28 last.

J. T. DUNN.

EDWARD DIVERS, M.D., F.I.C., F.R.S.

EDWARD DIVERS was born in London in 1837, and was educated at the City of London School. He subsequently studied chemistry under Professor A. W. Hofmann at the Old College of Chemistry, Oxford Street, and in 1866 he graduated as M.D., at Queen's College, Galway. He was in private practice until 1873, when, at the invitation of the Japanese Government, he, with other Englishmen, went to that country to establish a College of Engineering. This College ultimately became part of the Imperial University, and Divers was appointed Professor of Chemistry. In 1886 he retired, and was made Emeritus Professor; he received the second class of the order of the "Sacred Mirror," and the third class of the order of the "Rising Sun."

On his return to England he at once took an active part in the affairs of the Chemical Society and the Society of Chemical Industry. In 1893 he was elected a Fellow of the Royal Society.

The name of Divers will always be associated with the subject of the oxides of nitrogen and sulphur, and with hyponitrites, of which he was the discoverer. In conjunction with Shimose, he was the first to show that when tellurium monoxide is heated in hydrochloric acid gas, it is converted into tellurium dichloride.

Divers will be missed by a wide circle of friends, for his charming personality, kindliness, and urbane manners endeared him to many.

He died on April 8.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE Monthly Meeting of the Society was held on Wednesday evening, April 3, in the Chemical Society's Rooms, Burlington House. The President, Mr. L. Archbutt, F.I.C., occupied the chair.

The minutes of the previous Ordinary Meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. L. Goodban, A.I.C., and R. F. Easton were read for the second time, and certificates in favour of Messrs. Harold Thomas Cranfield, Assistant Lecturer in Chemistry and Assistant Analyst at the Midland Agricultural and Dairy College, Kingston, Derby; Ernest Gabriel Jones, M.Sc. (Victoria and Liverpool), F.I.C., City Laboratories, 36, Dansie Street, Liverpool, Deputy Public Analyst and Deputy Agricultural Analyst for the City of Liverpool; and William Henry Roberts, M.Sc. (Victoria and Liverpool), F.I.C., City Laboratories, 36, Dansie Street, Liverpool, Public Analyst for the City of Liverpool, and the County Boroughs of Blackburn, Preston, Bootle, and Barrow-in-Furness, Official Agricultural Analyst for the City of Liverpool and Borough of Bootle, were read for the first time.

Messrs. M. E. Balston, M.A., H. A. Caulkin, B.Sc., F.I.C., and C. R. Wilkins, B.Sc., were elected members of the Society.

The following papers were read: "The Separation of Arsenic from Antimony," by Stanley W. Collins, B.Sc., F.I.C.; "The Estimation of Ferric Iron in Presence of Certain Organic Substances," by John Theodore Hewitt, M.A., D.Sc., Ph.D., F.R.S., and Gladys Ruby Mann; "The Relation of the Kirschner and Polenske Values in Margarines containing Cocoanut or Palm Kernel Oils," by E. Richards Bolton, H. Droop Richmond, F.I.C., and Cecil Revis; "Note on the Milk of a Small Herd," by Edward Russell, B.Sc., F.I.C.; and "A Convenient Apparatus for Obtaining an Average Sample of Gas and for Regulating the Flow of a Gas into an Evacuated Vessel," by Frank Sturdy Sinnatt.

THE SOURING OF MILK.

By H. DROOP RICHMOND, F.I.C., and HORACE C. HUISH.

(*Read at the Meeting, February* 7, 1912.)

Part I.—Method used.

The rate of souring of milk is determined by a series of acidity estimations at intervals, and depends on the difference in the acidity at a given interval from that at the commencement; as milk is a substance in which the concentration of the hydrogen ions is low, the end reaction with the most convenient indicator—phenolphthaleïn—is not very sharp. We have taken the point of neutralisation to correspond with the appearance of a faint pink colour, but we find that under varying conditions of light, and to the eyes of different operators, there is an appreciable variation in the end-point; between two or more experienced operators who have learned to appreciate the point at which a very faint pink colour appears there may be a difference of as much as 2°, and this difference may increase sometimes up to 5° with operators of less experience. Even the same operator does not always make very concordant duplicate determinations if the conditions differ.

Even using a blank, we do not find that the accuracy of the determination is greatly increased, and we have experimented in several directions with a view of increasing the accuracy of this determination. By colouring the milk faintly green (the colour complementary to pink), it was found that the accuracy was slightly, though not very markedly, increased, especially if a green-tinted blank were used; but after a prolonged experience of this method we came to the conclusion that it was wrong in principle to try and work from a colour, but that the best method would be to endeavour to work to the appearance of a definite tint.

We find that, although the colour given by rosaniline to milk is not exactly the same tint as that yielded by phenolphthaleïn when made alkaline, it is in very dilute solution sufficiently near to enable it to be used as a standard tint, and the method we now employ is this: Eleven c.c. of the milk to be tested is placed in each of two similar beakers, and to one, which serves as the standard tint, one drop of a 0·01 per cent. solution of rosaniline acetate in 96 per cent. alcohol is added; to the other 1 c.c. of a 0·5 per cent. solution of phenolphthaleïn is added, and the milk is titrated with $\frac{N}{11}$ strontia solution till its tint is equal to that of the standard. The result expressed as cubic centimetres of normal alkali per litre we term "degrees of acidity" (rosaniline standard), or, more shortly, R. S. We find that not only do different operators obtain closely concordant results, but that the nature of the light makes no difference in the end-point. The results are about 1·5° higher on the average than those obtained when titrating to the appearance of a faint pink colour.

By the use of the rosaniline standard we have far more confidence in the accuracy of the determination of small increases in acidity, and we may mention incidentally that the accuracy of the determination of the aldehyde figure, which depends likewise on a difference between two titrations, has also been increased.

PART II.—THEORETICAL CONSIDERATIONS.

In endeavouring to trace the course of the souring of milk we have made certain assumptions. The first is that it is due to micro-organisms, or that, if due to enzymes secreted, these do not diffuse away from the micro-organisms into the liquid; or, in other words, the amount of acidity produced at any moment is proportional to the micro-organisms present at that moment. The second assumption is that the rate of diffusion of the acid produced away from the micro-organisms is rapid compared with the rate of production.

These assumptions lead us to the differential equation:

$$dm = \mathrm{k}da \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

(m = number of micro-organisms; a = acidity.)

If we make the further assumption that the increase in the number of micro-organisms is proportional to the number present at any moment, we may write from this assumption and from (1) the differential equation

$$da = \mathrm{k}'adt \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

(t = time),

which leads to the equation

$$\log a = \mathrm{k}'t + c \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3),$$

which leads to a simple logarithmic curve for the souring of milk.

On the assumption that no increase of micro-organisms takes place, but that each micro-organism produces acid at a definite rate, the differential equation

$$da = \mathrm{k}''dt \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

results, leading to the equation

$$a = \mathrm{k}''t + c' \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5),$$

which shows a straight line as the curve.

If we assume that the micro-organisms do not increase, and that the rate of production of acidity falls off in proportion to the amount of acid already developed acting for a unit of time, we arrive at the differential equation

$$da = k''' \frac{a}{t} dt \quad . \ . \ . \ . \ . \ . \quad (6),$$

which on integrating gives us—

$$\log a = k''' \log t + c'' \quad . \ . \ . \ . \quad (7).$$

The curve of this equation is a parabola, though not necessarily a rectangular parabola.

PART III.—EXPERIMENTAL.

From the mean of a very large number of acidity determinations at known periods of time we have constructed the table below. This shows the acidity developed at intervals of five hours from the time of milking, when the milk was kept at a temperature of 68° F. There has frequently been a difference of several units in the acidity developed in different samples, but by averaging the results of a large number we believe we have obtained a fair representation of the average souring of milk.

Average Souring of Milk.

Time in Hours.	Acidity.	Calc.	Time in Hours.	Acidity.	Calc.
10	0	0·2	60	71	77·1
15	0·1	0·5	65	74	74·3
20	0·3	1·1	70	76·5	77·1
25	2·3	2·5	80	82	81·5
30	6·0	5·7	90	85	85·0
35	13·0	13·1	100	88	88·9
40	30·0	29·9	110	91	90·7
45	50	50·5	120	93	93·1
50	62	61·1	130	95	95·2
55	67	66·8	140	97	97·0

The formula used for calculating the acidity up to 45° acidity is

$$\log_{10} a = 0{\cdot}072\, t - 1{\cdot}406,$$

which is of the type of (3); and that used after 45° is

$$\log_{10} a = 1{\cdot}621 + 0{\cdot}184 \log (t - 42{\cdot}2),$$

which is of the type of (7). It is interesting to note that these two curves do not meet, indicating that there is a short period during which another curve, possibly of the type of (5), expresses the results.

The change from one branch of the curve to another is quite sharp, and takes place at 45°, which is the point at which micro-organisms cease to develop in milk (*cf.* Revis and Payne, *J. Hygiene,* 1906, 216); there is no other break in the curve, that mentioned by one of us and Miller (ANALYST, 1907, **32,** 144) at 65° not having a real existence.

To try and elucidate this sudden change in the rate of souring of milk at the point when an acidity of 25° has been developed, we have made a number of careful experiments in which continuous observations were made over a period of forty-eight hours, determinations in some cases being made hourly. It will not be necessary to give these experiments in full. The following is an abstract of the results:

1. In three series of experiments in which milk to which a definite amount of alkali had been added, and milk to which a definite amount of acid had been added, were allowed to sour side by side, it was found that the point at which the break occurred was advanced or retarded by an amount equal to the quantity of acid or alkali added. Thus, a milk with an acidity of 18·2° was reduced in acidity to 3·3° by the addition of caustic soda, and increased to 28·6° by the addition of hydrochloric acid. The points at which the breaks occurred were 45°, 60°, and 34°, respectively.

2. It was found in every case that the addition of alkali slightly accelerated the rate of souring, and that of acid slightly retarded it, but to a very small extent.

3. Experiments on pasteurised milk to which either pure cultures of lactic organisms or a little stale milk was added showed a greatly increased rate of souring. The greatest acceleration of souring was shown by a sample of milk which was allowed to become partially sour, and was then neutralised with soda and pasteurised, and inoculated with a trace of the unpasteurised milk.

4. It was found that in every case, no matter what the rate of souring, the curves were very similar. There were, however, slight differences (best seen on plotting out the logarithms of the acidity against time). In some cases a distinct acceleration of the rate of souring was seen, and in others a very distinct retardation.

From these results we conclude that—

(*a*) On growing in milk the organisms developing acidity become more active.

(*b*) The organisms are retarded by the acidity they develop, and in the majority of cases this retardation is balanced by the acceleration due to their growing in milk.

(*c*) At an acidity equal to 45° the retardation becomes very great. The point 45° of acidity depends on the nature of the salts present in milk, as in whey it is about 30°, and in a lactose solution about 20°. It is probable that these acidities represent the same concentration of the hydrogen ions.

It follows as a corollary that the organisms which normally cause the souring of milk are not those whose normal habitat is milk, and it is not improbable that they are of intestinal origin.

DISCUSSION.

Mr. C. REVIS said that he was glad to hear that the authors did not consider that the ordinary lactic acid organisms found their natural habitat in milk. He (the speaker) had for some time been of opinion that the lactic acid organisms usually found in milk were derived principally from cow-dung. It might be contended that such organisms, when found in milk, often came from the udder, but *Streptococcus mastitis*, which grew in the udder in cases of mastitis, was probably from the same source. One observer, however, considered that lactic acid organisms were derived from the cow's saliva. He thought, however, that the cow-dung was the principal source of the organisms, and that milk was certainly not their natural habitat. The problem from a bacteriological point of view was a very difficult one, there being no means of ascertaining at any moment how many organisms were present in the milk, how many were active, or at what rate they were dying out. Grimme, in some work on this subject, had obtained curves identical with those obtained by the present authors, shewing that there was at first no measurable increase in acidity, although the organisms must have been multiplying. Was there a stage in the life of the organism which had to be reached before it exercised a certain activity, which afterwards gradually decreased? At the point at which there began to be a decrease in the rate of acid production, it might be that the action of the organisms was inhibited by the acid, but he thought it probable that a greater number of them were dying out at the same time, and that the decrease in acidity might be due simply to the fact that more of the organisms were caused to die off through the acidity they produced than were being produced by multiplication of those still active. He had found with *B. coli* that the activity of that organism and the results it produced were profoundly affected by slight changes in reaction of the nutrient medium. The lactic acid organisms were undoubtedly very sensitive to the acid they produced, for if a culture were left for a fortnight or three weeks it would become absolutely sterile. With a pure culture the problem was simpler, but if lactic acid organisms were grown in the presence of other organisms common to milk which did not themselves produce acid, the rate of acid production by the lactic acid organism was often much modified. It had to be remembered that up to the point of coagulation of the milk the organisms were not exposed to the same acidity as they were after that point. The lactic acid at first was neutralised by the calcium in combination with the casein, and although the casein exerted an equivalent chemical activity, it might not be equivalent bacteriologically, and so be less inimical to the development of the organisms.

Dr. Lessing mentioned that a method had been published by Dr. Schryver and himself some years ago for measuring bacterial reactions of this kind by means of electrical conductivity. They had found it possible, when the action of the bacteria was inhibited by antiseptics, to see whether the changes went on, and so to ascertain whether the action was due to enzymes alone, or to bacteria alone, or to both together.

The President asked whether the shape of the curve was not a good deal dependent on the conditions of the experiment.

Mr. Richmond said that the curve was always of the same shape, whatever its conditions, though its dimensions sometimes varied. The period during which no increase in acidity was indicated was determined by the point at which it was possible to detect acidity. Personally he did not think that less than ½ degree could be detected with certainty, and it was an appreciable time before so much acid as that was produced, so that the production of acid might be going on at its regular rate for some time before it was possible to know anything about it. They had had in mind the method of Dr. Lessing and Dr. Schryver, and intended to make use of it as soon as they could obtain the apparatus and had had sufficient experience of its use.

* * * * *

THE ESTIMATION OF AMMONIA IN CARBONATED WATERS.

By G. D. ELSDON, B.Sc., A.I.C., and NORMAN EVERS, B.Sc., A.I.C.

(*Read at the Meeting, March* 6, 1912.)

During the examination of a series of samples of soda water, our attention was drawn to the smallness of the figures which we obtained for free ammonia, even in those waters which contained considerable quantities of albumenoid ammonia. Only four out of twenty samples contained any free ammonia at all, and of these 0·005 part per 100,000 was the highest. Some typical results are shown in Table I.

Table I.

Sample.	Parts per 100,000.	
	Free Ammonia.	Albumenoid Ammonia.
A	0·000	0·040
B	0·000	0·011
C	0·000	0·007
D	0·000	0·009
E	0·002	0·005
F	0·005	0·006

For the estimation of free ammonia, the contents of two syphons were transferred to a Winchester quart, the whole thoroughly shaken to remove the gas, and the ammonia estimated in the usual manner in 500 c.c. One c.c. of Nessler solution was used to 50 c.c. of distillate, the Nessler solution containing: Potassium iodide, 6·0 per cent.; mercuric chloride, 2·5 per cent.; potassium hydroxide, 15·0 per cent. (Frankland, "Thorpe's Dictionary of Applied Chemistry," vol. iii., p. 980).

In order to find out whether the presence of carbon dioxide in the distillate affects the estimation of free ammonia, a definite amount of standard ammonium chloride solution (1 c.c. = 0·00001 grm. ammonia) was added to an ordinary potable water known to be ammonia free. This water was then carbonated and the ammonia estimated as usual. Several similar estimations were carried out with results as set out in Table II.

Table II.

Sample.	Original Water.	After Carbonation.
A	0·004	0·001
B (1)	0·010	0·004
B (2)	0·010	0·005
C	0·020	0·003
D (1)	0·017	0·005
D (2)	0·017	0·007

The amount of ammonia found in each 50 c.c. of distillate was very unusual—*e.g.*, in the case of sample D (2) the first cylinder contained 0·000, the second 0·006, the third 0·001, and the fourth 0·000, suggesting that the carbon dioxide, which would be nearly all driven over into the first 50 c.c. of distillate, affects the colour produced by the Nessler reagent. We observed in some cases a transient yellow colour as the Nessler solution was added to the first 50 c.c. of distillate, but this entirely disappeared on shaking. On adding further quantities of Nessler solution to these cylinders, a permanent colour was produced in some cases; whilst in other cases, after a few moments' standing, a red precipitate appeared which proved to be mercuric iodide.

Effect of Carbon Dioxide on Nessler's Reagent.—Ten c.c. of Nessler solution were added to 500 c.c. of water containing 0·060 parts per 100,000 of free ammonia. The usual yellow colour was produced, but, on carbonating, this colour was immediately destroyed and, after a few minutes, precipitation of mercuric iodide began.

Two series of standards were made up, each containing 0·5, 1, 2, and 3 c.c. of standard ammonium chloride. The first was prepared with ordinary ammonia free water, and the second with carbonated ammonia-free water. It was found that on adding 1 c.c. of Nessler solution no colour was produced in any of the cylinders prepared with carbonated water, although the usual gradation was observed in the others; on adding a second c.c. of Nessler solution to the carbonated series, immediate precipitation occurred in all the cylinders.

From the above experiments it was quite obvious that the presence of carbon dioxide in quantity seriously affects the colour produced on adding Nessler solution to dilute solutions of ammonia. Our attention was then directed to the quantities of carbon dioxide which would thus interfere.

For this purpose a number of cylinders were taken containing a known fixed amount of ammonia and varying quantities of carbon dioxide, the latter being introduced by adding suitable amounts of standard acid and standard sodium carbonate. It was found that the presence of carbon dioxide in quantities exceeding about five parts by weight per 100,000 diminishes the colour produced, and that no colour is produced with quantities of carbon dioxide exceeding about 50 parts per 100,000. When the amount of carbon dioxide present approaches saturation, precipitation of mercuric iodide takes place in a short time. If a larger quantity of Nessler solution is used, the amount of carbon dioxide necessary to affect the colour is greater, but the tendency to precipitation is increased. It seems probable that the effect on the colour is caused by the reduction of the amount of caustic potash present, as hydrochloric acid in equivalent quantities has a somewhat similar action. The presence of sodium bicarbonate also interferes with this colour in precisely the same way as carbon dioxide. Sodium carbonate has no effect.

Modifications Attempted.—In order to get over the above difficulty, the effect of using a Nessler solution of greater alkalinity was tried. Although the results obtained by this method showed a distinct improvement, they were by no means satisfactory.

The removal of carbon dioxide by boiling with a slight excess of hydrochloric acid was then tried, the free hydrochloric acid being driven off by evaporation to dryness. The residue was dissolved in 500 c.c. of ammonia-free water, and the ammonia estimated as usual. The results were good, but the method was tedious.

Process Recommended.—Finally we adopted the following method: After removal of as much carbon dioxide as possible by shaking in a Winchester, 500 c.c. of the water are transferred to the distillation flask and 5 c.c. of $\frac{N}{1}$ sulphuric acid (or more if the alkalinity of the water requires it) are added. Fifty c.c. are then distilled off and rejected, thus removing the carbon dioxide. An equivalent quantity of standard sodium hydroxide is then added, and the usual amount of sodium carbonate. The estimation of free and albumenoid ammonia is then proceeded with in the usual manner. Using this process, we have examined a number of samples of water carbonated in the laboratory; the results are set out in Table III.

TABLE III.

Waters Carbonated in the Laboratory.

Source.	Ammonia Parts per 100,000.					
	Original Water.		Carbonated Water.			
			Ordinary Method.		Suggested Method.	
	Free.	Albumenoid.	Free.	Albumenoid.	Free.	Albumenoid.
Ammonia-free water	0·000	0·000	0·000	0·000	0·000	0·000
Upland surface water, raw	0·003	0·009	—	—	0·003	0·009
,, ,, ,, filtered ...	0·001	0·005	0·000	0·006	0·001	0·007
,, ,, ,, ,, ...	0·000	0·004	0·000	0·006	0·000	0·006
Stream water A	0·006	0·013	0·001	0·017	0·008	0·019
,, B	0·025	0·020	0·003	0·023	0·025	0·021
,, C, filtered	0·000	0·006	0·000	0·010	0·000	—
Deep well water	0·000	0·000	—	—	0·000	0·002
,, ,, filtered	0·000	0·004	0·000	0·008	0·000	0·008
Pond water A	0·065	0·065	0·055	0·065	0·065	0·065
,, B	0·055	0·045	0·017	0·045	0·055	0·045

From the above table it will be seen that the results obtained for free ammonia by the suggested process agree with those obtained on the uncarbonated water by the ordinary method. It is obvious that, if the first 50 c.c. of distillate obtained from a carbonated water by the ordinary method is divided or diluted for the purpose of Nesslerising, the amount of carbon dioxide present, and therefore the error, will be proportionately less.

The albumenoid ammonia is slightly increased by carbonation, whether it is estimated by the ordinary method or by the suggested method. This increase in albumenoid ammonia seems to take place immediately on carbonation, and no further increase takes place on standing. That no albumenoid ammonia is due to impurities in the carbon dioxide used is proved by the fact that, in the case of ammonia-free water (prepared by distillation with alkaline permanganate), no albumenoid ammonia was found after carbonation.

Acid Effluents.—It is sometimes necessary to estimate ammonia in effluents containing large amounts of free acid; this is usually done by making alkaline with sodium carbonate and distilling. It is evident that the carbon dioxide evolved may in some cases be sufficient to affect the estimation of ammonia, and to obtain a correct result the water must be made neutral with sodium hydroxide before adding sodium carbonate.

Commercial Soda-Water.—The following results were obtained with samples of commercial soda-water procured from ordinary sources:

TABLE IV.

Sample.	Ammonia Parts per 100,000.

G	0·000	0·004	0·003	0·004
H	—	—	0·002	0·002

Note.—Since reading this paper we have studied the effect of carbon dioxide on Nessler solution prepared both according to the formula given in Fresenius, "Quantitative Analysis," vol. ii., p. 128, and according to that given in Sutton, "Volumetric Analysis," seventh edition, p. 465. Although the results obtained show an improvement on those given in our paper, owing to the larger amount of potash present, we find that carbon dioxide in amounts exceeding about fifty parts by weight per 100,000 causes a reduction in the colour obtained; this amount of carbon dioxide is much less than would be obtained in the first 50 c.c. of distillate from a carbonated water.

We have also compared the colour produced by the various Nessler solutions (made according to these formulæ) with a given quantity of ammonia, and find that there is very little difference between them.

DISCUSSION.

The **PRESIDENT** remarked that, as the Nessler solution contained a large excess of potash, which must already contain some carbonic acid, it seemed rather strange that a small extra quantity of carbonic acid should have so great an effect. If this action occurred in aerated waters which had been shaken to remove most of the carbonic acid, it must occur also in many natural waters which contained considerable quantities of carbonic acid capable of being given off on boiling, so that, apparently, such waters also should be acidified, and the carbonic acid boiled off, before the free ammonia was determined.

Mr. W. T. **BURGESS** said that he understood the authors to say that better results were obtained when the quantity of Nessler solution was increased. His own practice, particularly with waters likely to contain very little free ammonia, was to use, for the 100 c.c. Nesslerised, 6 c.c. of Nessler solution prepared according to the formula of Frankland, containing 62·5 grms. of potassium iodide per litre; and working in this way he had not noticed any diminution in the free ammonia due to carbonic acid. In carbonated waters as much as possible of the carbonic acid was of course got rid of before the ammonia determination was commenced.

Mr. E. M. **HAWKINS** suggested that it might be possible to avoid two distillations by adding an excess of recently ignited caustic lime, which would combine with the carbonic acid and render the addition of sulphuric acid unnecessary. From his own experience, he was inclined to think that the use of caustic lime would be attended by satisfactory results, and it would not, as far as he could see, cause any difficulty in the subsequent process of determining the albumenoid ammonia.

Mr. A. **CHASTON CHAPMAN** remarked that, while the authors had undoubtedly shown that some effect was produced on Nessler solution by carbonic acid, he was inclined to think that this effect would not have been noticeable had a more sensitive Nessler solution of the usual composition been used.

Mr. **EVERS**, in reply, said that the neutralisation of only about one-tenth of the potash present was sufficient to lessen the colour. He did not know whether the addition of caustic lime would be advantageous, but, as a matter of fact, the distillation was practically one continuous process. He should imagine that, if a Nessler solution containing more potassium iodide were used, the tendency towards precipitation would be greater. Dr. Thresh recommended a solution which gives, on adding it to the distillate, about the same strength as Sutton's as regards potassium iodide, but about one and a half times the strength of potash. With such a solution some colour, at any rate, would be obtained in most cases, but it would be reduced in many cases by the carbon dioxide, and in the ordinary way such a reduction might not be noticed.

NOTE ON A NEW PRESERVATIVE FOR MILK, CREAM, ETC.

BY G. A. STOKES.

(*Read at the Meeting, March* 6, 1912.)

I HAVE recently examined a number of samples of milk which contained a new preservative, consisting of sodium nitrite, formaldehyde, and water, sold under the name of "Mystin" (*cf.* Monier-Williams, ANALYST, 1912, 155). This preparation, owing to the presence of sodium nitrite, fails to respond to Hehner's test and Schiff's reagent. In estimating the fat by the Gerber process, the presence of formaldehyde will generally be detected.

By adopting the following methods, as little as 2 drops of preservative per 100 c.c. of milk may be detected:

1. A portion of the milk is coagulated with dilute sulphuric acid, filtered, and a solution of diphenylamine in sulphuric acid added to the clear filtrate. The formation of a deep blue colour shows the presence of nitrite (or nitrate).

2. One hundred c.c. of the milk are acidified with 5 c.c. of strong phosphoric acid and distilled in a current of steam. About 10 c.c. are distilled into an equal volume of Schiff's reagent; if a pink coloration develops within five minutes the presence of formaldehyde is indicated. "Mystin" added to milk in the proportion of 3 c.c. per litre was found to be a fair preservative. Thus, after three days the acidity developed was only equivalent to 0·24 per cent. of lactic acid, whereas the same milk unpreserved showed an acidity equivalent to 0·69 per cent. of lactic acid.

DISCUSSION.

Dr. MONIER-WILLIAMS said that he was very glad to have heard Mr. Stokes's paper, because it directed attention to one or two new points. It was curious that the addition in this way of so little as 1 part of formaldehyde in 300,000 should be sufficient to preserve milk for three days. It was generally understood that, when formaldehyde was used as a milk preservative, a considerably larger quantity than this was required. It was interesting to note that potassium chlorate and potassium nitrate also interfered with the Hehner reaction. The action of these two substances might very likely depend on a direct oxidation of the colouring matter or of the formaldehyde, and possibly other oxidising agents might have a similar effect, if present in sufficient amount.

Mr. W. BACON remarked that possibly the increased antiseptic effect of the formaldehyde in this mixture might be due to the action of the nitrite in preventing condensation of the formaldehyde with the amino-acids of the milk proteids.

Mr. STOKES, in reply, said that he ought perhaps to have mentioned that his experiments were made during somewhat cold weather. Possibly in warmer weather the preservative effect might not have been so good. He had met with two cases in which this preservative was present in samples taken under the Sale of Food and Drugs Act.

THE ESTIMATION OF FERRIC IRON IN PRESENCE OF CERTAIN ORGANIC SUBSTANCES.

By JOHN THEODORE HEWITT, D.Sc., Ph.D., M.A., F.R.S., and GLADYS RUBY MANN.

(*Read at the Meeting, April* 3, 1912.)

Recently, one of the authors of this communication desired to measure the rate at which certain organic substances were oxidised by alkaline permanganate. It was an easy matter to stop the reaction at any instant by adding an excess of ferrous sulphate and dilute sulphuric acid; it was not, however, quite obvious how the amount of unchanged ferrous salt or of the ferric salt produced could be determined. Determination of unchanged ferrous salt is out of the question, as the residual organic matter may, and in many cases did, act as a vigorous reducing agent on acid solutions of dichromate or permanganate, hence a method for estimation of the ferric salt had to be adopted. Methods depending on the use of stannous or titanous chlorides had to be abandoned, as the organic substances in some cases contained nitro-groups, and consequently recourse was had to methods involving the use of thiosulphate.

The original method, due to Scherer, of considering the reaction finished when no further increase of the violet coloration was noticed on adding the thiosulphate to the ferric solution does not give very sharp results, so that the methods in which the reaction

$$2Fe^{\cdots} + 2S_2O_3'' = 2Fe^{\cdot\cdot} + S_4O_6''$$

is allowed to become complete, and the excess of thiosulphate is determined with iodine were examined. (Kremer and Landolt, *J. pr. Chem.*, 1861, **84**, 339; *Zeitsch. anal. Chem.*, 1862, **1**, 214; Oudemanns, *Zeitsch. anal. Chem.*, 1867, **6**, 129; 1870, **9**, 342; compare Balling, *ibid.*, **9**, 99.) The direct method of adding potassium iodide to the ferric solution,

$$2Fe^{\cdots} + 2I' = 2Fe^{\cdot\cdot} + I_2,$$

and titrating the liberated iodine with thiosulphate (F. Mohr, *Annalen*, 1860, **113**, 257; *Zeitsch. anal. Chem.*, 1863, **2**, 243; C. D. Braun, *J. pr. Chem.*, 1860, **81**, 423; *Zeitsch. anal. Chem.*, 1864, **3**, 452), would have been sufficiently accurate (see Joseph, *J. Soc. Chem. Ind.*, 1910, **29**, 187; Schatz, *Pharm. Zeit.*, 1910, **55**, 292) but for the fact that it was impossible to allow the iodine to remain in contact with the organic matter, which was frequently of unsaturated or phenolic character.

Experiments were consequently made with Oudemann's method, various organic substances being added at the same time. Generally 20 c.c. of an iron alum solution, about decinormal (5·585 grms. ferric iron per litre) in strength, were mixed with a solution of the organic compound under examination, then 3 c.c. of 1 per cent. copper sulphate and 1 c.c. of 1 per cent. ammonium thiocyanate added and $\frac{N}{10}$ thiosulphate solution run in until the colour of the ferric thiocyanate disappeared. Even with the copper salt as catalyst the end-point was never sharp, and the excess of thiosulphate was immediately titrated with standard iodine with starch as indicator.

Although the added organic substances are capable of reacting with iodine in many of the cases examined, the velocity of the reaction,

$$I_2 + 2S_2O_3'' = 2I' + S_4O_6'',$$

so far exceeds the speed at which the iodine is used by the organic substance that no difficulty was found in determining the end-point.

It must be admitted that better results are obtained when the operator has acquired practice; a very important point is not to use a greater excess of the thiosulphate than necessary, and to titrate this excess as rapidly as possible.

Mineral acid is added, if required, to break up feebly ionised salts (*e.g.*, ferric acetate); on the other hand, any large excess affects the estimation injuriously on account of the decomposition of the non-ionised thiosulphuric acid.

It is as well to standardise the thiosulphate on a ferric solution, since, if the standardisation be carried out with copper sulphate, the results obtained for iron appear to be rather low. The standard iron solution may be made by dissolving 48·22 grms. of iron-ammonia alum in water with the aid of 75 c.c. $\frac{N}{1}$ sulphuric acid and making up to 1 litre; if necessary, the iron may be estimated in this solution gravimetrically. The agreement which may be expected on titrating equal volumes (20 c.c.) of the same iron solution is shown in the following table (1 c.c. iodine = 1·003 c.c. thiosulphate):

	1.	2.	3.
Thiosulphate added	20·10	20·09	20·50
Iodine for back titration	0·35	0·40	0·76
Thiosulphate consumed by iron ...	19·75	19·69	19·74

The titration might conceivably be affected by—

1. The formation of a non-ionisable ferric compound or of a complex ferric anion.
2. Reduction of ferric to ferrous compound by the added organic substance.
3. Reaction of the iodine with the added organic substance as well as with the thiosulphate.

Whilst rapid work obviates any trouble due to the second or third causes, it intensifies that due to stability of non-ionisable ferric compounds. In the table of results it will be noticed that a very large excess of ammonium sulphate has the expected effect, which is not, however, great enough to make the titration useless unless very large amounts of the sulphate are present. Acetates give no trouble if mineral acid be added, acetic acid itself having but a slight influence. The deep colour produced by salicylates and salicylic acid interferes seriously, and the quantity of mineral acid which must be added to inhibit this is too great to allow of a subsequent safe titration with thiosulphate. The titration was practically unaffected by sugars and not greatly by tartaric acid or citric acid in presence of the amount of mineral acid (75 c.c. $\frac{N}{1}$ sulphuric acid per litre) used in making up the iron solutions.

In the table the results show the effect of the substances added. Twenty c.c. of the ferric solution (0·112 grm. iron) were first directly titrated, and the titration was then carried out with equal volumes of the same solution, the substance which might affect the result being added in gradually increasing quantities. The first column gives the name of the added substance, the second shows the weight thereof, and the third the volume in which the added substance was dissolved. In the fourth column the net volume of the thiosulphate employed in titrating the ferric iron is given—*i.e.*, the gross volume of thiosulphate added less the equivalent of the iodine used in the back titration.

ON THE RELATION BETWEEN THE KIRSCHNER AND POLENSKE VALUES FOR MARGARINES CONTAINING COCOANUT OR PALM KERNEL OILS.

BY E. RICHARDS BOLTON, H. DROOP RICHMOND,
AND CECIL REVIS.

(*Read at the Meeting, April* 3, 1912.)

IN a paper published last year (ANALYST, 1911, **36**, 333), it was pointed out that the determination of the Kirschner value would enable the presence of small quantities of butter-fat to be estimated in the presence of cocoanut oil, and, further, that in itself it furnished a reliable figure for the percentage of cocoanut oil in the absence of butter-fat. The figures then given for the Kirschner values for mixtures containing no butter-fat fell practically on a straight line, but when the mixture contained butter-fat up to 10 per cent. a somewhat irregular curve was obtained. We have reinvestigated this point, and find that the irregularity was due to the fact that the values obtained for mixtures containing up to 15 per cent. of cocoanut oil were carried out with an Irish butter of very low Reichert-Meissl value (22), while the other values were obtained by using a butter of much higher Reichert-Meissl value (30); and we had not at that time recognised how sensitive to the presence of butter the Kirschner value was. We have therefore redetermined the values for those mixtures which contained the butter of low Reichert-Meissl value, with a butter of more normal figure, and are now able to make the following deductions:

1. That for the Kirschner values for both cocoanut and palm kernel oils (with or without admixture of butter-fat up to 10 per cent.) a straight line can be plotted which will represent, with very great closeness, the values experimentally obtained (see curves).

Further, for any percentage of cocoanut or palm kernel oils the difference in the Kirschner values for "no butter-fat" and for any percentage of butter-fat (up to 10 per cent.) will be proportional within very small limits to the percentage of butter-fat; the closeness of the agreement indicates that the relation will also hold for higher percentages of butter-fat.

2. On examining the values obtained both for cocoanut and palm kernel oils, it was seen that the Polenske value was practically independent of the amount of butter-fat present, when present up to 10 per cent. in the mixture, and is practically dependent on the presence of the cocoanut or palm kernel oil only. The mean value was therefore calculated from the four values obtained for mixtures corresponding to each different percentage of cocoanut or palm kernel oil (see Table I.), and on plotting these mean values a regular curve was obtained. The following equations have been worked out for these "mean value" curves:

$$x\,(\text{C.N.O.}) = 12{\cdot}3\,(\text{P} - 0{\cdot}45)^{0{\cdot}747};$$

$$x\,(\text{P.K.O.}) = 16{\cdot}72\,(\text{P} - 0{\cdot}45)^{0{\cdot}806};$$

where $x =$ the percentage of cocoanut or palm kernel oil.

TABLE I.

Cocoanut Oil.		Butter-Fat.

	Kirschner	0·38	0·94	1·69	2·99
25 per cent.	Reichert-Meissl ...	3·91	4·85	5·53	6·54
	Polenske	2·91	2·61	2·96	2·93
	Kirschner	0·54	1·15	1·94	3·08
50 per cent.	Reichert-Meissl ...	6·05	6·60	7·70	9·10
	Polenske	7·06	7·16	6·90	7·30
	Kirschner	1·10	1·56	2·27	3·37
75 per cent.	Reichert-Meissl ...	6·97	8·34	9·20	10·50
	Polenske	12·36	11·91	12·20	12·30
	Kirschner	1·50	1·91	2·57	3·68
100 per cent.	Reichert-Meissl ...	8·08	—	—	—
	Polenske	16·02	—	—	—
	Kirschner	2·01	—	—	—

These relations show that the influence on the Polenske figure of 1 per cent. of cocoanut oil is the same as that of about 1·75 per cent. of palm kernel oil. The figures obtained from the equations for palm kernel oil are almost identical with the experimental figures, but the agreement is not quite so good in the case of cocoanut oil, and we have not taken into account the value for 100 per cent. in calculating the equation to this curve. The values in the latter case show somewhat irregular fluctuations, which are probably due to the distillation of the volatile insoluble acids in cocoanut oil, on account of their lower molecular weight than those of palm kernel oil, being more influenced by the other constituents of the mixture. The chief difference is in the value for cocoanut oil itself, the experimental value being 16·5 as against 17·05 calculated from the formula. We are, after many experiments, of the opinion that it is not possible to obtain the true value for cocoanut oil in the ordinary apparatus, and this point will be referred to later.

We therefore point out that the Polenske value acts as an "indicator," so that, when a margarine containing cocoanut or palm kernel oils is examined by the Reichert-Meissl-Polenske-Kirschner process, reference to this mean curve at once determines the percentage of cocoanut or palm kernel oil apart from other values. The corresponding Kirschner value obtained from the typical curve then determines the presence or absence of butter-fat, the Reichert-Meissl value acting as a confirmatory figure, and controlling the small fluctuations which may occur in the Kirschner value occasioned by a variation in butyric acid content of different butters.

The tables (II. and III.) here given for cocoanut and palm kernel oils, with and without admixture of butter-fat, are the typical values obtained from the curves which are also given, and we feel that they will prove a reliable guide provided that the method be carried out under standard conditions laid down in the paper previously referred to, the standard apparatus being also employed (ANALYST, 1904, 29, 155).

On account of the similarity of the results obtained for cocoanut and palm kernel oil, the following formula will give the percentage of butter present with either fat for the Kirschner and Polenske values found experimentally:

$$\text{Butter per cent.} = \frac{K - (0{\cdot}262\,P^{0{\cdot}63} + 0{\cdot}09)}{0{\cdot}242};^{*}$$

or nearly as exactly by the more simple formula:

$$\text{Butter per cent.}\ \frac{K - (0{\cdot}1\,P + 0{\cdot}24)}{0{\cdot}244.}$$

The following formulæ connect the Kirschner value and percentage of butter-fat when neither cocoanut nor palm kernel oil is present:

$K = 0{\cdot}236\,B + 0{\cdot}33$, or, with a small increase in the probable error, $K = 0{\cdot}244\,B + 0{\cdot}28$, which is practically the formula given above.

Exception may be taken to the above formulæ, on the ground that it supposes a certain fixed value for the butyric acid content of the butter present. While this is undoubtedly true, the variations so caused will not in the vast majority of cases lead to errors of any great magnitude, and the percentage of butter determined by the formula has usually been within 0·5 per cent. of that actually present.

We think it necessary to draw attention to an observation we have made recently. In the standard apparatus, that portion of the still-head which passes through the cork and into the interior of the distillation flask is provided with a small hole in the side to prevent the collection of condensed liquid in the still-head.

---

[*] Values of $(0{\cdot}262\,P^{0{\cdot}63} + 0{\cdot}09)$:

P.	Value.	P.	Value.
0·5	0·26	8	1·06
1	0·35	9	1·13
2	0·50	10	1·21
3	0·61	11	1·28
4	0·72	12	1·34
5	0·81	13	1·41
6	0·90	14	1·47
7	0·98	15	[illegible]

As originally designed by Polenske, this hole had a fixed distance from the stopper of the flask. Insufficient attention is paid to this point by makers of the apparatus, and we have found that if the hole is much more than 1 cm. from the lower surface of the cork, low Polenske values may be obtained with high percentages of cocoanut oil; and we think that if this method be made a standard one, particular attention should be given to this point.

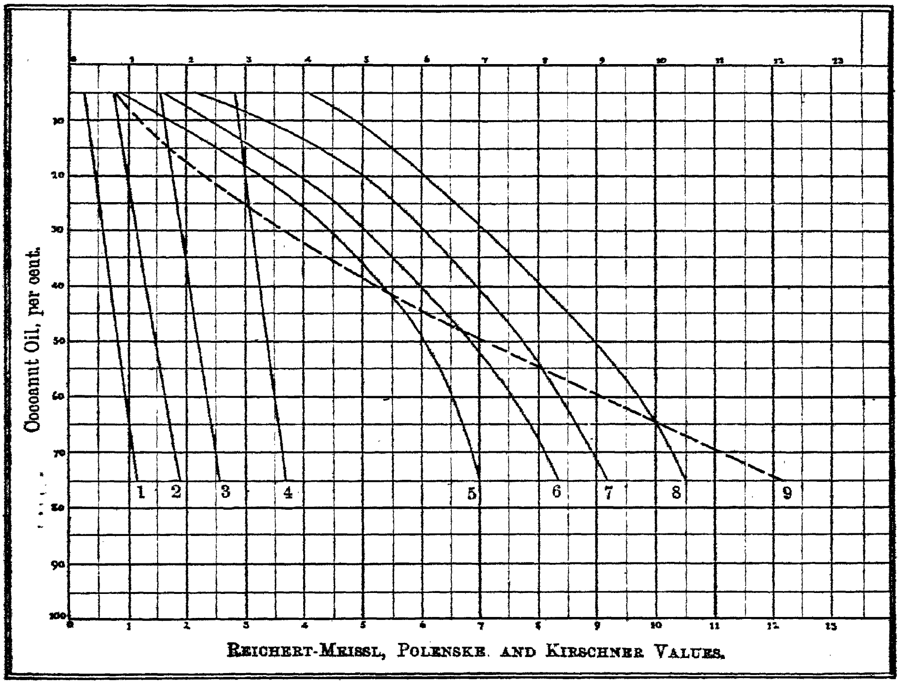
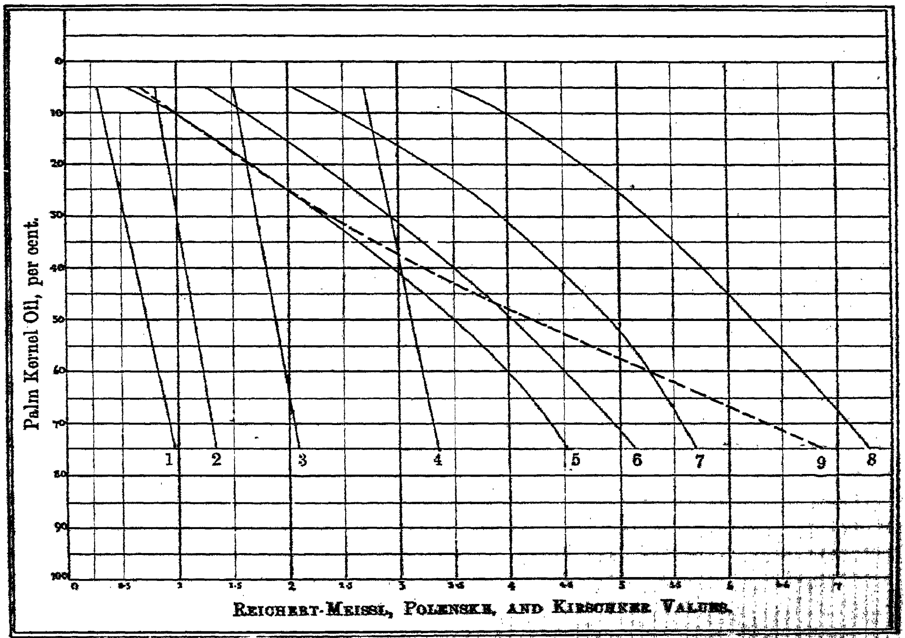
THE RELATION BETWEEN THE KIRSCHNER AND POLENSKE VALUES FOR BUTTER-FAT.

As the Kirschner value for butter is almost entirely obtained from the butyric acid present, it is evident that a relation between the Polenske value and the Kirschner value will be more sensitive than the relation, at present accepted, between the Reichert-Meissl and Polenske values. We tentatively put forward the following table with the hope that other workers will criticise or verify the figures:

Kirschner Value.		Polenske Value.
20	... ...	1·60
22	... ...	2·10
24	... ...	2·65
26	... ...	3·20



1. Kirschner, 0 per cent. butter.
2. ,, 2 ,, ,,
3. ,, 5 ,, ,,
4. Kirschner, 10 per cent. butter.
5. R.-M., 0 per cent. butter.
6. ,, 2 ,, ,,
7. R.-M., 5 per cent. butter.
8. ,, 10 ,, ,,
9. Mean Polenske.



1. Kirschner, 0 per cent. butter.
2. ,, 2 ,, ,,
3. ,, 5 ,, ,,
4. Kirschner, 10 per cent. butter.
5. R.-M., 0 per cent. butter.
6. ,, 2 ,, ,,
7. R.-M., 5 per cent. butter.
8. R.-M., 10 per cent.
9. Mean Polenske.

A variation of ± 1 must be allowed in the Polenske value corresponding to any particular Kirschner value, but it would appear that less than 5 per cent. of cocoanut oil will cause the Polenske value to fall outside this limit, except in those cases in which cows have been specially fed for the purpose of upsetting the Polenske process. In conclusion we desire to express our thanks to Messrs. G. A. Payne and H. R. Burnett for carrying out the experimental part of the investigation.

DISCUSSION.

Mr. W. BACON asked whether, in the form of apparatus with a very large distilling tube, this tube was insulated by some non-conducting material? If not, since the tube was so close to the neck of the flask, a great deal of condensation would be likely to occur.

Mr. E. M. HAWKINS asked whether, in a mixture consisting of cocoanut oil and of butter, of which the Kirschner figure was known, it would be possible, from the Polenske and Kirschner figures, to determine with a fair degree of certainty the proportion of cocoanut oil?

Mr. REVIS said that with the special tube described there was no condensation at all, the distillation being, as a matter of fact, more rapid than with the ordinary form. He should like once again to emphasise the importance of always using the same standard pattern of apparatus. The exact details did not matter, provided they were the same in every case. If that were so, the results obtained by different workers would agree, and the results obtained by each would be consistent and concordant among themselves. They (the authors) had found that the Polenske, Reichert-Meissl and Kirschner processes were all three quite as accurate and definite as an ordinary titration of acid and alkali. The question asked by Mr. Hawkins as to cocoanut oil and butter mixtures involved some difficulty, because butter varied so greatly as regards its proportion of butyric acid. As they had pointed out, a much more sensitive relationship was shown between cocoanut oil and butter fat when the Kirschner and Polenske figures were used than when the Reichert-Meissl and Polenske figures were used. They put forward their results quite tentatively, but believed the process to be capable of showing the presence of as little as 3 per cent. of cocoanut oil in butter fat. There must always be some doubt as to the exact quantity of butter fat present in a mixture, because of the varying nature of the butter itself.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Chemical Valuation of Digitalis. J. Burmann. (*Bull. Soc. Chim.*, 1912, **11**, 221.)—The author has already shown (*Bull. Soc. Chim.*, 1910, **7**, 973) that in Keller's method of judging of the value of digitalis by the examination of its active glucoside, digitoxin, it is only a pseudo-digitoxin that is estimated, and his results have been confirmed by Kraft (*Schweiz. Woch. Chem. Pharm.*, 1911, 12-13). For the estimation of the total glucosides soluble in chloroform, 100 grms. of the liquid, obtained by dialysing the digitalis with 20 per cent. alcohol, are mixed with 60 grms. of absolute alcohol, and made up to 190 grms., with 50 per cent. alcohol. A mixture of 30 grms. of basic lead acetate solution (sp. gr. 1·240) and 30 grms. of absolute alcohol is then added, the liquid stirred and filtered, and 125 grms. of the filtrate (=50 grms. of the dialysate) treated with hydrogen sulphide, and filtered from the lead sulphide through a Buchner's funnel. The precipitate is washed two or three times with 50 per cent. alcohol, and the filtrate and washings concentrated under reduced pressure (preferably below 50° C.) to about 50 c.c. to expel the alcohol, after which 2 c.c. of 10 per cent. ammonia solution are added, and the liquid extracted with chloroform for one and a half to two hours. The chloroform extract is filtered into a tared 200 c.c. Erlenmeyer flask, the solvent evaporated on the water-bath, and the residue dried at 100° C. in a current of dry air. It is next taken up with 3 grms. of chloroform, the solution mixed with 7 grms. of absolute ether, and the glucosides reprecipitated by the addition of 50 grms. of petroleum spirit. After standing for some hours, the supernatant liquid is decanted and replaced by the same quantity of petroleum spirit, the flask being well shaken and allowed to stand. Finally, the liquid is again decanted, and the residue dried on the water-bath in a current of dry air until constant in weight. The glucosides thus separated are in the form of an amorphous white powder, and give the reactions typical of Keller's digitoxin. They may be crystallised by dissolving 0·03 to 0·04 grm. in 1 c.c. of absolute alcohol and adding 0·5 c.c. of water. After standing for several hours the deposit will show under the microscope acicular crystals grouped in rosettes (ψ-digitoxin or Kraft's hydrodigitalin) and prismatic tables (digitoxin). The crystals may be separated by means of their different solubilities in ether and water, and identified by their melting-points (145° to 150° C., and 247·5° C. respectively). In this way the following results were obtained in the examination of four dialysates of digitalis:

	1. Per Cent.	2. Per Cent.	3. Per Cent.	4. Per Cent.
Total glucosides	0·152	0·148	0·118	0·111
Glucosides by Keller's method ...	0·118	0·116	0·091	0·085
Digitoxin	0·034	0·032	0·027	0·026
Proportion of digitoxin	22·5	21·6	22·0	23·4

Physiological experiments upon animals showed that the glucosides soluble in chloroform were more toxic than Keller's digitoxin.

C. A. M.

Baking Qualities of Flour. Willard and Swanson. (*Chem. News*, 1912, **105**, 97-99.)—Failure to correlate the behaviour of flours with their gliadin-gluten ratios suggested that the differences observable might be caused by substances present in very small amounts. The production of a good loaf depends on the physical properties of the gluten, and these may be much affected by small quantities of associated substances. Such substances may also operate in quite a distinct manner—viz., by favouring or inhibiting the growth of the yeast, and among these would be the amino acids produced from the wheat proteins by the hydrolytic action of the yeast. The addition of unextracted bran to flour had a notably deteriorating effect on the loaf as regards both volume and texture. If the bran were previously extracted with cold or hot water the effect was less marked on loaf texture, and the addition of bran extract to the flour was very favourable. The fact that extracted bran and bran extract each produced better results than when entire bran is used was unexpected but confirmed on repetition. Figures are given showing the effect of various substances on loaf volume. Extracts derived from wheat scourings were, on the whole, undesirable, causing sticky doughs; peptones had no effect till present in large quantity, and were then deleterious as they produced marked stickiness. Glycocoll was markedly bad in every way, the dough being sticky, runny, and stringy, and resembling that from badly germinated wheat; the loaf volume was reduced and the texture impaired. Leucin produced results like glycocoll, but less pronounced; it caused the development of a disagreeable odour. Aspartic acid proved slightly favourable, but asparagin was injurious. The latter, while shorten-ing the time of rising (probably by stimulating the growth of the yeast), weakened the gluten and so decreased the oven expansion and loaf volume. Similar effects are observed with flour from germinated wheats, and asparagin is known to be among the products of accompanying protein metabolism (*cf.* Ford and Guthrie, ANALYST, 1908, **33**, 323). Ammonium chloride had a most beneficial effect even in small traces, and appeared to assist yeast growth, as the time of rising is shortened. Ammonium acetate had a similar but less marked effect, but in larger amounts impaired the texture. Ammonium tartrate and phosphate had but little effect. Sodium bicarbonate was detrimental alike to time of rising and volume of loaf, while sodium phosphate, sodium formate, and potassium nitrate call for no special comment. A detailed study of the effects of germination of wheat on the resulting flour was made, material being prepared from corns germinated for from 1 to 5 days. Up to 3 days little effect was produced, but after this time bad effects at once became apparent; texture of loaf, volume, crumb, and alcohol-soluble protein all being adversely affected. The deleterious influence of flour from germinated wheat was strongly manifested even when only 1 part in 30 of sound flour was employed, while with larger amounts the product showed that the mixtures were quite unfit for bread-making. H. F. E. H.

Detection of Fluorine in Foods, etc. A. Sartori. (*Chem. Zeit.*, 1912, **36**, 229-230.)—For the estimation of fluorides in wine or fruit-juice, according to the author, 200 c.c. of the sample are treated with a few drops of 20 per cent. sodium sulphate solution and 10 c.c. of 10 per cent. barium acetate, and the mixture is allowed to stand for twelve hours. The precipitate is collected on a filter, incinerated and tested for fluorides by the waxed watch-glass method. The limit of sensitiveness by this method is about 0·3 mgrm. of fluorine. J. F. B.

Comparative Study of Methods for Determination of Hard and Total Soft Resins in the Hop. H. V. Tartar and C. E. Bradley. (*J. Ind. Eng. Chem.*, 1912, **4**, 209-213.)—It is shown that Siller's method (ANALYST, 1909, **34**, 485), though useful enough with Continental hops, leads to over-estimation of the soft resins when applied to seeded hops such as are grown in America or England. This is due to the extraction of fatty oil from the seeds (*cf.* Briant and Harman, *J. Inst. Brew.*, 1910, **16**, 5), which are crushed when the sample is put through a mincing machine as directed by Siller. On the other hand, Briant and Meacham's method (*J. Fed. Inst. Brew.*, 1897, **3**, 233) gives very much lower results for soft resins, and correspondingly higher ones for hard resins, than does the latest form of Lintner's volumetric method (ANALYST, 1909, **34**, 53; 1910, **35**, 352), or a new method described in the present paper. Lintner's original method (*Zeitsch. f. d. ges. Brauw.*, 1898, **21**, 407) gives results which accord well with those obtained by the method of Briant and Meacham, but both methods are believed to be faulty in that they fail to extract the whole of the soft resin. A hop which shows only 8 per cent. of soft resin when subjected to Briant and Meacham's process or the original Lintner process may yield 16 per cent. when analysed in accordance with Lintner's more recent proposals or by the authors' method. Lintner's new method differs from the old one only in the fine grinding of the sample, to which no objection can be taken when the final determination is to be made by volumetric process dependent on the acid function of the soft resins.

The new method described is as follows: A 10 grm. sample of hops is extracted with ether for eight to ten hours. The ethereal extract thus obtained is filtered, and the filtrate made up to 200 c.c. Half this volume is used for the determination of total resins, the other half for the determination of soft resins. For the determination of total resins, 100 c.c. is placed in a 250 c.c. flask and evaporated at about 40° C. to very small bulk, the last of the ether being removed in a vacuum desiccator at ordinary temperature. The residue is taken up in alcohol, filtered free from wax, and the filtrate made up to 100 c.c. Of this 100 c.c., a portion of 20 c.c. (equivalent to 1 grm. of hops) is transferred to a tared beaker, and the alcohol removed by evaporation in a vacuum oven at 50° C. For the determination of soft resins the remaining 100 c.c. of the ether extract is taken down to dryness exactly as in the determination of total resins. The residue is taken up with about 100 c.c. of petroleum ether (b.p. 40° to 45° C.), stirring with a rod and leaving to stand some time. The hard resin is then removed by filtration, the petroleum ether removed from the filtrate exactly as the ether was removed at an earlier stage, and the residue taken up with alcohol. The alcoholic solution is filtered from wax, made up to 100 c.c., and 20 c.c. (equivalent to 1 grm. of hops) is transferred to a tared beaker, and evaporated and weighed as in the determination of total resins. When dried in the manner described, there is much less change of composition—as judged by the absence of browning—than when resort is had to higher temperatures, and a constant weight is obtained, which is never the case when a temperature of 80° C. is employed.

The authors believe their method to be the most accurate available, but they consider Lintner's modified method to be the best method for commercial purposes, as it is rapid, and yields results which seldom differ by more than a few tenths of 1 per cent. from those yielded by their own method. Even with 10 grm. samples the sampling error cannot with certainty be kept below 0·3 per cent. G. C. J.

Tests for Linseed Oil and its Adulterants. J. F. Liverseege and G. D. Elsdon. (*J. Soc. Chem. Ind.*, 1912, **31**, 207-208.)—The following modification of the well-known Livache test for quantitatively expressing the drying-power of oils has been found to yield uniform results: Litharge, finely-powdered and passed through a No. 40 sieve, is spread out in a thin layer in an incubator at 20° to 22° C. overnight to become constant in weight. About 10 grms. of this litharge are introduced into a flat-bottomed German silver dish, 3 inches diameter and 1 inch deep, 0·7 to 0·9 grm. of oil added, and after weighing, 5 c.c. of methylated ether (sp. gr. 0·720) are run into the mixture, and the litharge spread out in a uniform layer by thoroughly rocking the dish. The dish and contents are kept in the incubator at 21° C. and weighed after one, two, or more days, until the weight is either constant or diminishing, and the weight gained then expressed in terms of percentage of the oil taken. The added ether is volatilised after half an hour, and leaves an inappreciable residue. By this test, raw linseed oil ceases to gain weight in two days, and then usually loses weight. With boiled oils, the oxidation is usually complete in one day. The following are typical figures:

	One Sample.	Per Cent. Maximum.	Minimum.
Raw Linseed Oils.			
Gain after two days	17·4	18	15
,, ,, three days	16·9	—	—
,, ,, fourteen days ...	15·9	—	—
Boiled Linseed Oils.			
Gain after one day	14·1	14	12
Gain after two days	13·6	—	—

Soya Oil.—Gain = 8·4 to 8·9 per cent.

Cotton-seed Oil.—Gain = 6·6 per cent.

Rape Oil and Arachis Oil.—Gain = 2·5 per cent.; after twenty-one days, rape oil, 5·7; arachis oil, 4·1 per cent.

Olive Oil (2 samples).—Gain = 0·6 and 1·4 per cent. in two days; after twenty-one days, 2·5 and 3·4 per cent. respectively.

Resin Oil.—Loss = 0·3 per cent. in one day; then gain = 9·9 per cent. in two days, and 19·4 per cent. in thirteen days.

Thus, drying oils do not gain after about two days, while non-drying oils may continue to gain for weeks. The gain in weight of oils of a particular class varies with the iodine value, and there is evidence of some relationship between these figures for oils of different classes. A. R. T.

Chemical Composition of some New Zealand Meat Extracts. A. M. Wright. (*J. Soc. Chem. Ind.*, 1912, **31**, 176.)—Moisture, organic matter, mineral salts, chlorine, fat, and total nitrogen were determined by the methods described by the author (*J. Soc. Chem. Ind.*, 1907, **26**, 1229); acidity by titration with $\frac{N}{10}$ potassium hydroxide and phenolphthaleïn and calculating as lactic acid; insoluble and coagulable proteins (*U.S. Dept. of Agriculture, Bureau of Chem.*, *Bull.* 107, p. 115); proteoses by the zinc sulphate method (*ibid.*); peptone-like bodies and polypeptides by precipitation, with the proteoses, by the tannin salt-reagent, their amount being found by difference (*J. Amer. Chem. Soc.*, 1906, **28**, 1485); nitrogen as total meat bases by deducting the nitrogen present as ammonia from the nitrogen in the tannin salt filtrate; ammonia by the magnesium oxide method (*U.S. Dept. of Agriculture, Bureau of Chem.*, *Bull.* 107, p. 9); purin bases by Schittenhelm's method (*ibid.*, *Bull.* 90, p. 129); creatin and creatinin by Folin's colorimetric method (*Zeitsch. physiol. Chem.*, 1904, **41**, 223); phosphoric acid and potash by examination of the ash (*U.S. Dept. of Agriculture, Bureau of Chem.*, *Bull.* 107, pp. 3, 4, and 11).

A "burned" flavour and a dark colour impair the commercial value of an extract; they are shown, by the analyses given of six samples, to be accompanied by undue amounts of peptone-like substances, intermediate between the peptones and the amino acids. The characteristic salts of meat extract are potassium dihydrogen phosphate and potassium monohydrogen phosphate; in general, the mineral constituents show great variations. O. E. M.

Acid-Soluble Phosphorus Compounds of some Feeding Materials. Hart and Tottingham. (*Twenty-Seventh Annual Report of the Agric. Exp. Sta. Univer. Wisconsin*, 95-106; through *Inter. Inst. Agric.*, 1912, 3, 398.)—Phytin, which is a complex organic phosphorus salt of potassium, magnesium, and calcium, is widely distributed, particularly in seeds, as a reserve material. It is present in the entire seeds of maize, oats, and barley, but is largely localised in the outer layers of the wheat seed; it could not be isolated from swedes or alfalfa (Lucerne) hay. Phytin phosphorus forms from 40 to 50 per cent. of the total phosphorus in the aforementioned seeds. In alfalfa which was cut at the most favourable stage of gro for forage, the inorganic phosphorus formed 63 per cent. of the total; there is also present about 17 per cent. of phosphorus in some unknown organic combination.

H. F. E. H.

Estimation of Saccharin in Foods. G. Possetto and G. Issoglio. (*Giorn. Farm. Chim.*, 1912, **61**, 5-11; through *Chem. Zentralbl.*, 1912, I., 754.)—The separation of the saccharin from the chief constituents of foods by dialysis is recommended. In the case of milk, jams, etc., a portion of the sample is rendered alkaline with sodium carbonate and submitted to dialysis for twenty-four hours; at the end of this time the dialysed solution is acidified with phosphoric acid, and the saccharin shaken out with ether. The dialysed solution obtained in a similar way from cocoa should be decolorised with animal charcoal before being shaken out with ether.

W. P. S.

Composition of Scammony Root and of Scammony Resin. F. B. Power and H. Rogerson. (*J. Chem. Soc.*, 1912, **101**, 398-412.)—Scammony root contains a small quantity of sucrose, an essential oil and furfuraldehyde, crystalline scopoletin and its glucoside, 3-4-dihydroxy-cinnamic acid, fatty acids, and a resin containing ipuranol, $C_{23}H_{38}O_2(OH)_2$, melting at 285° to 290° C.; a-methyl-butyric and tiglic acids; jalapinolic acid and its methyl-ester; valeric acid; and traces of other substances. Scammony gum-resin contains tiglic acid, a valeric acid, jalapinolic acid and its methyl-ester, and glucosides, dextrose, etc. The resins obtained from the root and the commercial gum-resin are thus similar in character, but not identical. A comparison of the resin from scammony-root with that obtained from the root of *Ipomœa orizabensis* (*J. Chem. Soc.*, 1912, **101**, 1-17), shows that the two products differ considerably in composition. Both the resins are complex in character, but consist to a large extent of the glucosides and methyl-pentosides of jalapinolic acid, $C_{15}H_{30}(OH)(CO_2H)$ and its methyl-ester. While, however, the methyl-pentose obtained from the hydrolysis of the resin of scammony root appears to be identical with rhamnose, that from the resin of *I. orizabensis* yields a new crystalline tetra-acetyl derivative. The resin from the last source contains also small amounts of hentriacontane, $C_{31}H_{64}$, and cetyl alcohol, which are not present in the resin from scammony root, and marked differences are observed in extracting the crude resins and the products of their alkaline hydrolysis with various solvents. The names by which these complex resins have hitherto been known, such as "jalapin" or "scammonin" should now be discarded, as they are not individual substances.

A. R. T.

Inversion of Sucrose by the Enzymes of Honey. O. Achert. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 136-139.)—Results of experiments carried out by the author show that honey which has not been heated above 55° C. is capable of inverting added sucrose; the inversion proceeds at the ordinary temperature and is more or less rapid. For instance, a mixture of honey and sucrose was prepared containing 22·0 per cent. of the latter; after the lapse of four months the mixture was found to contain only 2·2 per cent. of sucrose. When the honey has been heated to a temperature of 100° C., it loses its power of inverting sucrose. The quantity of free acids in the honey does not play any part in the process, as neutralised honey inverts sucrose at the same rate as does natural honey. W. P. S.

Estimation of Tannin in Wines. P. Malvezin. (*Bull. Soc. Chim.*, 1912, **11**, 300-303.)—The method described previously (ANALYST, 1911, **36**, 412) may be modified slightly in order to render the estimation more rapid, the chief alteration being that the zinc-tannin precipitate is collected on a filter immediately after the wine and precipitant have been boiled for the prescribed period of five minutes. After the precipitate has been washed, it is dissolved in dilute sulphuric acid and the solution titrated with $\frac{N}{10}$ permanganate as described. The factor 0·120 should be employed for calculating the quantity of gallotannic acid from the volume of permanganate solution required for the titration, and the titration should be continued until a pink coloration is obtained which does not disappear within three minutes.

W. P. S.

Detection of Small Quantities of Zinc in Wine. A. Straub. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 140.)—The following process is described for the detection of small amounts of zinc in wines, for instance, in wines which have been treated with potassium ferrocyanide and a zinc salt in the fining operation (*cf.* ANALYST, 1905, **30**, 264). From 100 to 200 c.c. of the wine are boiled, hot sodium carbonate solution is added, and the mixture heated for some length of time; the precipitate is then collected on a filter, washed, dissolved in a small quantity of hydrochloric acid, and the solution oxidised by heating with potassium chlorate. An excess of sodium acetate is now added, the solution is boiled, filtered to remove iron and aluminium hydroxides, etc., and the filtrate then tested with hydrogen sulphide.

W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Microscopic Differentiation of Hemp and Flax Fibres. P. Sonntag. (*Ber. Deutsch. botan. Ges.*, 1912, **29**, 669; through *Chem. Zentralbl.*, 1912, I., 1058.)—With the microscope focussed on the upper surface, flax shows a right-hand spiral forming an average angle of 10·21 degrees with the cell axis. With a deeper focus, a left-hand spiral of a steeper twist is observed. Hemp shows the same double spiral, but at an average angle of only 3·7 degrees. In both cases the structure is only observed in thin bast cells after boiling in water or acetic acid. Observation is best carried out on the broken ends of a torn fibre. O. E. M.

Seventh Report on Research Work of the Metropolitan Water Board. A. C. Houston. 1912.—This Report consists of the following six sections: 1. Search for pathogenic organisms in raw river water. 2. The comparative vitality of "cultivated" and "uncultivated" typhoid bacilli in artificially infected samples of raw river water. 3. The comparative vitality of the typhoid bacillus in raw Thames water at different temperatures. 4. On the biological characters of *B. coli* isolated from (1) raw river water, (2) stored water, and (3) stored and filtered water. 5. On the advantages of passing raw river water through small reservoirs antecedent to storage in large reservoirs. 6. On the advantages of occasionally using precipitation methods antecedent to the storage of raw river water in large reservoirs. Among the conclusions arrived at by the author are the following: 1. The typhoid bacillus and Gärtner's bacillus are not habitually present in small amounts, such as 10 c.c., of raw river water; and since the water will ultimately be stored for several weeks and then filtered, the margin of security is very great, in view of the extremely high death-rate of uncultivated typhoid bacilli when added artificially to river water. 2. In the Sixth Research Report (ANALYST, 1911, **36**, 185) it was shown in a "girl carrier" case that "uncultivated" typhoid bacilli perish much more rapidly than "cultivated" organisms. A "male carrier" case amply confirms the previous finding, and it may be taken as true that thirty days' storage of river water is tantamount to sterilisation so far as water-borne epidemic disease germs are concerned. 3. Laboratory experiments lead to the conclusion that the typhoid bacillus lives longer at low (32° to 41° F.) than at higher (50° to 98·6° F.) temperatures. For seven months in the year the mean river temperature of about 58° F. is specially unfavourable to the sustained vitality of the typhoid bacillus; during the remaining five months of the year the mean temperature of about 41° F. is much less favourable to the rapid death of this organism. Even at freezing-point the reduction of typhoid bacilli by the second week was over 99 per cent., and by the fourth week only one survived out of 3,029 added initially. In the case of the Metropolitan water-supply the author is of opinion that even in the coldest months of the year four weeks' storage of river water prior to filtration affords reasonable, if not absolute, protection from water-borne diseases. 4. This report is of a highly technical character, and deals with the physiological differentiation of numerous varieties of *B. coli*, using the direct plating-out method not preceded by cultivation in an enrichment liquid medium. 5 and 6. The author confirms his previous opinion (Third Research Report) as to the desirability of passing the *raw* river water through small reservoirs before storage. On three separate occasions, when samples were examined before and after such treatment, the percentage reduction, when averaged, was as follows: Bacteria, 36, ammoniacal nitrogen 15, albumenoid nitrogen 5·2, permanganate 7, turbidity 19, colour 8. The pre-storage treatment may be advantageously supplemented by the use of coagulants such as sulphate of alumina or alumino-ferric, and among other benefits derivable is the possibility of utilising the worst quality of flood water, and so preventing the depletion of the storage reservoirs under any conditions save those of drought. H. F. E. H.

Sterilisation of Water and Dairy Materials by Ultra-Violet Rays. M. Ringelmann. (*J. d'Agric. Prat.*, 1911, **75**, 619-621; through *Inter. Inst. Agric.*, 1912, **3**, 266.)—Ultra-violet rays from a mercury lamp traverse quartz or rock crystal, but not glass and thin layers of air. Water must be free from matter in suspension; the sterilisation on an industrial scale of liquids like wine, beer, milk, or broth, which contain colloid substances, is not to be expected, owing to the low penetrative qualities of the rays in such media. The walls of the lamp should not be in direct contact with water to be sterilised, since the yield of rays falls off in proportion as the temperature of the lamp is lowered. On a laboratory scale milk has been successfully sterilised by allowing films not exceeding a few millimetres in thickness to flow between quartz plates, the rate of flow being regulated by the inclination of the plates. Water for butter-making is favourably affected, an impure sample after treatment causing a prolongation in the life of butter made with it from eight days to a month. The most useful application of the rays is in the sterilisation of drinking water. H. F. E. H.

ORGANIC ANALYSIS.

Detection of Tertiary Alcohols. M. Guerbet. (*Comptes rend.*, 1912, **154**, 713-715.)—A means of distinguishing between primary, secondary, and tertiary alcohols is based upon the differences in their behaviour when heated with potassium hydroxide (*cf. Comptes rend.*, 1911, **153**, 1487). A mixture of 3 c.c. of the alcohol and 3 grms. of potassium hydroxide (previously dehydrated by fusion) is heated for sixteen hours at 230° C. in a sealed tube. After cooling, the point of the tube is broken under water, and the gases collected and measured. In the case of primary or secondary alcohols the amount of gas will be considerable, whereas with tertiary alcohols it will only amount to a few c.c. at most, or there may be absorption of water into the sealed tube. The solid product of the reaction is then treated with water. If the alcohol was primary or secondary, it will have been completely transformed into the potassium salt of the corresponding acid, and will be entirely soluble, whereas in the case of secondary or tertiary alcohols an oily layer of about the same volume as the original alcohol will be formed upon the surface of the water. C. A. M.

Aromatic Grass Oils. Part II. (*Bull. Imp. Inst.*, 1911, **9**, 333-340.)—Part I. of this article (ANALYST, 1912, 61) dealt with citronella oils, and the present part is devoted to lemon-grass oils. These are derived mainly from the two grasses, *Cymbopogon flexuosus* and *C. citratus*, the former yielding oils soluble in two or more volumes of alcohol (70 per cent.), and the latter giving, as a rule, oils not completely soluble in even ten volumes alcohol (90 per cent.). An oil from *C. pendulus* (India) also yields an "insoluble" oil.

Ceylon Lemon-grass Oils.—Three samples distilled from *C. citratus* gave the following results:

	1.	2.	3.
Yield of oil, per cent.	0·22	0·25	0·37
Sp. gr., 15°/15° C.	0·892	0·891	0·893
Opt. rotation, 100 mm. at 20° C.	−0·42°	−0·65°	+1·12°
Citral by sodium bisulphite, per cent.	75·0	74·0	76·0
Solubility	Not completely soluble even in 10 vols. of 70, 80, or 90 per cent. alcohol.		

Two other oils examined, stated to be *flexuosus* oils, were found to be mixtures of such oil with the oil from *C. nardus* (citronella grass), and gave abnormal results.

Indian Lemon-grass Oils.—Four samples yielded results as follow:

	"Tyrna" Oil.	"Cochin" Oil.	"Mariani" Oil.	"Ceylon" Oil.
Odour	—	Fine	—	—
Sp. gr., 15°/15° C.	0·902	0·905	0·914	0·906
Opt. rotation, 100 mm. at 20° C.	-0·7°	-0·65°	-0·1°	-0·1°
Citral, by sodium bisulphite, per cent.	72·5	84·5	73·0	76·0
Solubility in 70 per cent. alcohol	Not completely sol. in 10 vols.	Sol. 1: 2. More alcohol produced slight turbidity.	Not completely sol. in 10 vols.	
Solubility in 90 per cent. alcohol	Sol. in quantities up to 1 vol.; cloudy on addition of more alcohol.	Sol. in all proportions; excess of alcohol produced slight turbidity.	Sol. in quantities up to 1 vol.; turbid on addition of more alcohol.	

The "Cochin" lemon-grass oil thus belongs to the group of "soluble" oils, and is exceptionally rich in citral. Most commercial lemon-grass oils contain from 70 to 75 per cent. of citral.

Uganda Lemon-grass Oils.—The following are typical of six oils (from *C. citratus*) examined from this source:

	1 (Entebbe).	2 (Entebbe).	3.
Sp. gr., 15°/15° C.	0·872	0·881	0·894
Opt. rotation at 20° C. ...	-0·12°	+0·17°	-0·4°
Aldehydes by sodium bisulphite, per cent.	64·5	70·5	75·0
Solubility in alcohol	Not completely sol. in 10 vols. of 80 per cent.	Not completely sol. in 10 vols. of 80 per cent.	Insol. in 10 vols. of 70 per cent.

Bermuda Lemon-grass Oil.—A sample of this oil from *C. citratus* showed on analysis: Sp. gr., 15° C., 0·8689; optical rotation at 20° C., -0·35°; citral, 40 per cent.; not completely soluble in 70 per cent., or in 80 per cent. alcohol. The percentage of citral is very low.

Montserrat Lemon-grass oil is of the insoluble type, and one sample examined contained over 74 per cent. of citral.

A. R. T.

Detection of Carotin. M. Tswett. (*Ber. Deut. Botan. Ges.*, 1912, **29**, 630-636. Through *Chem. Zentralbl.*, 1912, I., 951.)—For colouring matters belonging to the same group as carotin the name *carotinoids* is suggested. For the detection of carotin an alcoholic or petroleum spirit extract of the colouring matter is first obtained, and its elective solubility in a two-phase system of 80 per cent. alcohol and petroleum spirit is estimated. Should a portion of the colouring matter be electively soluble in the petroleum spirit it is possibly carotin. After removal of all alcohol the absorption capacity of the petroleum spirit solution is then tested with calcium carbonate, and should the solution retain its colour in the presence of an excess of the absorbent agent, its spectrum should be examined. The positions of the two principal absorption bands in the spectrum of carotin are somewhat differently placed by different observers. In the author's experiments with carotin derived directly from the leaves these bands occurred at 492 to 475 $\mu\mu$ and 460 to 445 $\mu\mu$ respectively. With regard to the micro-chemical detection of carotin, it was found that the potassium hydroxide method of Molisch (*Ber. Deut. botan. Ges.*, 1896, **14**, 18) and the author's resorcinol method (*Botan. Centralbl.*, **81**, 83) did not give entirely definite reactions. In the latter method the tissue containing chlorophyll is treated with concentrated resorcinol solution, which dissolves the plasmatic proteins and lipoids. If, then, about 1 per cent. of hydrogen potassium phosphate be added, the lipoids agglomerate into green globules and there separate, here and there, bundles of yellow crystals, which also contain red crystals. These masses of crystals consist of xanthophyllene and carotin. C. A. M.

Errors in the Estimation of Cholesterol by the Ritter Method; Effect of Autolysis on Cholesterol. H. J. Corper. (*J. Biol. Chem.*, 1912, **11**, 37; through *Chem. Zentralbl.*, 1912, I., 1055.)—Ritter's method of estimating cholesterol (*Zeitsch. f. physiol. Chem.*, 1901, **34**, 430) was investigated, pure cholesterol and ox-spleen being used; it was found that the use of sodium ethoxide causes unavoidable errors. With too little, the esterification of the fats is incomplete, and the amount of cholesterol is over-estimated; with too much, the cholesterol cannot be completely extracted from the salt-mixture by ether, and too little is found. The cholesterol content in the spleen of the dog is not materially altered by autolysis. Ox spleen contains about 0·4 per cent. of cholesterol calculated on the moist substance. O. E. M.

Estimation of Citric Acid. D. S. Pratt. (*U. S. Department of Agriculture, Bureau Chem.*, through *Chem. Eng.*, 1912, **15**, 72-74.)—The following method yields satisfactory results in the examination of fruit juices, etc., containing citric and other organic acids in admixture. The citric acid is oxidised to acetone dicarboxylic acid, and the acetone produced is weighed as a mercury sulphate addition-product. Fifty grms. of the juice are treated with 110 c.c. of alcohol (95 per cent.) to remove pectin bodies. The liquid is filtered after fifteen minutes and the residue washed with more of the alcohol. The solution is diluted to an alcoholic strength of about 50 per cent., and barium acetate solution (20 per cent. in water) added to precipitate all the citric acid. After stirring, allowing the precipitate to settle, filtering the solution and thoroughly washing the precipitate on the paper with alcohol (50 per cent.) to remove sugar, the paper and its contents are dried until alcohol is removed. (Ether may be used in place of alcohol at this stage for washing the precipitate.) About 50 c.c. of water and 3 to 5 c.c. of syrupy phosphoric acid are added to the barium citrate, which, on warming, completely dissolves, when the liquid is filtered and the paper and residue washed till the solution measures 100 c.c. An aliquot part of this solution, containing about 0·05 to 0·15 grm. citric acid, is measured into a distilling flask, 5 to 10 c.c. of phosphoric acid added together with 400 c.c. of hot water. When briskly boiling, potassium permanganate solution (0·5 grm. per litre) is run in from a dropping funnel at the rate of 1 to 2 drops per second till the pink coloration is permanent throughout the liquid. The apparatus used by the author consists of a distillation-flask (500 c.c. capacity) attached to a spiral condenser, the former carrying a funnel, the stem of which extends ½ inch through the stopper, and which is drawn out to a small bore. The distillation-flask contains a glass rod, to the lower end of which is fused a short piece (½ inch) of small tubing, the device helping to produce steady ebullition. As the permanganate is added drop by drop, the acetone produced by oxidation of the citric acid is distilled off as soon as formed, and further oxidation prevented. The receiver contains 30 to 40 c.c. of Denigès' reagent, prepared by adding, with constant stirring, 200 c.c. of strong sulphuric acid to 50 grms. of mercuric oxide and 500 c.c. of water, heating, if necessary, on the water-bath till solution is complete, and filtering the liquid after cooling and diluting to 1 litre. The distillation is continued till only 50 to 100 c.c. of solution remain undistilled, when the solution in the receiver is boiled gently under a reflux-condenser for three-quarters of an hour after the liquid becomes milky. The solution is filtered hot through a Gooch crucible, washed with water, alcohol, and finally ether, and dried in the water-oven for half an hour. The weight of the precipitate, which is, according to Denigès, $(2HgSO_4.3HgO)_3.4CH_3.CO.CH_3$, multiplied by 0·22, gives the amount of citric acid in the fruit juice taken. In many cases precipitation of barium citrate and its subsequent solution in phosphoric acid are unnecessary, but sugar-containing products should be examined as described, since sugar retards the oxidation of the citric acid. Malic and tartaric acid do not interfere with the process. Duplicate determinations agree within 2 or 3 mgrms. of citric acid with the quantities specified. The factor given (0·22) does not correspond with any simple formula, and has been arrived at as a mean of a number of experiments. A. R. T.

Analysis of Textile Finishes. E. Schmidt. (*Chem. Zeit.*, 1912, **36**, 313-315.) —The author proposes a scheme for the identification of finishing materials in textiles. The finish is dissolved in as concentrated a form as possible by extraction with organic or inorganic solvents. Fats, resins, and mineral substances are estimated in separate samples. The substance extracted from the cloth and free from fat is dissolved in water. The aqueous solution is treated with a few drops of nitric acid, and the separation of a gelatinous precipitate would indicate the presence of norgin. The precipitate is warmed slightly and filtered; the filtrate is cooled and tested with a neutral solution of ammonium molybdate. If a white flocculent precipitate is formed, either at once or after a short time, the presence of glue is indicated.

After standing, the solution is filtered, neutralised with ammonia, and treated with an excess of alcohol. The formation of a precipitate may indicate the presence of starch, dextrin, gums, plant mucilages, or norgin; dextrose and glycerol remain in the filtrate. J. F. B.

Quantitative Estimation of Hydroxy-, Amino-, and Imino-Derivatives of Organic Compounds by Means of the Grignard Reagent, and the Nature of the Changes taking Place in Solution. H. Hibbert. (*J. Chem. Soc.*, 1912, **101**, 328.)—Hibbert and Sudborough's method (*J. Chem. Soc.*, 1904, **85**, 933) gives low results with most hydroxy-compounds if phenetole is the solvent used; the fatty alcohols up to and including propyl alcohol behave quite abnormally in both phenetole and amyl ether. Aromatic and most fatty hydroxy-compounds give accurate results in amyl ether, alone or in admixture with ketones, esters, etc. In phenetole, but not in amyl ether, aromatic amines give low results. Hibbert and Sudborough's method (*J. Chem. Soc.*, 1909, **95**, 477) for the estimation of amino- and imino-groups is not applicable to the lower fatty amines, as these form stable additive compounds with the magnesium methyl iodide, with the result that gas is not evolved, or only slowly, and on heating. Pyridine appears to be the most suitable solvent for hydroxyl compounds, and primary and secondary amines, but investigation of the lower fatty alcohols and fatty amines in this respect has not been carried out. Dimethylaniline may apparently also be employed. O. E. M.

New Method for the Separation of Tertiary from Secondary and Primary Amines. H. Hibbert and A. Wise. (*J. Chem. Soc.*, 1912, **101**, 341.)—The primary and secondary amines form additive compounds with magnesium alkyl halides which immediately decompose at ordinary temperatures, with evolution of the corresponding fatty hydrocarbon:

$$(1)\ R{\cdot}NH_2 + MgR'I = R{\cdot}NH(MgI) + R'H$$

$$(2)\ R_2 : NH + MgR'I = R_2 : N\ (MgI) + R'H$$

while tertiary amines, having no available hydrogen atom, yield additive compounds incapable of this decomposition. To the mixed amines, alone or dissolved in ether, is added excess of an ethereal solution of magnesium methyl iodide or bromide, the ether distilled off, and the product heated to 200° to 280° C. in an oil-bath, when the tertiary amine distils over. The other amines are recovered by steam distillation from sodium hydroxide. O. E. M.

Elm-Seed Fat. A. Pawlenko. (*Chem. Rev. Fett- u. Harz-Ind.*, 1912, **19**, 43-44.)—The seeds of the elm-tree contain about 45 per cent. of kernels, which on extraction with petroleum ether yield a greenish-yellow fat (26·1 per cent.) belonging to the cocoanut-oil group. A sample thus extracted gave the following values: Sp. gr. at 20° C., 0·9559; solidification-point, 3·5° C.; melting-point, 5·7° C.; acid value, 5·57; saponification value, 277·3; Hehner value, 75·45; Reichert value, 3·75; and iodine value, 32·2. The fat contained 56·2 per cent. of capric acid with smaller quantities of butyric and oleic acids, and 14·82 per cent. of glycerol. The shells of the nuts also yielded about 2 per cent. of a hard yellow wax-like fat, melting at 59·5° C. and having a saponification value of 187. The kernel fat had a pleasant taste and odour and was apparently well suited for the purposes of food. It also yielded a hard soap which was particularly soluble in cold salt water, but which separated on the surface on heating the salt solution to 78° C. The extracted residue contained 7·9 per cent. of nitrogen, and ought, therefore, to be a valuable feeding stuff. C. A. M.

Characteristics of Cotton Wax. C. Piest. (*Zeitsch. angew. Chem.*, 1912, **25**, 396-399.)—A sample of crude American cotton (ash, 2·44 per cent.; Schwalbe's copper value, 3·57) yielded the following amounts of extract to different solvents: Ether, 0·74; benzene, 0·87; petroleum spirit, 0·50; and alcohol, 1·20 and 1·27 per cent. The alcoholic extract had a saponification value of 159, and iodine value of 22·1. In the case of nine samples of normal cotton purified for nitration the following range of values was obtained: Copper value, 0·65 to 1·47; ash, 0·12 to 0·27; wood-gum, 0·32 to 0·90; ether extract, 0·09 to 0·37; carbon tetrachloride extract, 0·12 to 0·32; and alcoholic (absolute) extract, 0·24 to 0·53 per cent. The cotton wax in the normal purified wool was soluble to the extent of about 50 per cent. in absolute alcohol, whilst about 25 per cent. was soluble in ether and in carbon tetrachloride. In respect of its melting-point, saponification value, and iodine value, it closely resembled Japan wax. When present in cotton wax it has the effect of increasing the copper value. C. A. M.

Refractometric Estimation of the Strength of Formaldehyde Solutions. L. T. Reicher and F. C. M. Jansen. (*Chem. Weekblad.*, 1912, **9**, 104-109; through *Chem. Zentralbl.*, 1912, I., 949.)—Experiments with Zeiss's immersion refractometer have shown that the refractometric reading is a linear function of the concentration of a formaldehyde solution. If 15·5 be subtracted from the reading, and the difference be divided by the factor 3·17, the result will give the percentage of formaldehyde in the solution. C. A. M.

Hübener's Bromide Method for the Estimation of Caoutchouc. F. W. Hinrichsen and E. Kindscher. (*Chem. Zeit.*, 1912, **36**, 217-218, 230-232.)—Hübener's method for the estimation of caoutchouc in vulcanised rubber (ANALYST, 1909, **34**, 170 and 365) by bromination in presence of water has been criticised by various authors, and recently in an adverse manner by Esch (ANALYST, 1911, **36**, 558). The present authors had already shown that the estimation of the combined bromine after oxidation with nitric acid involves serious losses of bromine, which, however, may be avoided if the substance be oxidised by fusion with alkali carbonates. It is now shown, however, that if this source of error be eliminated the method devised by Hübener becomes fundamentally unsound, and invariably yields results which are much too high. The investigations of the authors on mixtures of known composition lead to the following conclusions: (1) In the case of soft vulcanised rubbers, complete bromination is very difficult to attain, because the sample cannot be ground sufficiently fine; there is no means whereby the final point of the bromination in presence of water may be recognised. (2) The precipitated bromide always contains an excess of bromine above the theoretical quantity, owing to the occlusion either of bromine or brominated compounds. The method of purifying the bromide by washing with alcohol and carbon tetrachloride, recommended by Hübener, is quite insufficient. (3) Superbromination invariably takes place, and the caoutchouc values calculated from the combined bromine are too high. This error is only partially compensated by the opposing error due to loss of bromine when the compound is oxidised by boiling with nitric acid in presence of silver nitrate. (4) The estimation of the uncombined sulphur in the aqueous filtrate from the bromide precipitate is unreliable; considerable quantities of the combined sulphur are continuously oxidised and are estimated in the aqueous filtrate. (5) Consequently, the percentage of vulcanisation sulphur found in the bromide is always too low. (6) The theoretical basis of Hübener's method, differentiating unvulcanised caoutchouc, caoutchouc monosulphide and disulphide, is therefore left at present without experimental support. J. F. B.

Source of Error in the Kjeldahl-Gunning Method. P. A. W. Self. (*Pharm. J.*, 1912, **88**, 384-385.)—The author finds that considerable loss of ammonia may take place by volatilisation from the boiling acid liquid when the temperature rises above a certain point, and that this loss is markedly accelerated as the liquid approximates to the composition $KHSO_4$. In some experiments made, practically the whole of the ammonia was lost from highly concentrated potassium sulphate and sulphuric acid mixtures. It is pointed out that there is a limit to the amount of organic substance which may be used in an experiment in order to avoid loss of nitrogen, and approximately this is, where 25 c.c. of sulphuric acid and 12 grms. of potassium sulphate are employed, not more than 3·5 grms. of a carbohydrate material, 3·0 grms. of a fatty product containing from 5 to 10 per cent. of oil or fat, and 1·5 grms. containing 80 to 90 per cent. of oil or fat. At least 15 grms. of sulphuric acid should remain at the end of the heating period. A. R .T.

Estimation of the Molecular Weight of Small Quantities of Fatty Acids. W. Arnold. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 129-135.)—Full details are given for estimating the molecular weight of small quantities of water-soluble and other fatty acids by titration with potassium hydroxide solution and determining the weight of the resulting soap. An essential part of the process consists in powdering the soap residue before it is dried, it having been found that the last traces of water cannot be expelled from a compact mass of soap. A quantity of the fatty acid is placed in a flask and neutralised by the addition of alcoholic $\frac{N}{10}$ potassium hydroxide solution; in the case of solid fatty acids, a portion of the potassium hydroxide is added, and the contents of the flask warmed to dissolve the fatty acid, the final part of the titration being carried out after cooling the solution, as slightly more alkali is required for the neutralisation when the solution is hot. Phenolphthaleïn is used as the indicator, and the amount of solid matter introduced by this solution must be estimated separately and an allowance made. The soap solution is then transferred to a weighed platinum basin, evaporated slowly, and the residue dried for forty-five minutes in a water-oven. The residue is now broken up into a fine powder by the aid of a small spatula, and the drying continued for a further two and a half hours. The molecular weight is then calculated from the formula:

$$M = \frac{(s - v \times f) \times 20000}{v}$$

where M is the molecular weight, s the weight of the soap, v the number of c.c. of $\frac{N}{20}$ potassium hydroxide solution used, and f the potassium equivalent $\left(\frac{39-1}{20000}\right)$ of each c.c. of the latter solution; should the potassium hydroxide contain traces of salts, their quantity must be estimated by sulphating a definite volume of the solution, and correcting the equivalent accordingly. Results of experiments with a series of fatty acids, ranging from butyric acid to stearic acid, show that the method yields correct figures; in over 90 per cent. of the analyses the figures found agreed within 2 units of those required by theory. W. P. S.

Method for Determining the Relative Reactivity of Organic Compounds. H. Hibbert. (*J. Chem. Soc.*, 1912, **101**, 341.)—The total theoretical quantity of methane is not in general evolved on the interaction of a hydroxy-compound and an excess of magnesium methyl halide in phenetole; the amount is not affected by the presence of ketones, esters, etc. If, however, there is insufficient Grignard reagent, it will be apportioned between the hydroxy-compound and the ketone, according to their relative reactivity for it. To 0·2880 grm. (1 mol.) of α-naphthol was added 3 mols. of the ketone, 6·0 c.c. of phenetole, and 5·0 c.c. of magnesium methyl iodide in phenetole, this being the quantity necessary to react with all the α-naphthol. The methane evolved was measured, and the reactivity-factor calculated as the theoretical volume evolved by 0·2880 grm. of α-naphthol, divided by that found. The known greater reactivity of fatty over aromatic ketones is reflected in the table of results on a series of ketones. O. E. M.

Estimation of Oxalic Acid in the Leaves of Conifers. J. Otto. (*Zeitsch. anal. Chem.*, 1912, **51**, 296-300.)—Having observed by microscopic examination that the leaves of conifers contained apparently varying quantities of calcium oxalate crystals, the amount varying with the age of the leaves, the author estimated the quantity actually present. Pine leaves (needles) one year old were found to contain from 0·2 to 0·9 per cent. of oxalic acid, whilst older leaves contained up to 2·3 per cent. W. P. S.

Preliminary Notes on the Examination of Various Stick-Lacs and Shellacs. J. H. Hoseason and O. Klug. (*J. Soc. Chem. Ind.*, 1912, **31**, 165.)—Five kilogrms. of the stick-lac were ground, sifted through a 40-mesh sieve, and mixed; 5 grms. were macerated for twenty-four hours in warm distilled water, filtered, and washed. The dried filtrate is the coloured water extract. The dried residue was macerated with 90 per cent. alcohol, the extract evaporated to a syrup and dropped on fat-free cotton-wool, and rapidly extracted, after the alcohol had been driven off, with cold ether. The ether was removed by evaporation with alcohol, the liquid made up to 50 c.c. with alcohol, and 5 c.c. taken for (ether-soluble) resin and two portions of 20 c.c. for two Hübl tests. The residue in the cotton-wool was dissolved out with alcohol to 100 c.c., and 5 c.c. taken for (ether-insoluble) resin, and 40 c.c. for two Hübl tests. To insure drying, the film of resin substance in determining the resin must be very thin. The residue from the treatment with water and alcohol was extracted with chloroform; the wax obtained on evaporating off the chloroform contained a brown substance, included in the wax content. The final residue (woody fibre, insect remains, and probably protein colour compounds) was dried and weighed. Analyses of a series of stick-lacs, button-lacs, and shellacs are given. The necessity for a standard method of carrying out the Hübl test is emphasised.

O. E. M.

New Method for the Determination of the Reducing Sugars. E. C. Kendall. (*J. Amer. Chem. Soc.*, 1912, **34**, 317-341.)—Briefly, the method consists in modifying Fehling's reagent by substituting potassium carbonate for caustic soda, and salicylic acid for Rochelle salt. The cuprous oxide is filtered off, dissolved in hot nitric acid, and the copper determined by the modified iodide method as previously described by the author (ANALYST, 1912, 66). Potassium carbonate is shown to be the most satisfactory alkali, and gives more copper than sodium carbonate with the same weight of sugar. Rochelle salt causes some spontaneous reduction of copper, and the citrate solution proposed by Benedict (*J. Biol. Chem.*, 1908, **5**, 485) is found to be inaccurate owing to depression and variation caused in the reducing power of the sugar in its presence. An alkaline salicylate solution replacing the alkaline tartrate was found to give no spontaneous reduction of copper even after seven hours heating in the boiling-water bath, and changes in the weight present had but very small effect on the reducing power of the sugars. It is not possible to replace salicylic acid by sodium salicylate, although the acid must be present in the alkaline solution as the potassium salt. Numerous experiments are described in which variations in procedure were made in order to obtain optimum conditions. For the preparation of standard tables by the new method, specially purified sugars were used, and their purity carefully checked by the polariscope and otherwise. The author prepared maltose by the barley diastase method of Baker (ANALYST, 1908, **33**, 393); the other sugars were purchased and recrystallised. The method of reduction was as follows: The sugar employed was measured out in solution of appropriate strength into a 200 c.c. Erlenmeyer flask, and the total volume made up to 100 c.c. Five grms. of dry salicylic acid were then added, followed by 15 c.c. of copper sulphate solution (equivalent to 2 grms. of $CuSO_4 5H_2O$) and 25 c.c. potassium carbonate solution (equivalent to 15 grms. of the carbonate) without any agitation of the flask. This order must be adhered to. The flasks are now shaken with a rotary motion. As soon as the salicylic acid has dissolved, the flask is immersed in the boiling-water bath for twenty minutes. The cuprous oxide is filtered on a perforated porcelain dish covered with asbestos felt, and finally dealt with by the author's method alluded to above. The sugars for which tables are given are glucose, invert sugar, lactose, and maltose.

H. F. E. H.

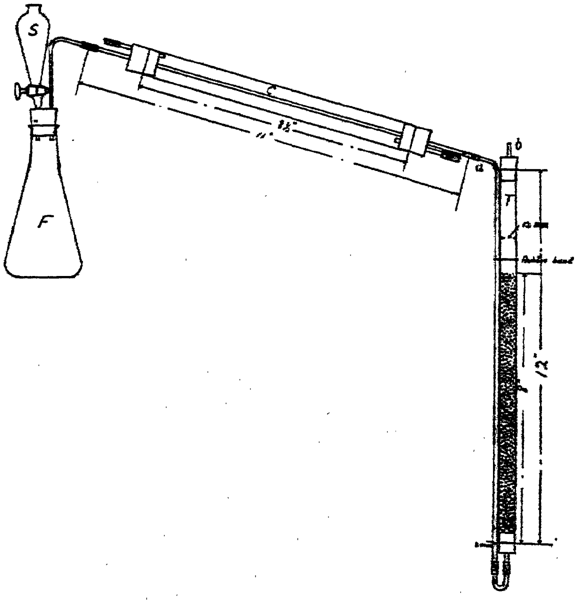
INORGANIC ANALYSIS.

Separation and Estimation of Arsenic and Antimony. G. Bressanin. (*Ann. chim. anal.*, 1912, **17**, 81-84.)—Blattner and Brasseur have proposed to estimate quantities of arsenic such as occur in commercial mineral acids as follows: Hydrochloric acid, if of lower sp. gr. than 1·16, is first brought up to this density by addition of pure sulphuric acid (sp. gr. 1·45), and 50 c.c. are taken for the test. Iodide of potassium (5 c.c. of a 30 per cent. solution) is added, and the arsenious iodide filtered off on asbestos and washed with a few c.c. of pure hydrochloric acid containing 10 per cent. of potassium iodide. The precipitate is then dissolved in water, the solution saturated with sodium bicarbonate, and the sodium arsenite titrated with $\frac{N}{10}$ iodine. Sulphuric acid, if free from tin and lead, is diluted until its sp. gr. is 1·45, and treated similarly. In presence of lead or tin it is first diluted with an equal bulk of pure hydrochloric acid. The author finds that the method underestimates arsenic in hydrochloric acid by 2 per cent. of the amount present, but that it is quite satisfactory with sulphuric acid free from lead or tin. In presence of these metals hydrochloric acid must be added, but its amount must not exceed one-third of that of the sulphuric acid, or the results will be low. The washing with hydrochloric acid containing potassium iodide is said to do more harm than good, and it is found better to reduce the amount of potassium iodide employed for precipitation to 2 or 3 c.c. The arsenic in hydrochloric acid may be estimated exactly by mixing the acid with twice its volume of sulphuric acid (sp. gr. 1·45), adding 2·5 c.c. potassium iodide solution, filtering, washing with a mixture of pure hydrochloric acid (sp. gr. 1·16) and pure sulphuric acid (sp. gr. 1·45) in the proportions 1 : 2, and proceeding as already described. The iodide reaction affords a very sensitive qualitative test for arsenic in mineral acids, a faint but distinct yellow opalescence appearing instantly if even so little as one part in a million be present.

The author has extended the method to the estimation of antimony in sulphuric acid. The optimum concentration of acid is that which corresponds to a sp. gr. of 1·5 or a little higher. Potassium iodide is added, and the precipitate washed with pure acid of the same density, and then redissolved by means of a 10 per cent. solution of Rochelle salt. Since antimonious iodide is soluble in concentrated hydrochloric acid, the method is not applicable to that acid, but the same circumstance affords a basis for the separate estimation of arsenic and antimony. The substance is dissolved in sulphuric acid (sp. gr. 1·5), and the solution made up to a definite volume with acid of this strength. In one aliquot portion arsenic and antimony are estimated together in the manner described for antimony, whilst, in another, arsenic is estimated alone after adding to the sulphuric acid solution one-third of its volume of hydrochloric acid, which prevents the precipitation of antimonious oxide. G. C. J.

Short Method for Determination of Soluble Arsenic in Commercial Lead Arsenates. B. E. Curry and T. O. Smith. (*J. Ind. Eng. Chem.*, 1912, **4**, 198-201.)—The method of the American Association of Official Agricultural Chemists involves the shaking of 2 grms. of the sample with 2 litres of water eight times daily for ten days. It is shown that identical results may be obtained by continuous stirring for eighteen hours. The authors find it more convenient to work with 500 c.c. of water, but the results thus obtained do not accord with those obtained by the official method, since lead arsenate itself is soluble to some extent in water. If 0·45 be added to the percentage of arsenic acid found when using only 500 c.c. of water for extraction, the result thus corrected will agree exactly with that obtained by the official method. But since 2 litres of water at 20° C. dissolve as much lead acetate as corresponds to 0·6 per cent. of arsenic acid in a 2 grm. sample, and since commercial lead arsenate contains only from 0·1 to 3 per cent. (usually about 0·3 per cent.) of free arsenic acid, it is suggested that the official method should require the extraction to be made at a fixed temperature, say 20° C., and that from the apparent percentage of arsenic acid found there should be made a deduction at the rate of 0·03 for each 100 c.c. of water used for extraction. G. C. J.

Volumetric Determination of Carbonic Acid. L. T. Bowser. (*J. Ind. Eng. Chem.*, 1912, 4, 203-205.)—The carbonate (1 grm.) is weighed out into the 100 c.c. flask, *F*, and covered with about 50 c.c. of water. The absorbing tower, *T*, containing glass beads, is charged with 10 c.c. of 50 per cent. caustic potash. Sufficient dilute hydrochloric acid to decompose the carbonate is admitted to the flask through the tap-funnel, *S*, the top of which is constricted to allow of connection to a rubber tube, by means of which the acid can be blown in against the back-pressure of the absorbing apparatus. When action slackens, the contents of the flask are heated to boiling, and water is distilled over until the tower is nearly filled. The tap of the funnel is then opened, the absorbing apparatus disconnected at *a*, and its contents discharged through *a* into a 100 c.c. flask by blowing at *b*. A guard tube containing soda lime may be used between the mouth and *b*, but is said to be unnecessary. The tower is filled up with water three times after removing the cork through which *b* passes, and the washings blown over into the 100 c.c. flask. This is then filled to the mark, and 25 c.c. taken for titration. With phenolphthaleïn as indicator, and in presence of 10 c.c. alcohol, normal acid is run in nearly to neutralisation, the titration being completed with $\frac{N}{10}$ acid. The addition of alcohol



facilitates the determination of the end-point. At this stage, the excess of caustic alkali is neutralised and the carbon dioxide all exists as bicarbonate. Methyl orange is then added, and the titration completed as usual, each c.c. of $\frac{N}{10}$ acid required at this stage corresponding to 4·4 mgrm. carbon dioxide in the 25 c.c. or other aliquot taken for titration. Correction must be made for any carbon dioxide in the reagents employed, and this correction is determined by a blank experiment. Where a large number of determinations of carbon dioxide have to be made, the method is more rapid than any other, since three determinations may be completed in an hour, and the results, in the hands of an experienced operator, are accurate to within one drop of an $\frac{N}{10}$ solution. G. C. J.

Analysis of Cement and Cement Raw Materials. B. Blount. (*Institute of Chemistry Lectures on Cement*, 1912.)—*For silica and chief bases:* 0·5 grm. of the cement is thoroughly mixed with a few c.c. of water in a shallow 6 inches evaporating basin; about 20 c.c. strong hydrochloric acid are then added, the whole again well mixed until the cement has dissolved almost completely, evaporated to dryness, and baked for an hour at a temperature of at least 200° C. The dry residue is digested with 30 c.c. strong hydrochloric acid, the solution diluted with water, and the silica and insoluble residue filtered off. The filtrate is precipitated with a slight excess of ammonia and bromine, and heated until only just alkaline. To the filtrate from the alumina and ferric hydroxide about 10 c.c. ammonia (sp. gr. 0·880) are added, the solution heated to boiling, and the lime precipitated by the addition of 25 c.c. of a hot 4 per cent. ammonium oxalate solution. The precipitated calcium oxalate is boiled for two or three minutes, allowed to stand for an hour, and then filtered. The filtrate is evaporated until a pasty residue is obtained, about 50 c.c. strong nitric acid added, the dish covered, and the heating continued until the ammonium salts have been destroyed. The residue is dissolved in a few c.c. of water and hydrochloric acid, heated with a slight excess of ammonia and a few drops of ammonium oxalate solution, and the small precipitate thus obtained is filtered off. This precipitate does not usually exceed 0·0015 grm., and in ordinary work may be neglected. To the filtrate about one-third of its volume of strong ammonia is added, and magnesia precipitated by the addition of 2 to 3 c.c. of a 10 per cent. solution of sodium phosphate. The precipitate is allowed to stand, with occasional shaking, for two hours, filtered, and ignited at the mouth of the muffle. The precipitates of silica and insoluble residue, iron and alumina, and lime are gently burnt off with their filter-papers, and then ignited for an hour at the highest temperature of the muffle.

For insoluble residue and sulphuric anhydride: 0·5 grm. of the cement is dissolved as above, evaporated to dryness, the residue taken up in 10 c.c. hydrochloric acid, and the solution filtered off after dilution. In the filtrate SO_3 is precipitated with barium chloride and estimated as usual. The precipitate of silica and insoluble residue is washed back into the dish and digested with a saturated solution of sodium carbonate, when the insoluble residue only is left undissolved. This is filtered off, washed, ignited, and weighed. Its weight, deducted from that of the silica plus insoluble residue obtained above, gives the quantity of combined effective silica.

For loss on ignition; carbonic acid and water: 0·5 grm. of the cement is ignited in platinum for half an hour in a gas muffle at a temperature of about 800° C.

For carbonic acid: 2 to 5 grms. are decomposed with hydrochloric acid, and the carbonic acid, after purification, is collected in a weighed potash bulb.

For alkalis: 1 grm. of the cement is taken and the silica and chief bases are removed as above. The residue remaining after the destruction of ammonium salts is treated with baryta to remove magnesia and afterwards with ammonium carbonate. The alkalis are weighed as chlorides and separated by means of platinic chloride.

For sulphides: The cement is decomposed with hydrochloric acid in an atmosphere of coal gas, the evolved sulphuretted hydrogen being absorbed in lead acetate solution and weighed as lead sulphate.

The determinations of carbonic acid, alkalis, and sulphides are usually unnecessary.

Separation of alumina and ferric oxide: The freshly precipitated hydroxides obtained either by fusing the ignited oxides with potassium bisulphate, dissolving in dilute hydrochloric acid and precipitating with ammonia, or from a separate portion of cement, are dissolved in dilute hydrochloric acid, evaporated to a small bulk and poured into a strong solution of pure caustic soda. After digestion the precipitated ferric hydroxide is filtered, redissolved in hydrochloric acid and reprecipitated with ammonia.

A more rapid determination may be made by dissolving 1 grm. of cement in dilute hydrochloric acid, reducing with pure granulated zinc and titrating the largely diluted ferrous solution with $\frac{N}{20}$ potassium permanganate solution.

Limestones: If nearly pure, may be analysed as described under cement. The insoluble siliceous matter, after ignition, is treated with hydrofluoric acid and sulphuric acid and ignited: the residue, if appreciable, is fused with sodium carbonate and analysed in the usual manner.

For siliceous and argillaceous limestones which contain a considerable amount of insoluble matter, it is advisable to ignite 1 grm. of the finely-ground sample at the full temperature of the muffle for an hour. The ignited product should be almost completely soluble and may be analysed as described under cement.

Separate portions are taken for the determination of sulphate and carbonic acid in the usual manner.

If necessary, pyrites is estimated by digesting the finely-ground sample with *aqua regia,* removing nitric acid by evaporation with hydrochloric acid and precipitating the total sulphates in the diluted filtered solution by means of barium chloride.

Clay, shale, etc.: 0·5 grm. of the finely-ground sample is fused with about 3 grms. pure sodium carbonate in a platinum crucible for half an hour with occasional shaking. The fused mass is dissolved in hot water and hydrochloric acid and the solution evaporated to dryness and baked for the estimation of silica as described under cement. The filtrate should be evaporated and baked a second time to separate a further small quantity of silica. From this point the analysis is conducted exactly as described under cement. Double precipitation is made if a large proportion of magnesia is present. The purity of the silica is tested by means of hydrofluoric and sulphuric acids. Alumina and ferric oxide are separated by fusion with potassium bisulphate as described above. For rapid work the bisulphate melt may be dissolved in dilute hydrochloric acid, reduced with zinc and titrated with permanganate solution.

The estimation of "loss on ignition," sulphates, carbonic acid and pyrites are made in the usual manner.

If necessary, alkalis may be determined by decomposing the finely-ground sample with hydrofluoric and sulphuric acids. After removing excess of sulphuric acid at a gentle heat, the residue is dissolved in hydrochloric acid, the chief bases removed as usual, and the estimation completed as described under cement.

For shales and clays which contain a large proportion of calcareous matter, it is advisable to extract the sample with hydrochloric acid and to analyse the soluble and insoluble portions separately. G. J. A.

Quantitative Separation of Copper from Arsenic, Aluminium, Zinc, Tungsten, and Tin by Means of Hydrogen Peroxide in Presence of Sodium Hydroxide and Sugar. P. Jannasch and O. Routala. (*Ber.*, 1912, **45**, 598-604.) —When a solution of copper sulphate is mixed with sufficient cane sugar, so that no precipitate is formed on the addition of excess of sodium hydroxide, the whole of the copper may be precipitated as cuprous oxide by the addition of hydrogen peroxide and warming. For the estimation of copper alone, 0·3 grm. of copper sulphate is dissolved in about 75 c.c. of water and 3 grms. of cane sugar and 10 c.c. of a 10 per cent. solution of sodium hydroxide are added in the cold; 20 to 25 c.c. of 6 to 8 per cent. hydrogen peroxide are then added and precipitation is completed by warming for about fifteen minutes on the boiling water-bath. The cuprous oxide is filtered off, washed with boiling water, and incinerated until fully oxidised. For the separation of copper from other metals it is generally advisable to have about 6 grms. of sodium hydroxide and 5 grms. of cane sugar present in 100 c.c. of the solution. The complete precipitation of the copper may be controlled by adding a further 5 c.c. of the peroxide after heating on the water-bath. After the cuprous oxide has been filtered off, the sugar must be removed before the other metals can be precipitated, except in the case of arsenic. Arsenic is precipitated as magnesium ammonium arsenate, aluminium by means of ammonia, zinc as carbonate, and tin as stannic acid. For the oxidation of the sugar, the liquid should be evaporated in a platinum dish, treated several times with strong nitric acid, evaporating to dryness each time, then with nitric acid and hydrogen peroxide, and finally heated so as to fuse the contents of the dish. Precautions are necessary to prevent the oxidation of the cuprous oxide during filtration. J. F. B.

Valuation of Fluorspar. E. Bidtel. (*J. Ind. Eng. Chem.*, 1912, **4**, 201.)— The following method gives excellent results when applied to Illinois fluorspars, which contain, in addition to calcium fluoride, silica (0·4 to 13 per cent.), and calcium carbonate (0·2 to 15 per cent.), and small amounts of lead sulphide (nil to

2 per cent.), and ferruginous zinc sulphide (nil to 2 per cent.). One grm. of the dry and finely-powdered sample contained in a small Erlenmeyer flask is digested with 10 c.c. of 10 per cent. acetic acid on the water-bath for an hour, with occasional shaking. The undissolved matter is filtered off on a 7 cm. filter, and washed four times with hot water. Under these conditions ·0015 grm. of calcium fluoride passes into the filtrate. The filter-paper is burnt and the residue ignited and weighed. The loss in weight due to treatment with acetic acid, less ·0015 grm., is calculated as calcium carbonate. In some fluorspars other carbonates may be present, but their amount is usually very small. About 1 grm. of yellow mercuric oxide in the form of a cream is next mixed in with the residue in the platinum crucible, and the mixture dried, raised to a dull red heat, cooled, and weighed. Any lead originally present as sulphide will now exist as sulphate. About 2 c.c. of hydrofluoric acid are next added to expel silica, and, after evaporation to dryness, the operation is repeated twice with about 1 c.c. of hydrofluoric acid. A few drops of hydrofluoric acid are again added, together with some macerated filter-paper, and this is followed by a few drops of ammonia to precipitate the iron. The contents of the crucible are next dried, raised to a dull red heat, cooled, and weighed. The loss since the last weighing is reported as silica. After addition of 2 c.c. of hydrofluoric acid and a few drops of nitric acid, the crucible is covered and its contents digested on the water-bath for half an hour. The lid is then removed, and the contents of the crucible are evaporated to dryness. If not perfectly white, the residue is evaporated again with hydrofluoric acid. After moistening with a few drops of hydrofluoric acid, the residue is digested for half an hour on the water-bath with 10 c.c. of a solution containing 400 grms. ammonium acetate, 20 grms. citric acid, and 200 c.c. of strong ammonia per litre. The insoluble matter is filtered off, washed with ammonium acetate solution, and then with hot water, ignited, and weighed. In the author's experience, the residue thus obtained is pure calcium fluoride, and ·0029 grm. should be added to its weight for losses due to the solubility of calcium fluoride in acetic acid and in ammonium acetate. The residue should, however, be examined for barium by conversion to sulphate, fusing the sulphate with sodium carbonate and solution of the fused product in hydrochloric acid. Illinois fluorspars do not contain heavy spar or gypsum, but the frequent request to analysts to estimate barium sulphate leads the author to suppose that it is a not uncommon constituent of fluorspar. It is pointed out that calcium sulphate, if present, would be partly leached out by the dilute acetic acid and estimated as carbonate.

G. C. J.

Estimation of Magnesia in Admixture with Magnesium Carbonate. V. Fortini. (*Chem. Zeit.*, 1912, 36, 270-271.)—Where the import duty on magnesia is high the attempt is sometimes made to smuggle it in admixed with magnesium carbonate, and under the description of magnesium carbonate, on which the duty is never more than half as much and may be less. A determination of carbon dioxide alone occupies some time, and alone is insufficient, as the description of the article may allow the presence of asbestos and other substances which would reduce the percentage of carbon dioxide below that corresponding to $MgCO_3$. Advantage may be taken of the fact that magnesia dissolves in hydrochloric acid with considerable evolution of heat, whereas this is not the case with magnesium carbonate. The author makes use of Tortelli's thermoleometer (Analyst, 1909, **34**, 168), but any calorimeter which allows of the use of hydrochloric acid of sp. gr. 1·1 may be used. With Tortelli's instrument, 1 grm. of magnesia added to 25 c.c. of dilute hydrochloric acid raises the temperature of the acid 37° C., 0·1 grm. raising it 3·7° C. Commercial magnesium carbonate always contains basic carbonate, but never enough to vitiate this test, which aims at detecting gross frauds such as alone could benefit the importer.

G. C. J.

Estimation of Nitrates and Nitrites in Water by Schlœsing's Method. A. Huizinga. (*Zeitsch. anal. Chem.*, 1912, **51**, 292.)—This method does not always yield correct results when the water is evaporated after the addition of magnesia, and the gas, obtained by boiling the residue with hydrochloric acid and ferrous chloride, treated with sodium hydroxide solution. The results are invariably inaccurate when nitrites are also present in the water. The following modification of the method of preparing the water total solids for the estimation is therefore recommended: One litre of the water (in the case of rain-water 5 litres are taken) is rendered alkaline with potassium hydroxide and evaporated to a volume of about 100 c.c.; 4 c.c. of $\frac{N}{10}$ permanganate solution are then added, the mixture is boiled, filtered, and the filtrate again boiled after the addition of a further quantity of permanganate solution and 2 c.c. or more of dilute sulphuric acid. The acid solution is now rendered alkaline, filtered, and the filtrate evaporated to a volume of about 20 c.c.; 2 c.c. of acetic acid, or a quantity sufficient to acidify the solution, are added, and the evaporation is continued to dryness. The residue is then treated in a Schlœsing's apparatus in the usual way, but, carbonates having been decomposed by the evaporation with acetic acid, the evolved gas is not collected over sodium hydroxide solution. The results obtained do not differ by more than 0·1 mgrm. from the quantity of nitrogen actually present.

W. P. S.

Use of a Mixture of Nitric Acid and Hydrogen Peroxide in Analytical Work. P. Jannasch. (*Ber.*, 1912, **45**, 605-607.)—1. *For the Destruction of Organic Matter.*—In forensic analysis, after the animal matter has been destroyed by treatment with potassium chlorate and hydrochloric acid, the search for metals of the hydrogen sulphide group is complicated by the formation of yellowish-brown precipitates, mainly of organic nature. This organic matter is not readily destroyed by repeated evaporation with fuming nitric acid, but it is easily oxidised by a mixture of nitric acid and hydrogen peroxide. The precipitate obtained with hydrogen sulphide is treated once or twice with red fuming nitric acid and heated to dryness on the water-bath. The residue is then treated in a similar manner with a mixture of ordinary 65 per cent. nitric acid, sp. gr. 1·4, and 15-20 per cent. hydrogen peroxide obtained by diluting Merck's 30 per cent. "perhydrol" with water. In this way the metals are completely freed from organic impurities. This method possesses the advantage of introducing no non-volatile reagents.

2. *For the Removal of Ammonium Salts.*—The ordinary 65 per cent. nitric acid, sp. gr. 1·4, is recommended in preference to the fuming acid for the purpose of

removing ammonium chloride by evaporation. In the case of ammonium nitrate a little concentrated hydrochloric acid is added at the same time. Ammonium sulphate cannot be volatilised by nitric acid alone; repeated evaporation with strong hydrochloric and nitric acids is recommended, or else the mixture of nitric acid and hydrogen peroxide. Ammonia is driven off from ammonium phosphate best by evaporation with strong nitric acid and bromine. In the analysis of complex silicates, after the precipitation of the calcium as oxalate, the filtrate is evaporated nearly to dryness, the residue is moistened with water to a pasty consistence and then evaporated to dryness with 25 c.c. of 65 per cent. nitric acid. If this operation be repeated with 10-15 c.c. of the acid, only traces of ammonium salts remain, which can readily be volatilised by short heating on an asbestos-covered gauze. The magnesia is then precipitated by mercuric oxide. J. F. B.

New Method for Testing Paint Films and Preservative Coatings for Iron and Steel. W. C. Slade. (*J. Ind. Eng. Chem.*, 1912, 4, 189-198.)—The method depends on the periodical measurement of the electric current passing through a circuit which includes a bare wire anode, a normal solution of potassium chloride, a cathode consisting of a wire helix of specified dimensions, coated with the paint to be investigated, and an external resistance of 100 ohms. The apparatus illustrated in the paper shows several electrolyte tanks about 28 ins. by 7 ins. by 8 ins. each of which will accommodate 14 of these elements or "paint cells," as they are termed. The electrolyte in the neighbourhood of the painted helix is continuously aerated, whilst that surrounding the bare wire is protected from access of oxygen. A clockwork arrangement provides for all the paint cells being elevated out of the electrolyte at 3, 6, 9, and 12 o'clock, and for their re-immersion at 1, 4, 7, and 10 o'clock. At or about 2, 5, 8, and 11 o'clock, the current in each circuit is measured after cutting out the external resistance and substituting a milliammeter, also of 100 ohms resistance. Most of the author's experiments have extended over 300 hours, but it appears that as much information may be gained in 200 or perhaps even in 150 hours. Apparatus has been designed and is illustrated in the paper for securing paint films of uniform thickness. The helices are dipped in the well-shaken paint mixture, allowed to drain until dropping begins, and then mounted horizontally on a slowly rotating wheel, so that the paint flows round the wire instead of draining away in drops. If the electrolytic theory of corrosion be admitted, the method reproduces closely the conditions to which painted steel work is exposed. When a paint-cell is first connected up, no current, or a current of a few thousandths of a milliampère, passes. But with time this current always increases and may reach 0·5 milliampère or thereabouts. This is explained as follows: When the electrolyte has penetrated the paint-film sufficiently to establish contact with the iron, the hydrogen ions that tend to polarise are depolarised by the oxygen of the air which is in solution, and the operation of the cell commences. With increased porosity comes an increased rate of diffusion, and an increased rate of depolarisation, and a decrease in film resistance. The current consequently increases. At this time any depolarising power possessed by linoxyn that may still be unsaturated should show its influence. To maintain the equilibrium of ionic charges within the solution, metallic iron must pass into solution at some point in the form of ferrous ions. This takes place almost wholly at the undepolarised electrode. The ferrous ions unite with the hydroxyl ions (corresponding to the hydrogen ions removed by depolarisation) to form ferrous hydroxide, which in turn is oxidised to ferric hydroxide. Some rust forms at the cathode, but its amount is very small compared with that formed at the anode. The numerical results obtained admit of varied mathematical treatment in attempts to classify paints as a result of this test. Several such methods of treatment are discussed. G. C. J.

Estimation of Phosphoric Acid in Presence of Colloidal Silicic Acid. P. Mélikoff and M. Becaia. (*Comptes rend.*, 1912, **154**, 775.)—The usual method of estimating phosphoric acid is faulty if colloidal silicic acid is present, but accurate results may be obtained by the use of permolybdate reagent (Analyst, 1912, 107). Thus, two portions of 50 c.c. disodium phosphate solution, to each of which had been added 50 c.c. colloidal silicic acid containing 0·581 grm. SiO_2, gave 0·1725 and 0·2067 instead of 0·1211 grm. P_2O_5, on estimation, by means of magnesia mixture, of the phosphoric acid in the precipitate obtained with molybdate, which is thus shown to carry down silica. When, however, this precipitate of mixed phosphomolybdate and silicomolybdate is treated four times in twenty-four hours with permolybdate reagent (equal volumes of 30 per cent. hydrogen peroxide and 15 per cent. ammonium nitromolybdate) and washed on a filter with the reagent, the filtrate heated to 40° or 50° C. to destroy excess of hydrogen peroxide, and the phosphoric acid determined in it by means of magnesia mixture, 0·1193 and 0·1209 grm. P_2O_5 (instead of 0·1211) were obtained. O. E. M.

Estimation of Small Quantities of Potassium. E. A. Mitscherlich, K. Celichowski, and H. Fischer. (*Landw. Vers.-Stat.*, 1912, **76**, 139-155; through *Chem. Zentralbl.*, 1912, I., 853.)—The method proposed consists in precipitating the potassium in the form of potassium cobaltinitrite and titrating this nitrite with permanganate solution; it is suitable for the analysis of soil extracts, and is stated to be more accurate than the platinum method. Two hundred and fifty c.c. of an aqueous extract of a soil are treated with 5 c.c. of concentrated nitric acid and 5 drops of dilute sulphuric acid, and evaporated to dryness; after the residue has been ignited in order to destroy organic matter, it is treated with 1 drop of concentrated sodium carbonate solution and a few c.c. of water, and again evaporated to dryness. The residue is now heated until fusion commences, cooled and neutralised with nitric acid; any excess of acid is removed by evaporating the mixture to dryness. Five c.c. of hot water are added to the residue, and the solution is treated with 3 c.c. of a 10 per cent. cobalt chloride solution and 5 c.c. of a 10 per cent. sodium nitrite solution; the mixture is now evaporated to dryness at a temperature of 80° to 90° C., and stirred frequently during the evaporation. When cold, the residue is treated with 3 c.c. of 10 per cent. acetic acid, 10 c.c. of water are then added, and the insoluble portion is collected on a filter and washed six times with a 2·5 per cent. sodium sulphate solution, 3 c.c. of this solution being used each time. A definite volume of $\frac{N}{50}$ potassium permanganate solution (in quantity somewhat more than sufficient to oxidise the nitrite) is placed in a beaker, diluted with 100 c.c. of water, and heated nearly to boiling on a water-bath; the contents of the filter are now introduced into the beaker, and when manganese dioxide begins to separate, about 2·5 c.c. of dilute sulphuric acid are added drop by drop. As soon as the yellow nitrite precipitate has dissolved, the excess of permanganate is titrated with $\frac{N}{10}$ oxalic acid solution. Each c.c. of $\frac{N}{10}$ permanganate solution is equivalent to 0·000157 grm. of K_2O (*cf.* ANALYST, 1911, **36**, 606). W. P. S.

Iodometric Estimation of Selenium in Sulphur and Pyrites. P. Klason and H. Mellquist. (*Zeitsch. angew. Chem.*, 1912, **25**, 514-518.)—Sulphur (100 grms. or more) is placed in porcelain boats, each of which contain 10 to 15 grms, in a combustion tube 100 cm. in length and 20 mm. in diameter. At the forward end of the tube is an asbestos plug which is kept cool. A current of air is drawn through the tube and the combustion of the sulphur started by means of a Bunsen burner. The action then proceeds without external heating, but at end of the combustion each boat is heated to volatilise any adherent selenium before it is withdrawn. The results show that the cool asbestos plug retains all but an unweighable trace of the selenium which passes forward as a fog with the small quantity of sulphur trioxide which is always formed. The radish-like odour characteristic of selenium compounds may always be detected, but the results show that the loss at this stage must be negligible, and that under the conditions of the experiment the volatile selenium suboxide of Berzelius can only be formed in traces. The tube and asbestos plug are treated with a solution of potassium cyanide to dissolve the selenium, and the resulting solution made strongly acid with hydrochloric acid and evaporated until crystallisation begins, in order to precipitate the whole of the selenium as selenious acid. The precipitate is collected on a Soxhlet asbestos filter of large dimensions, with the wide portion of the tube 280 mm. long and 10 mm. in diameter. The filtering plug of asbestos is supported on a platinum cone, and, after drying the precipitate, a second plug of asbestos is introduced an inch or so into the tube. The precipitate is next heated and a current of oxygen led through the tube. Since the precipitate invariably contains some sulphur, and as selenious acid is reduced by sulphur dioxide, the oxidation of the selenium to selenious acid does not begin until all the sulphur has been expelled. The selenious acid sublimes to a cooler part of the tube, and, if contaminated by unoxidised selenium, the flame is directed on the sublimate, which is driven backwards and forwards along the tube until quite white. The selenious acid is finally dissolved in water and the solution diluted to 100-300 c.c., and acidified with two or three drops of concentrated hydrochloric acid for each 100 c.c. of solution. The acidified solution is heated in a flask on the water-bath, the air in the flask displaced by carbon dioxide, and 2 to 5 grms. potassium iodide added. When the iodide has dissolved, the flask is shaken, cooled in running water, and placed in the dark for an hour. The liberated iodine is then titrated with $\frac{N}{100}$ thiosulphate, using starch as indicator. $SeO_2 = 4I$. Selenium when present in sulphur in the proportion of 0·5 oz. to the ton, or less, may be estimated in this way with an error not exceeding 5 per cent., but, when determining such small quantities, the hydrochloric acid and potassium iodide used must be free from traces of chlorine and iodate respectively.

Pyrites, when heated in boats in a combustion-tube even in a current of oxygen, does not part with the whole of its selenium, about 55 per cent. remaining with the ash if the heating be by means of a Bunsen burner. But the importance of this work depends on the recent observation (Klason, *Verein. Zellstoff u. Papierchemiker*, 1909, 61) that minute traces of selenium in the liquor of a sulphite-cellulose factory exercise a most prejudicial influence, and in factory practice much of the selenium present in the pyrites remains with the ashes. The authors, therefore, consider that the result of a roasting experiment gives, perhaps, more useful practical information than an estimation of total selenium, though they practise both. When a Bunsen flame is used, the ashes contain about 8 per cent. of sulphur, whereas the burned pyrites of a sulphite cellulose factory is said to contain 4 per cent. of sulphur, as a rule. The authors, therefore, complete their combustion in an electric furnace at such a temperature that the ashes contain about 4 per cent. of sulphur if the heating is discontinued when the odour of sulphur dioxide can no longer be detected. Under such conditions as much as 75 per cent. of the selenium may be expelled from the pyrites.

For the estimation of total selenium in pyrites, 25 grms. are dissolved in concentrated hydrochloric acid, with addition of potassium chlorate. After filtering from insoluble matter and reducing iron to the ferrous state by means of zinc, the selenium is precipitated by addition of stannous chloride to the hot solution. The elementary selenium is filtered off on asbestos, and freed from arsenic by solution in potassium cyanide and reprecipitation by means of hydrochloric acid. The pure selenium is then collected on the Soxhlet filter, and oxidised to selenious acid, and estimated volumetrically as already described. G. C. J.

NOTE BY ABSTRACTOR.—The objection to selenium in bisulphite lyes intended for use in sulphite cellulose factories depends on the fact that even a small fraction of 1 mgrm. per litre brings about the rapid destruction of the lye by production of sulphuric acid and gypsum. Selenium is 500 times more powerful than sulphur as a catalytic agent in the production of sulphuric acid from sulphurous acid.

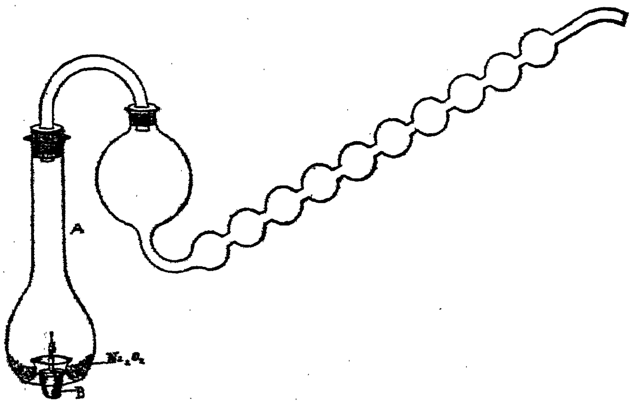
Estimation of Sulphur and of Halogens in Small Quantities of Organic Substances. J. Donau. (*Monatsh.*, 1912, **33**, 169-176.)—The method employed is essentially that of Carius, but the apparatus described has been devised so as to admit of the application of that method to quantities such as are weighed on a micro-balance. The tubes employed are about 9 cm. long before sealing off, with a thickness of wall of 1 mm. and an internal diameter of 6 mm. The end first sealed up is given a just perceptibly bulbous form, whilst the next centimetre of the tube is blown out into a distinct but still very small bulb. The substance for analysis is weighed out in and handled by means of a special platinum spoon, which is constructed from a disc of foil, 3 mm. in diameter and 0·05 mm. thick, and a piece of wire 3 cm. long and 0·1 mm. in diameter. The disc is given a hemispherical shape by placing it on a rubber bung and pressing with a suitably-shaped piece of wood. The wire is then welded on to the cup thus formed. Into this spoon not more than 5 mgrms. of the substance are placed, and the spoon, resting in a larger piece of foil, is then weighed on the micro-balance. By means of a special pair of forceps the spoon is pushed right to the end of the Carius tube, held in a horizontal position, and its contents are transferred to the more distant bulb by turning the handle of the spoon through 180 degrees. The spoon is then withdrawn, replaced on the foil on the micro-balance, and reweighed. By means of a similar spoon, silver nitrate, or barium chloride, as the case may be, is introduced into the more distant bulb, and then 2 drops of nitric acid are introduced into the second bulb by means of a pipette with a bent point. Still keeping the tube horizontal, it is sealed off so as to be about 7 cm. long. The terminal capillary need not be longer than 0·5 cm. The tube is now placed in a vertical position, capillary uppermost, in a furnace of special construction. This consists of a cylinder or prism of copper some 10 cm. high, with a cross-sectional area of 30 to 40 sq. cm. From the top of this cylinder or prism, a number (*e.g.*, 4) of 16-mm. holes are bored to within 1 or 2 cm. of the bottom. One of these holes accommodates a thermometer; the others form the chambers for the reception of the Carius tubes, which rest on asbestos plugs. The open mouths of the chambers are covered with an asbestos plate, and the furnace is placed on a tripod and heated by means of a powerful Bunsen burner. When decomposition is complete and the tubes have cooled, the internal pressure is released in the usual manner; but the tubes are sprung in the plane of maximum diameter of the upper bulb which contained the nitric acid before the tubes were placed in a vertical position after sealing. The end thus cut off, which may be given a lip, provides a minute beaker for handling the precipitate before filtering. The washings from the larger half are transferred to this. Precipitates of barium sulphate are evaporated several times with hydrochloric acid, the residue taken up in water containing hydrochloric acid, and the precipitate filtered off on the micro-filter previously described (ANALYST, 1912, 68). It is washed with about 5 drops of hot water, dried, placed on a piece of platinum-foil and ignited, placed quickly whilst still hot in a desiccator, removed after half a minute, and weighed. In halogen determinations, the water used for washing the rejected portion of the Carius tube is evaporated to 1 or 2 drops, a few drops of water are added, and the silver halide filtered and washed as already described. As superficial reduction of the silver halide is unavoidable, the platinum filter is exposed for about a minute to an atmosphere of chlorine or bromine, as the case may be, and then dried with its contents at 130° C. Experiment shows that the platinum filter is not sensibly attacked by exposure in this way to chlorine or bromine, and the treatment must not be omitted, or low results will be obtained. One mgrm. of sulphur, chlorine, or bromine, can be estimated with an error not exceeding 2 per cent.

G. C. J.

Estimation of Sulphur in Petroleum. J. McC. Sanders. (*J. Chem. Soc.*, 1912, 101, 358-365.)—Two methods are given for the estimation of the total sulphur of kerosenes, and a method for loosely-combined sulphur, all of which have yielded rapid and good results with all classes of petroleum.

For Total Sulphur—(1) *With the Parr Calorimetric Bomb.*—From 2 to 3 grms. of sample in a porcelain basin are treated with 0·01 grm. of potassium bromide dusted over the surface, and 4 c.c. of fuming nitric acid run in from a pipette. When action has ceased, the liquid is evaporated at 100° C., till somewhat viscous and dark brown in colour. About 0·5 grm. light magnesium oxide is now stirred into the mass, which is heated over a small flame, with continuous stirring, till the product tends to solidify on cooling. The amounts of magnesia used and the time of heating should be such as to allow the easy removal of the product on cooling, the remaining trace of oily matter being taken up with a little magnesia, warming, and scraping out with a spatula. The granular mass resulting is placed in the calorimeter, the standard amount of peroxide added, and the mixture stirred with an iron rod. The bomb is closed and fired with due precautions by the electric fuse. When the combustion is over (forty-five seconds), the bomb is cooled, opened, and the fused mass dropped into 25 c.c. water in a nickel beaker, the washings from the bomb added, and the liquid cautiously acidified with hydrochloric acid. After quick filtration through cotton-wool the liquid is boiled to get rid of chlorine, neutralised with ammonia, again acidified with hydrochloric acid, and the sulphate precipitated with barium chloride as usual. The results agree closely with those given by the Mahler bomb. When the amount of sulphur present is less than 0·01 per cent., Method 2 is more accurate.

(2) *Modified Lamp Method.*—A special form of lamp-chimney and lamp are required; the chimney is made from a Kjeldahl Jena-glass flask by softening the bottom in the flame and producing a re-entrant bulb by aspiration (see figure). The annular space round the bottom of this chimney holds 6 grms. of sodium peroxide and 0·5 grm. of anhydrous cobalt chloride, and this apparatus is connected with a Meyer absorption-tube, the corks being covered with tin-foil. Three or four bulbs are filled with water to which a little sodium peroxide has been added. The lamp consists of a very small platinum crucible closely packed with recently ignited asbestos, in which a small wick of asbestos is embedded. The wick passes through the central perforation of a Rose's crucible lid, and is supported by a small piece of pipe-clay tubing of such length that when the lamp is in position the top of the wick support is a little above the upper rim of the annular cavity of the chimney. Four to five grms. of the sample are weighed into the lamp, which is placed in position and lighted, the filter-pump being so operated as to draw a rapid current of air through the apparatus. When nearly all the petroleum has been burnt, the bottom of the lamp is heated by a small spirit-flame to drive off the remaining petroleum, the lamp being finally heated to low redness. After cooling, the chimney and liquid in the



bulbs, etc., are washed into a large beaker, the liquid acidified by hydrochloric acid, boiled to expel chlorine, and precipitated by barium chloride in the usual manner.

Method for Loosely-Combined Sulphur.—Some commercial samples of lamp oils contain sulphur in the form of unstable compounds, which may be estimated as follows: Finely-cut copper turnings are warmed with potassium cyanide solution (10 per cent.) till the metal is cleaned, when it is washed with air-free water, and finally with methyl alcohol, and the copper closely packed into Erlenmeyer flasks (100 c.c.) so as to fill them. Fifty c.c. of the petroleum are run into such a flask, which is closed with a cork carrying an air-condenser tube. The flask is heated for ten minutes on a hot-plate, the cork and tube removed, and the petroleum evaporated till only 10 c.c. remain. After cooling, 50 c.c. potassium cyanide solution are added, the liquid warmed in contact with all the turnings, which are stirred to facilitate the solution of the sulphide. The solution is poured through cotton-wool, the metal washed with water, and this transferred to the wool filter. From this solution the sulphur may be obtained by oxidation with bromine, and treatment with hydrochloric acid and barium chloride as usual.

When the density of the sample is known at the room-temperature, it is convenient to measure, instead of weigh, the amount required, the sulphur per cent. being found as follows when 3 c.c. are taken for analysis:

$$S = \frac{P \times 45{\cdot}76}{D \times 10};$$

where S = percentage of sulphur, P = weight of barium sulphate found, and D = density of the sample. A. R. T.

New Method for the Separation of Thorium. T. V. Smith and C. James. (*J. Amer. Chem. Soc.*, 1912, 34, 281-284.)—Sebacic acid in neutral solutions of thorium salts gives a voluminous granular and readily filtered precipitate, which, when dried and ignited, may be weighed as thorium dioxide. The reaction is quantitative, and shows good agreement with the results obtainable with oxalic acid. The precipitant is used in boiling solution saturated at that temperature. The mean of six determinations with sebacic acid showed an average weight of 0·2788 grm. of the dioxide in 50 c.c. of standard thorium nitrate solution as against 0·2786 grm. by the oxalic acid method. Solutions of cerium, praseodymium, lanthanum, neodymium, samarium, and yttrium, give no precipitate even on boiling; dysprosium, erbium, and thulium were not tested, as these elements rarely occur in ordinary thorium minerals. Test mixtures of rare earths were made up with varying quantities of thorium, the thorium in all cases being found with a very close approximation to accuracy. The separation is recommended for use on the large scale, as sebacic acid is readily prepared by heating castor oil soap with sodium hydroxide, when, owing to its slight solubility in cold water, it can be easily recovered. Other acids which give no precipitate with the rare earths, but precipitate thorium more or less quantitatively, were also investigated, but, owing to difficulties of filtration, or for other reasons, were not found satisfactory. Among them were phenoxyacetic, mucic, anisic, and aspartic acids. Pyrotartaric acid appears to precipitate thorium quantitatively in hot solutions, but is more expensive than sebacic acid. H. F. E. H.

Rapid and Exact Estimation of Tungsten in Ferrotungsten. R. Fieber. (*Chem. Zeit.*, 1912, **36**, 334.)—The material (0·5 grm.) is reduced to the finest possible state of division and oxidised by warming gently with 10 to 15 c.c. of bromine. Concentrated hydrochloric acid (30 c.c.) is next added, and, if anything remains undissolved, a further 5 to 10 c.c. of bromine. The excess of bromine is driven off by heating on the hot-plate, and then 1 to 2 c.c. of nitric acid and 2 or 3 drops of hydrofluoric acid are added. The object of the latter is to prevent the adherence of tungstic acid to the beaker during the subsequent evaporation. The contents of the beaker are next concentrated to very small bulk, the residue taken up with 40 c.c. of dilute (1 : 5) hydrochloric acid, the solution boiled, and the precipitate given some minutes to settle. The precipitate is filtered off on a double filter, washed alternately with hot water and dilute hydrochloric acid, moistened with a solution of ammonium nitrate, burnt, ignited, and weighed. The tungstic acid thus obtained is pure yellow in colour, and contains, as sole impurity, silica, which is removed by treatment with hydrofluoric and sulphuric acids. The whole series of operations may be performed in two to two and a half hours, and the results are said to be exact. G. C. J.

Analysis of Ferro-zircon. L. Weiss and W. Trautmann. (*Zeitsch. anal. Chem.*, 1912, **51**, 303-304.)—The method of separating zirconium oxide from iron oxide, alumina, and silica, described by Wunder and Jeannert (ANALYST, 1912, 36), is found to be quite untrustworthy. When zirconium oxide is fused with sodium carbonate and the melt extracted with water, the insoluble residue contains a considerable quantity of sodium zirconate which is readily dissolved by treatment with hydrochloric acid; the quantity of zirconium oxide thus passing into solution amounts to from 12 to 14 per cent. of the total quantity, and a further 10 per cent. is rendered soluble by a subsequent fusion. Zirconium oxide is still more readily attacked by sodium carbonate when iron oxide is present. Further, the separation of alumina and silica from zirconium oxide and iron oxide cannot be attained by fusing the mixture with sodium carbonate and extracting with water. Considerable quantities of alumina and silica remain insoluble. W. P. S.

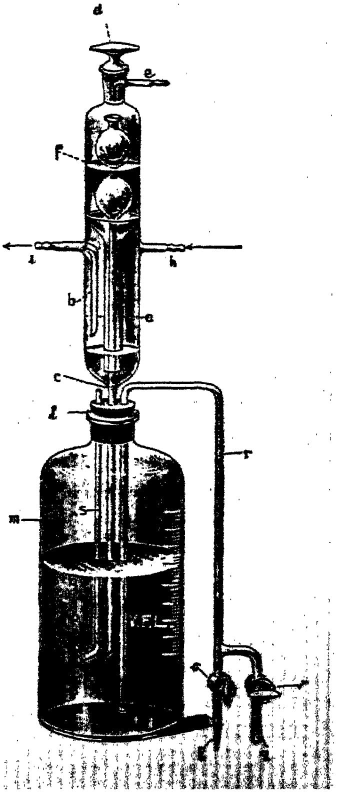
Modification of the Modified Winkler Method for the Determination of Sulphates in Water. H. W. Brubaker. (*J. Amer. Chem. Soc.*, 1912, **34**, 284-285.)—In the modified Winkler process the exact neutralisation of the hydrochloric acid with soda is tedious. The author changes the acidity to acetic acid by adding sodium acetate, and recommends the following procedure: 150 c.c. of the sample is measured into an Erlenmeyer flask, 10 drops of strong hydrochloric acid are added, and 0·1 to 0·2 grm. of barium chromate sprinkled in. The whole is brought to the boil, cooled at once, and then 5 grms. of sodium acetate are added. After filtration, 100 c.c. of the clear filtrate are transferred to a colorimeter cylinder, and made alkaline with sodium hydroxide. The standard for comparison should be made slightly stronger than this solution, and should be made up to 100 c.c. after making alkaline with soda. A blank determination, using distilled water, must be made to determine the correction to be allowed for the solubility of the barium chromate. Results by the gravimetric barium sulphate method, the author's method, and the modified Winkler method, showed an extreme variation of 1·5 parts per million when 100 parts of SO_4 per million were present. H. F. E. H.

APPARATUS, ETC.

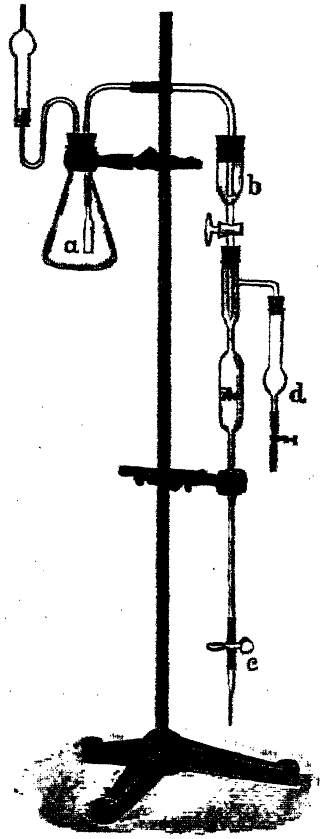
Modified Butyrometer Tube for the Estimation of Fat in Cheese. H. van Gulik. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 99-101.)—The tube described resembles in shape the ordinary form of tube, but is open at both ends, and the graduated portion is divided into forty divisions, which show percentages of fat directly when 3 grms. of cheese are used for the estimation; the ends of the tube are closed with rubber stoppers. For the estimation, 3 grms. of the finely-divided cheese are introduced into the tube, which has been previously one-half filled with sulphuric acid of sp. gr. 1·50. The tube and its contents are then heated in a water-bath at 70° C. until the cheese is dissolved, 1 c.c. of amyl alcohol is next added, and then sulphuric acid, so that the tube is filled up to the 35 mark. After the mixture has been submitted to centrifugal action for four minutes, the volume of the fat is read when the contents of the tube have been brought to a temperature of 65° C.

W. P. S.

Apparatus for Controlling the Evaporation or Distillation of Liquids, and for Cutting off the Supply of Gas to a Burner after any Desired Length of Time. E. Schirm. (*Zeitsch. anal. Chem.*, 1912, **51**, 301-302.)—The supply of gas to a burner below a distillation flask passes through the tubes *h* and *i*, and at the commencement of a distillation the stem *c* is passed through the cork of the flask so that the lower end of the stem is at any desired distance below the surface of the liquid. The cylindrical portion of the apparatus is filled with water up to the level *a*, and on applying suction to the tube *e* this water is drawn up to the level *f*; the tap *d* is then closed. When the distillation has proceeded so far that the level of the solution in the flask falls below the lower end of the stem *c*, air passes upwards into the cylindrical portion of the apparatus, and the level of the water falls, closing the end of the tube *b* and cutting off the supply of gas to the burner. If the apparatus be mounted as shown in the illustration, the supply of gas to a burner may be cut off by regulating the flow of water from the bottle *m* through the jet *t*; the tap *p* serves the purpose of



regulating the level of the water in the bottle. The time taken for the level of the water to sink from one division to another on the scale at the side of the bottle is determined, and the position of the end of the stem *c* may then be so adjusted that after a certain time the level of the water falls below it, allowing air to pass up the stem, and causing the gas-supply to be cut off as described above. W. P. S.



Apparatus for Measuring Liquids in an Atmosphere Free from Carbon Dioxide. T. Ekecrantz and H. Palme. (*Zeitsch. anal. Chem.*, 1912, 51, 292-294.)—The apparatus shown in the illustration is suitable for use in estimating the strength of calcium hydroxide or barium hydroxide solutions, or for measuring off solutions prepared with a volatile solvent. The solution is prepared in the Erlenmeyer flask, which is then attached to the rubber stopper, and a current of air free from carbon dioxide is drawn through the apparatus, the tube *d* being meanwhile closed and the clip *c* opened. The two drying-tubes are filled with soda-lime. The filter-tube *a* is now lowered into the solution contained in the flask, the clip *c* is closed, and suction is applied at *d* so that the solution is drawn over into the pipette. The first 50 c.c. collected in the pipette are run off, and a second quantity of 50 c.c. of the solution drawn over and used for the estimation. While the pipette is being emptied the tap below the portion *b* must be closed. W. P. S.

Use of Magnesia Rods instead of Platinum Wire in Analytical Work. E. Wedekind. (*Ber.*, 1912, 45, 382-384.)—For many purposes in the laboratory rods of magnesia composition may be used instead of platinum wire. These rods are not composed of pure magnesia, but of a more resistant composition, which is employed in the manufacture of supports for incandescent mantles. They are obtainable in lengths of 15 cm. and diameter of 1 mm.; after use the contaminated end of the rod may be broken off. The rods are useful for demonstration purposes, for flame tests, borax beads, manganese and chromium melts, and for driving off volatile matters from small quantities of substance. Spoon-shaped rods of larger diameter are also obtainable. J. F. B.

Constant-Temperature Heating Apparatus for Explosives and Experiments on the Decomposition of Nitrocelluloses. J. S. Brame. (*J. Soc. Chem. Ind.*, 1912, 31, 159.)—The vapour of a liquid of suitable boiling-point (toluene for 110° C.; toluene 3 volumes, xylene 1 volume, for 115° C.; amyl alcohol for 130° C.) is conducted from a copper boiler with safety tube through a copper jacket or heater, and thence through a condenser back to the boiler; it may be shut off from the heater, when it passes directly to the condenser through a ball-valve. The 2-grm. sample, dried at 40° C., is heated *in vacuo* in a 45 c.c. decomposition tube placed in the heater, which contains oil of high flash-point, and the water coming off in the first fifteen minutes is removed by a mercury pump, communication with which is then shut off, and the heating continued for six hours. The gases are then pumped off into a measuring burette. Experiments at 115° and 130° C. on insoluble, soluble, and highly soluble nitrocelluloses at progressive stages of stabilisation, gave results which showed small differences of stability more clearly than the parallel Will tests.

O. E. M.

Application of Ultrafiltration in Analytical Chemistry. R. Zsigmondy, E. Wilke-Dörfurt and A. von Galecki. (*Ber.*, 1912, **45**, 579-582.)—The use of collodion film filters, which has proved so valuable in colloid investigations, may with advantage be extended to the ordinary operations of gravimetric analysis. The perforated bottom of a porcelain funnel is covered with an ordinary, moist, ashless paper filter. The collodion film is placed on the top of this, and pressed down on the plate and slightly around the walls with the help of a suction-pump. By careful adjustment of the film at the corners an air-tight contact is assured. The precipitate is now poured on and filtered in the ordinary way, the filtration being assisted by powerful suction. The collodion film is prepared by pouring some dilute commercial collodion on a polished glass plate, slowly and carefully to avoid the formation of bubbles and to obtain an even layer. When the ether has evaporated, the film may be detached by steeping in water; the prepared films may be preserved for a long time in water. These filters, being extremely thin, free from ash, strong and smooth, fulfil a variety of requirements not satisfied by ordinary paper filters. After drying, the precipitate is easily detached and collected, or it may be incinerated with the film. The films give satisfactory results with the most difficult precipitates, such as colloidal gold, ferric hydroxide, stannic acid, etc., and are useful not only for all ordinary purposes, but also in connection with the Nernst microbalance.

J. F. B.

Comparative Examination of Engler's, Redwood's, and Saybolt's Viscosimeters. W. Meissner. (*Chem. Rev. Fett- u. Harz-Ind.*, 1912, **19**, 30-33, 44-49.)—The efflux period, t_r, measured by Redwood's viscosimeter, and t_s, by Saybolt's universal viscosimeter, may be reduced to Engler's degrees E, by means of the following formulæ:

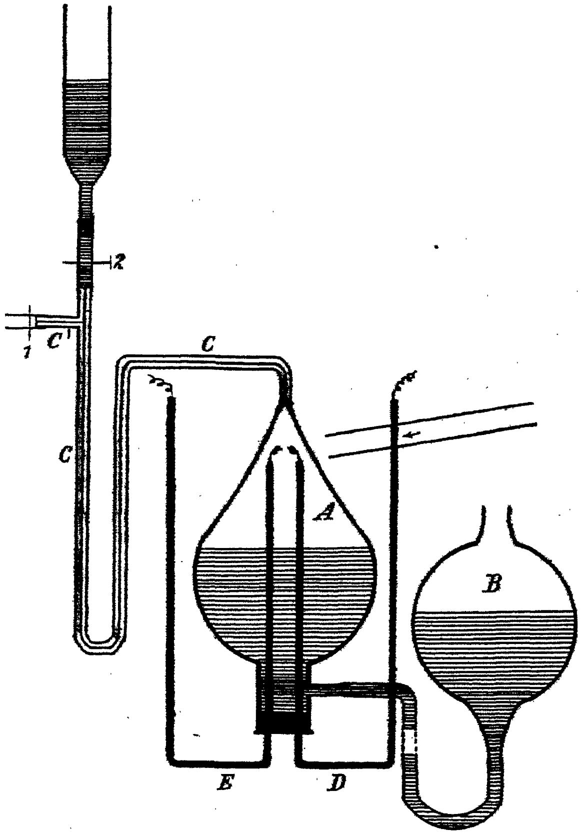
$$t_r = 192{\cdot}2\,k\,(1 + \sqrt{1 + \frac{0{\cdot}01624}{k_2}}$$

$$t_s = 228{\cdot}7\,k\,(1 + \sqrt{1 + \frac{0{\cdot}01309}{k}}.$$

$$k = 0{\cdot}08019\,E - 0{\cdot}07013\,{}^1/E.$$

The values thus calculated agreed within 4 per cent. of those observed with Redwood's apparatus, and within 2 per cent. in the case of Saybolt's apparatus. It is suggested that the results given by Redwood's viscosimeter might with advantage be divided by that given by rape oil, and the quotient regarded as the measure of the viscosity in an analogous fashion to the Engler degrees, for the most carefully purified rape oil must in course of time show alterations in its viscosity. The division of the efflux time by the water value will also increase the accuracy both of Redwood's and Saybolt's apparatus. C. A. M.

Apparatus for Rapid Removal of Nitrogen from Gas Mixtures by Sparking. F. Henrich and W. Eichhorn. (*Zeitsch. angew. Chem.*, 1912, 25, 468-470.)—The best method for the removal of nitrogen from gas mixtures is that of Travers, but, with the apparatus he described, the operation of sparking requires many hours even when quite small volumes of nitrogen have to be removed, and the operation has to be intermittent, as otherwise the glass apparatus is liable to crack in the neighbourhood of the electrodes on account of the high temperature. This latter trouble may be overcome in the apparatus now described by directing a current of air against the pear-shaped bulb in the neighbourhood of the electrodes. But the rapidity with which nitrogen may be removed with the apparatus now described depends more on the means provided for keeping the internal surface of the bulb moistened with caustic soda solution. The apparatus differs from a Hempel pipette only in the arrangement of the electrodes and in the T on the capillary. It is found advantageous to fuse the electrodes through the end of short pieces of special glass (3·5 mm. internal diameter) with a co-efficient of expansion closely approximating that of platinum, and to seal these tubes on to longer tubes of ordinary glass, which are bent in the manner shown,



and filled with mercury. The terminals are of platinum wire 0·35 mm. in diameter, folded on themselves three times as shown. When the apparatus is in continual use, they may be approximated or separated to get any desired length of spark by rotating the glass tubes in the rubber bung. A spark of 0·5 to 1 cm. is employed by the authors. The apparatus is filled with 5 per cent. caustic soda as usual, the clip 2 is closed and gas containing an excess of oxygen admitted at C^1 by opening the clip 1 after connecting to the supply of gas. The induction coil being set working, the clip 2 is opened for a second every few minutes to admit a little caustic soda solution, which spreads as a film over the inner surface of the bulb. For separating small quantities of the rare inert gases from large volumes of nitrogen, it is convenient to have a gas admission tube passing through the rubber bung at the base of the bulb and to admit a mixture of gas and oxygen from time to time, as the liquid in A approaches the level of the terminals. The apparatus will remove 50 c.c. of nitrogen in one hour, and with a more powerful induction coil the speed might be increased. G. C. J.

REVIEWS.

THE CHEMISTRY OF THE RUBBER INDUSTRY. By HAROLD E. POTTS, M.Sc. Pp. viii + 146. London: Constable and Co., Ltd. 1912. Price 5s. net.

Mr. Potts's volume forms one of a series of "Outlines of Industrial Chemistry," under the editorship of Guy D. Bengough, M.A., M.Sc., and its object, according to the author, is to "exhibit points of contact between chemistry and the industry." The analyst will naturally be mainly interested in the section dealing with analysis, regarding which Mr. Potts states that "the analytical processes of most importance have been critically described and explained." On the whole the author has very fairly accomplished his purpose, although here and there statements are made which may be fairly criticised. Thus, in dealing with the determination of moisture in raw rubber, it is stated that "drying in vacuum over sulphuric acid is accepted as the standard"; but the reviewer is unaware of any "standard" decision in this regard, and, as a matter of fact, the method occupies so much time that it is, as a rule, impracticable in technical work. In describing the estimation of nitrogen the author implies that the "usual" Kjeldahl process consists in the mercury-potassium-sulphide modification; most analysts would probably apply the term "usual" to the Kjeldahl-Gunning process, which, as a matter of fact, works very well on raw rubber. Mr. Potts rightly points out that the importance of a "direct" method of estimating rubber in the crude variety has been much exaggerated, but nevertheless devotes eight pages to its consideration. The recent work of Hinrichsen on the direct estimation of rubber in vulcanised goods by Hübener's method is scarcely in accord with the author's view that "it . . . appears to yield workable results"; but it is only fair to add that Mr. Potts clearly warns the analyst against "direct" methods.

generally. Broadly speaking, this little volume may be recommended to the analyst as affording an excellent bird's-eye view of the methods available for general rubber analysis as seen from a modern standpoint.

P. SCHIDROWITZ.

COCOA AND CHOCOLATE: THEIR CHEMISTRY AND MANUFACTURE. By R. WHYMPER. J. and A. Churchill. London, 1912. Pp. 315. Price 15s. net.

In this work the author's object has been "to provide a standard book of reference dealing with cacao from its growth till manufactured into cocoa and chocolate, and for the first time to trace the chemical composition of cacao from the fresh beans through their various stages of manufacture during fermentation, drying, and roasting." The volume is divided into three parts: (1) History, Botany, and Agriculture of Cacao; (2) Manufacture of Chocolate and Cocoa Powders; (3) Chemistry of Cacao. In the first chapter is gathered together a brief but very interesting historical account of this deservedly popular foodstuff, which began its Western life in the year 1528, when Cortes, returning from Mexico, brought it back to Europe. It was Linnæus, in 1720, who bestowed on it the dignified name of "Theobroma cacao," and the "Food of the Gods" has never gone back in public esteem; for while the consumption of coffee in the United Kingdom has remained stationary from 1899 to 1908, that of cocoa has increased in the same interval from 39,000,000 to 56,000,000 pounds. Not a few people may be surprised to learn that even cocoa, like alcohol, has not escaped scandal; for in 1624 a book was published in Vienna wherein it is stated that consumption of chocolate was largely responsible for many excesses, especially in the case of monks, for whom it was urged its use should be forbidden; and even as late as 1712 the *Spectator* wrote: "I shall also advise my fair readers to be in a particular manner careful how they meddle with romances, chocolate, novels, and the like inflamers, which I look upon as very dangerous to be made use of during this great carnival" (the month of May). Chapters II. to VII. are concerned with what may be called the natural history of cocoa and its preparation for the Western market, and this section contains numerous excellent photographs of picking and curing the beans. A chapter on the chemical composition of cacao beans brings the first section to a close. It is at this point that a protest appears necessary, since here for the first time, and again later, there are printed tables of analyses which look very well until they are compared with other tables by different investigators, each of whom works with his own methods and expresses his results in his own way, such as "starch," "extractives," "fibre or cellulose," etc. Unless some clue is forthcoming, which it seldom is, as to what each particular analyst chooses to label by these names, and, still more important, what his methods were, confusion is bound to result. The author appears to be conscious of this difficulty, for on p. 66 he has this optimistic but scarcely satisfying sentence: "Any variations which may be observed in the figures of analyses made by different individuals may be attributed to the varying quality of the cacaos examined, which, as has been previously pointed out, is largely dependent upon the conditions under which it is grown, and the processes to which the beans have been subjected." And yet eleven pages later (commenting on Table XI.) he says: "It is somewhat difficult to reconcile the results obtained by these two investigators, for the values obtained for albumin, starch, cellulose, and theobromine, are widely different."

Coming to the preparation of cocoa for the table, the author, it is seen, is amongst those who believe that "the nibs of cocoa beans alone should be used for cacao preparations, and that the inclusion of husk must be looked upon as adulteration." For the detection of added shell in cocoa powders, he would appear to attach the greatest importance to the pentosan determination, a complete investigation of which was communicated to the International Congress of Applied Chemistry by R. Adan, 1909 (ANALYST, 1911, **36**, 293).

The detection of "added shell" is of course one of the thorny questions of food analysis, the multiplicity of methods and continual suggestions for fresh ones alone being an indication that all is not quite satisfactory in this direction; and when, after enumerating methods by Filsinger, Weender, Tollens, König, Goske, Adan, and others, the author says that, "whatever the method used, the values obtained are a clear indication of the extent of adulteration of cacao preparations with husk," one can only feel admiration for his clear-sightedness. Concordant results can with difficulty be obtained for "cellulose" unless a more definite method for its estimation be employed than that described on p. 282, where boiling with "dilute mineral acid" and "warming with 1 per cent. soda" are recommended.

The U.S.A. official method for determining alkalinity of ash is described, "the value being expressed as the number of c.c. of $\frac{N}{10}$ sodium hydroxide to neutralise the ash obtained from 1 grm. of cocoa." This should, of course, read $\frac{N}{10}$ acid.

It is to be regretted that the author has not substituted for the tedious process of Dubois the useful polarimetric method of Lintner as modified by Ewers for the estimation of starch, or the space given to Dragendorf's obsolete method might thus advantageously have been used. Fuller details as to the analysis of milk chocolates would have been welcome, since the determination of milk solids and their proportions in chocolate is by no means an easy matter; while help might also have been afforded in dealing with some of the medicated chocolates and cocoas now so often met with.

In addition to the illustrations in the earlier part of the work already alluded to, numerous plates of plant and machinery are provided, and it is unfortunate that the single photomicrograph showing "pure cocoa" is so badly out of focus; in fact, all that can be made out are some large spiral vessels. The author states that "spiral bundles previously referred to as appearing in the shell are also to be found in the kernel," and that "pure cocoa will show isolated spirals," but must not contain "bundles of spirals typical of those appearing in the husk." No means, unless it is their "isolation," are suggested for their respective identification, and, in view of the very general practice of considering the presence of spiral vessels in cocoa as indicative of added shell, it would be interesting to learn the authority for the assertion that they really occur at all in the true kernel. Of course, the absence of these vessels does not in itself prove that no admixture of finely-ground husk has been made, since with modern refinements it is possible so to "fractionate" the husk by wind-sifting and otherwise, that the coarser elements are removed.

The print and general appearance of the volume are excellent; a good index and most useful bibliography of the literature add appreciably to its value; while practically every statement and table is provided with a footnote giving the publication from which it was derived. Recent works, such as Booth, Cribb, and Richards' long paper on chocolate (ANALYST, 1909, 34, 134) and the last addition of Allen, have been consulted, though some of the tables of analyses quoted have little more than an antiquarian interest, such, for example, being those from the Royal Society of Arts for 1874.

H. F. E. HULTON.

EIGHTH
International Congress of Applied Chemistry,
WASHINGTON AND NEW YORK,
September 4th to September 13th, 1912.

British Organising Committee.

Hon. President: THE RIGHT HON. SIR HENRY E. ROSCOE, F.R.S.

President: SIR WM. RAMSAY, K.C.B., F.R.S.

Chairman: DR. RUDOLPH MESSEL.

Hon. Secretary: CHARLES G. GRESSWELL,
Society of Chemical Industry,
9, Bridge Street,
Westminster, S.W.

Hon. Treasurer: DR. M. O. FORSTER, F.R.S.,
84, Cornwall Gardens,
South Kensington, S.W.

The Eighth International Congress of Applied Chemistry will be opened by the President of the United States at Washington, D.C., U.S.A., on Wednesday, September 4th, 1912. The other meetings will be held in New York from Friday, September 6th, to September 13th, 1912. There will be many entertainments during the week, and, afterwards, visits will be paid to factories and other places of interest throughout the United States and in parts of Canada.

As far as possible, all papers presented to the Congress will be printed and distributed before the opening session, and must reach Dr. Bernhard C. Hesse, Secretary, 25, Broad Street, New York City, not later than July 1st next. Rules may be obtained from the Hon. Secretary of the British Organising Committee.

A pamphlet (No. 3), containing general information, programme, details of excursions and visits to works, with forms of application for membership, may be obtained from the Hon. Secretary.

Persons contemplating membership in the Congress can obtain membership tickets from the Treasurer of the Congress, Wm. J. Matheson, 182, Front Street, New York City, by forwarding to him an application for membership and the membership fee, which is $5.00.

Membership tickets can also be obtained from the *Hon. Treasurer of the British Organising Committee*, who will accept £1 as the equivalent of $5.00.

JUNE, 1912. Vol. XXXVII., No. 435.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

The monthly meeting of the Society was held on Wednesday evening, May 1, in the Chemical Society's Rooms, Burlington House. The President, Mr. L. Archbutt, F.I.C., occupied the chair.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. H. T. Cranfield, E. G. Jones, M.Sc., F.I.C., and W. H. Roberts, M.Sc., F.I.C., were read for the second time; and certificates in favour of Messrs. Stanley Winter Collins, B.Sc. (Lond.), F.I.C., Assistant Lecturer in Chemistry, King's College, London; and Charles Bluthner Lessner, Analytical and Metallurgical Chemist, Carril, Spain, were read for the first time.

Messrs. R. F. Easton and L. Goodban, A.I.C., were elected members of the Society.

The following papers were read: "The Analysis of Lithopone," by W. L. Austin and Charles A. Keane, Ph.D., F.I.C.; "The Effect of Calcium on the Ammonium Molybdate Lead Assay," by C. O. Bannister and W. McNamara; "The Constituents of Oil of Savin," by J. Watson Agnew, F.I.C., and Robin B. Croad; and "The Detection of Heavy Petroleum in Paints and Vegetable Oils," by W. B. Pollard, B.A.

* * * * *

THE SEPARATION OF ARSENIC FROM ANTIMONY AND OTHER METALS, WITH SOME APPLICATIONS TO TOXICOLOGICAL WORK.*

By STANLEY W. COLLINS, B.Sc., F.I.C.

(*Read at the Meeting, April* 3, 1912.)

Friedheim and Michaelis (*Ber.*, 1895, **28**, 1414) have described a method for quantitatively separating arsenic from vanadium, molybdenum, and tungsten, by distillation with methyl alcohol in a current of hydrogen chloride. Under these conditions it is stated that arsenic trioxide forms a volatile methyl ester. In order to estimate the arsenic the distillate was treated with nitric acid and evaporated to dryness. The residue was dissolved in water, the solution made alkaline with ammonia, and the arsenic precipitated by magnesia mixture and weighed as magnesium pyroarsenate. In estimating arsenic pentoxide no reducing agent need be added, as it is reduced in presence of methyl alcohol and hydrogen chloride, with the formation of the volatile methyl arsenious ester.

---

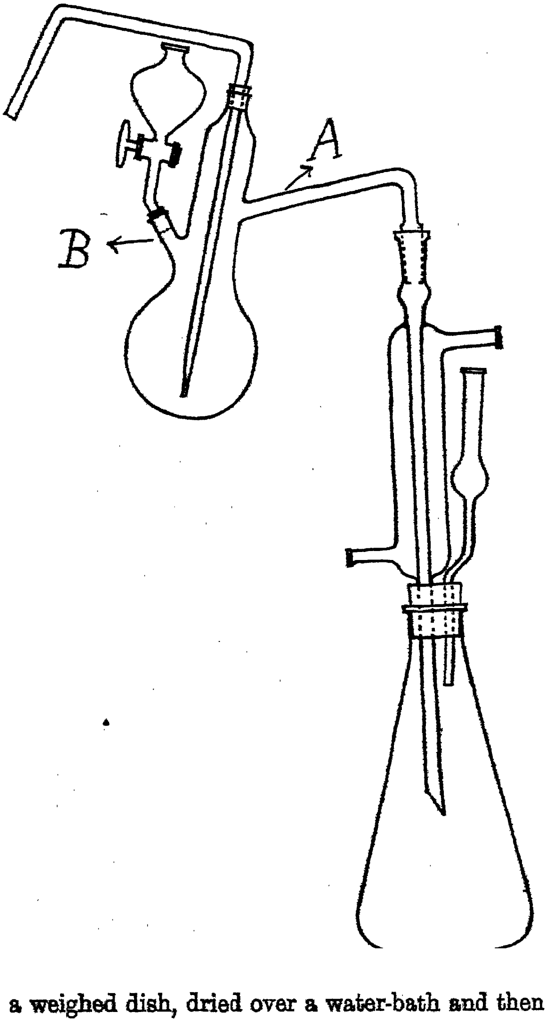
* This work was carried out under the provisions of the Analytical Investigation Scheme.

Cantoni and Chautems (*Annal. de Chim. anal.*, 1905, **10**, 213-214) proposed to separate arsenic from antimony by passing a current of dry air at the ordinary temperature through a solution of arsenic trioxide in hydrochloric acid to which methyl alcohol had been added. They state that under these conditions the arsenic can be completely distilled, leaving the antimony in the residue. It appeared desirable to determine the possible application of these methods to the separation of arsenic from antimony, particularly when these elements are present with organic matter.

The following form of apparatus (see illustration, p. 231) was devised and found to be satisfactory for the experiments involving distillations :

A pear-shaped distilling flask of about 300 c.c. capacity, with a wide neck about 4 cms. diameter and 8 cms. long, drawn down at the top for a small cork or ground joint through which passes the tube for delivery of hydrogen chloride. The flask is provided with a wide side-tube, *A*, about 1 cm. internal diameter, at about 4 cms. from the lower end of the neck. This tube is bent upwards at an angle of about 60 degrees with the neck, so that during distillation it is inclined upwards from the flask, which makes an angle of about 30 degrees with the vertical. This arrangement allows of rapid distillation, whilst it prevents the solution being carried over by spurting. The inlet tube *B*, of about 1 cm. diameter and 2 cms. length at the lower end of the neck, serves for the introduction of substances to be analysed, and into it, before the distillation is commenced, a tap-funnel is fitted by means of a cork or a ground joint, to allow of the addition of more methyl alcohol. In a later form of apparatus the inlet tube *B* was enlarged to about 1½ cms. diameter, thus making it more convenient for the introduction of substances to be analysed. The tap funnel was also ground in. The side-tube was ground into a Liebig's condenser, and bent so that, during an experiment, the condenser is in a position slightly sloping away from the distilling flask. The inside tube of the condenser is about 1 cm. in diameter and 40 cms. in length, passing through a cork into a 30-ounce conical flask. Through another hole in the cork a tube filled with glass beads is fitted. The jacket of the condenser is about 17 cms. long.

Several experiments were carried out on the lines proposed by Cantoni and Chautems (*loc. cit.*), but the method proved to be of no value ; for under the conditions described by these chemists only a small proportion of arsenic trioxide could be distilled, even when a current of dry air was passed for four hours. A more successful experiment was carried out by the method of Friedheim and Michaelis (*loc. cit.*). 0·2 grm. of arsenic trioxide was washed into the distillation flask with 50 c.c. of methyl alcohol, which was then saturated with dry hydrogen chloride. The flask was then heated on a water-bath ; the distillation was repeated twice with 50 c.c. of methyl alcohol, a slow stream of hydrogen chloride being passed during the distillation. On diluting the residue in the flask and passing in sulphuretted hydrogen, no arsenious sulphide was precipitated. The method used in this and many subsequent experiments for the estimation of arsenic in the distillate, consisted of saturating with sulphuretted hydrogen, after diluting with an equal volume of water, washing the precipitated arsenious sulphide with hot water, alcohol, a mixture of carbon disulphide and alcohol, alcohol, and then hot water. The precipitate was then washed from the filter-paper into a weighed dish, dried over a water-bath and then at 105° to 110° C., and weighed.



The precipitate was tested for antimony by digesting with strong hydrochloric acid, filtering, diluting and saturating with sulphuretted hydrogen. The antimony sulphide was dissolved in hydrochloric acid with a little potassium chlorate, and antimony obtained from the solution by means of pure iron wire.

Arsenic in the distillate was also estimated satisfactorily by titration with standard iodine solution. An experiment was made on 0·2 grm. of arsenic trioxide, with 0·2 grm. of antimony trioxide, with the result that about 0·02 grm. of antimony trioxide was found with the distilled arsenious oxide. It will thus be seen that the formation of antimony chloride and its subsequent volatility render the method inapplicable to the quantitative separation of arsenic from antimony. Many experiments were made in order to overcome this difficulty, in the course of which it was found that the volatility of arsenic trioxide in the vapour of methyl alcohol was considerably increased by the addition of strong sulphuric acid or phosphorus pentoxide to the arsenic trioxide and methyl alcohol before distillation; neither arsenic pentoxide nor antimony trioxide could be distilled under these conditions. Attempts were made to devise a method based on these facts for the quantitative separation of arsenic from antimony, but it was found that the removal of the last traces of arsenic was a tedious process, in which it was necessary to use a comparatively large volume of methyl alcohol. A complete separation was, however, effected by taking a mixture of methyl alcohol and the oxides and a sufficient quantity of sulphuric acid, and passing a stream of hydrogen chloride through for some time before commencing the heating. The passage of the gas was continued throughout the distillation. Under these conditions it was found that the arsenic was completely distilled, whilst the more basic antimony was retained by the sulphuric acid. When phosphorus pentoxide was substituted for sulphuric acid in these experiments, small quantities of antimony were carried over with the arsenic.

The following account of typical experiments illustrates the application of this method:

0·08 grm. of arsenic trioxide and 0·08 grm. of antimony trioxide were washed into the distilling flask with 30 c.c. of methyl alcohol and a mixture of 6 c.c. of sulphuric acid (sp. gr. 1·84) with 20 c.c. of methyl alcohol. Hydrogen chloride was passed in for ten minutes and the flask heated on a water-bath, the distillate being collected in a 30-ounce conical flask into which a small quantity of water was occasionally poured over the glass beads. The distillation was repeated twice with 50 c.c. of methyl alcohol. The arsenic in the distillate was precipitated by sulphuretted hydrogen, washed, and weighed; 0·0796 grm. was found. No antimony sulphide could be detected in the precipitate. This analysis was repeated, using 0·2 grm. of arsenious oxide and 0·2 grm. of antimony oxide with 8 c.c. of sulphuric acid (sp. gr. 1·84). 0·200 grm. of arsenic trioxide was found. In the next experiment the conditions were the same, with the exception that the arsenic in the distillate was titrated with iodine, after adding an excess of sodium bicarbonate. 0·200 grm. of arsenic trioxide was found.

2·0 grms. of antimony oxide with 0·1 grm. of arsenic trioxide were mixed with 15 c.c. of sulphuric acid (sp. gr. 1·84) and 50 c.c. of methyl alcohol. The distillation was repeated with the following volumes of methyl alcohol, 50 c.c., 50 c.c., 20 c.c., 20 c.c., when, on testing the distillate with sulphuretted hydrogen, no precipitate was obtained. 0·1002 grm. of arsenic trioxide was found. The precipitate was free from antimony.

3·0 grms. of antimony oxide with 0·1 grm. of arsenic trioxide were mixed with 15 c.c. of sulphuric acid (sp. gr. 1·84) and 50 c.c. methyl alcohol. Distillation was repeated as in the last experiment. 0·101 grm. of arsenic trioxide was found. In this case the precipitate contained antimony. The experiment was repeated, using 3·0 grms. of antimony oxide with 0·06 grm. of arsenic trioxide and a smaller quantity of sulphuric acid—*i.e.*, 10 c.c. A precipitate equivalent to 0·064 grm. of arsenic trioxide was found. Antimony was present in the precipitate.

The application of this method to the separation of arsenic pentoxide from antimony was next investigated. It was found that the arsenic from arsenic pentoxide could be distilled completely only in the presence of a reducing agent such as ferrous chloride. The following experiments show the results obtained for the estimation of arsenic pentoxide; the first one gave a satisfactory result for the separation of arsenic from other metals of the sulphuretted hydrogen group as well as from antimony:

0·06 grm. of arsenic pentoxide with 0·05 grm. of antimony oxide, 0·04 grm. of bismuth oxide, 0·03 grm. of mercurous chloride, 0·03 grm. of mercuric chloride, and 5 grms. of ferrous chloride, were introduced into the distilling flask with 50 c.c. of methyl alcohol. To these were added 10 c.c. of sulphuric acid (sp. gr. 1·84); hydrogen chloride was passed through the contents of the flask before and during the distillation, which was repeated twice with 50 c.c. and twice with 20 c.c. of methyl alcohol. The distillate was saturated with sulphuretted hydrogen and the precipitated arsenious sulphide, washed, dried, and weighed, as before. The weight of arsenic pentoxide found was 0·0596 grm. The precipitated arsenious sulphide was found to be free from antimony, bismuth, and mercury.

0·1 grm. of arsenic pentoxide with 2 grms. of antimony oxide was mixed in the distillation flask with 15 c.c. of sulphuric acid (sp. gr. 1·84), 50 c.c. of methyl alcohol, and 5 grms. of ferrous chloride. Hydrogen chloride was passed before and during distillation, which was repeated twice with 50 c.c. and twice with 20 c.c. of methyl alcohol. The weight of arsenic pentoxide found was 0·0998 grm., and there was no antimony in the precipitate.

These results indicate that this method is applicable, under suitable conditions, to the quantitative separation of arsenic from antimony and from other metals. Before pointing out the conditions necessary for this method, it is essential to give an account of an experiment which shows the influence of water on the volatilisation of antimony trichloride: 1 grm. of antimony oxide was mixed with 10 c.c. of sulphuric acid (sp. gr. 1·84) and 50 c.c. of water. Hydrogen chloride was passed in for about fifteen minutes as well as during the distillation. Sulphuretted hydrogen was passed into the distillate, which yielded an appreciable precipitate of antimony sulphide. To about 20 c.c. of the residual solution an equal volume of methyl alcohol was added, and hydrogen chloride passed through as before. Separate small volumes of the distillate were collected and saturated with sulphuretted hydrogen. A barely perceptible coloration was obtained in the first portions, but, as the alcohol was distilled off, the quantity of antimony sulphide precipitated became appreciable. It is evident, therefore, that the material used in this method should be sufficiently free from water, since, in presence of water, sulphuric acid fails to retain the antimony completely. With regard to the amount of sulphuric acid necessary to retain the antimony, 10 c.c. of acid (sp. gr. 1·84) is a convenient quantity for not more than 1 grm. of antimony oxide; whilst 15 c.c. of acid will retain up to 2 grms. of antimony oxide, and is the maximum quantity convenient to use with 50 c.c. of methyl alcohol, since with more than this amount the distillation becomes too slow. An experiment was next made in order to gain some idea of the maximum amount of arsenic trioxide which could be volatilised, using 50 c.c. of methyl alcohol. Arsenic trioxide 5 grms., with 10 c.c. of sulphuric acid, and 50 c.c. of methyl alcohol, were distilled in a stream of hydrogen chloride in the usual manner, and 0·96 grm. of arsenic trioxide was found to have been volatilised, an amount largely in excess of that used in any estimation. In the quantitative separation of arsenic from antimony, when not more than 0·2 grm. of arsenic trioxide was used, about 60 per cent. of the arsenic was volatilised in the first 50 c.c. of alcohol; a further 50 c.c. generally carried over all but a small amount, which was volatilised in the last 50 c.c. In presence of a large excess of antimony, it is advisable to add a further 10 c.c. of methyl alcohol and to test the distillate with sulphuretted hydrogen, as an additional 10 or 20 c.c. of methyl alcohol may be necessary to remove the last traces of arsenic.

Pure methyl alcohol, not specially dehydrated, was used in all these experiments. Commercial methyl alcohol is unsatisfactory, as the acids employed induce the formation of compounds of high boiling-point which retard the volatilisation of the arsenic. In an experiment in which ethyl alcohol was used, instead of methyl alcohol, the quantity of arsenic carried over was about half as great as would have been volatilised by the same volume of methyl alcohol.

It has been stated in this paper that the quantity of arsenic trioxide which could be distilled over was increased by mixing sulphuric acid with the alcohol and the oxide in the distillation flask, and that neither arsenic pentoxide nor antimony trioxide could be distilled in this manner. This suggests an easy test for arsenic trioxide in the presence of antimony as well as other metals. This method could only be applied as a test for arsenic trioxide in the presence of arsenic pentoxide when certain organic and other reducing agents were excluded.

The following experiments were made to test this method. Equal weights of the following substances were mixed—mercurous chloride, mercuric oxide, stannous chloride, cadmium oxide, antimony oxide. About 1 grm. of this mixture was placed in a small distilling flask, and 20 c.c. of methyl alcohol and 3 c.c. of sulphuric acid were added. The flask was attached to a condenser and heated by a flame, the distillate being collected in a small flask containing about 5 c.c. of water. On passing sulphuretted hydrogen through the distillate no precipitate was obtained. This experiment was repeated, using 1 grm. of the mixed substances with 0·3 grm. of arsenic pentoxide. No precipitate was obtained on passing sulphuretted hydrogen through the distillate. The experiment was again repeated, using 1 grm. of the mixed substances with 2 mgrms. of arsenic trioxide. A precipitate of arsenious sulphide was obtained on passing sulphuretted hydrogen through the distillate.

Application of this Method to the Separation of Arsenic from Antimony and Other Metals in the Presence of Organic Matter.

The character of the material for analysis will determine the mode of application. The separation can be effected without previous destruction of the organic matter if the arsenic be not intimately combined with the organic matter. The material should also be fairly dry.

The following experiment is an example of these conditions: 20 grms. of powdered biscuit material were placed in the distillation flask; 0·1 grm. of arsenic trioxide and 0·1 grm. of antimony oxide were washed into the flask with a mixture of 50 c.c. of methyl alcohol and 8 c.c. of sulphuric acid. Hydrogen chloride was then passed through the contents of the flask for about ten minutes. The flask was heated on the water-bath, a stream of hydrogen chloride being continued during the distillation, which was repeated twice with 50 c.c. and twice with 20 c.c. of methyl alcohol. The arsenic was precipitated from the distillate by means of sulphuretted hydrogen, washed, dried, and weighed, and an amount equivalent to 0·0986 grm. of arsenic trioxide was found.

For the next experiments I obtained specimens of viscera from a case which had been treated with salvarsan. In the first test 50 grms. of the kidney were heated in a Jena distillation flask with sulphuric acid, and the water distilled off as completely as possible. Then methyl alcohol was added and hydrogen chloride passed through the viscid contents of the flask, and the distillation effected as before. This method was not satisfactory. Ninety-eight grms. of the liver were treated with 10 c.c. of nitric acid (sp. gr. 1·4), and charred in the usual manner with sulphuric acid. The charred mass was washed into the distilling flask with 50 c.c. of methyl alcohol, and about 5 grms. of ferrous chloride were added. Hydrogen chloride was then passed in as usual, and the flask heated on the water-bath. The distillation was repeated twice with 50 c.c. and twice with 20 c.c. of methyl alcohol. The distillate was saturated with sulphuretted hydrogen, and the precipitated arsenious sulphide was purified by dissolving in ammonia and reprecipitating. The arsenious sulphide was then dissolved in nitric acid, the solution made alkaline with ammonia, and the arsenic precipitated as magnesium ammonium arsenate, and finally weighed as the pyroarsenate. Weight of arsenic trioxide per 100 grms. of the liver: From the sulphide, 3·6 mgrms.; from the pyroarsenate, 3·1 mgrms. The residue was found to be free from arsenic.

I am indebted to Mr. John Webster for the result of an estimation of arsenic in another portion of this liver. This estimation was carried out, in Dr. Willcox's laboratory, by the usual extraction method, the arsenic being finally weighed as magnesium pyroarsenate. Weight of arsenic trioxide found per 100 grms. of viscera was 3·3 mgrms. This result was confirmed by an estimation made by the Marsh-Berzelius method.

Attempts to confirm the statement of Friedheim and Michaelis (*loc. cit.*), that the volatility of arsenic trioxide in methyl alcohol and hydrogen chloride is due to the formation of a methyl arsenious ester, were unsuccessful. An excess of arsenic trioxide was heated with dehydrated methyl alcohol and sulphuric acid for some hours, also methyl alcohol with arsenic trioxide was treated with hydrogen chloride, and also with hydrogen chloride and sulphuric acid. In each experiment the distillate was fractionally redistilled, with the result that the boiling-point did not rise appreciably above that of methyl alcohol. The compounds of arsenic with alcohol radicles have been investigated by the following: J. M. Crafts (*Bull. Soc. Chim.*, 1870, **14**, 99) obtained arsenates and arsenites of the alkyl radicles of the general formulæ R_3AsO_4 and R_3AsO_3. For the arsenites he used three methods involving the interaction in a sealed tube of (1) ethyl iodide and silver arsenite at 150° C.; (2) arsenic bromide and sodium ethoxide; (3) arsenic trioxide and ethyl silicate at 200° C. The boiling-point of methyl arsenite is 128° C. Auger (*Compt. rend.*, 1902, **134**, 238, and 1906, **143**, 907) states that he obtained small yields of esters by heating arsenic trioxide and alcohol together in a sealed tube for some hours, although he did not succeed in isolating the esters. The maximum amount of esterification in the case of methyl alcohol is given as 6·5 per cent. The method of estimation of the amount of esterification appears not to be very satisfactory (*cf. J. Chem. Soc.*, 1908, **93**, 1367). In experimenting with propyl, normal butyl, and isobutyl alcohol with arsenic trioxide, he states that good results were obtained by removing the water formed either by fractional distillation or by passing the alcohol and water vapour over calcium carbide in an adapter, when the water is removed and the alcohol returns to the flask in which the reaction is taking place.

W. R. Lang, J. T. Mackey, and R. A. Gortner (*J. Chem. Soc.*, 1908, **93**, 1364) obtained a yield of 33·8 per cent. of methyl arsenite by heating methyl alcohol and arsenic trioxide together in the presence of anhydrous copper sulphate under a reflex condenser, and fractionating the resulting liquid under diminished pressure. They state that they have prepared methyl arsenite by a similar method without the anhydrous copper sulphate. No statement is made as to yield obtained.

J. T. Mackey (*J. Chem. Soc.*, 1909, **95**, 605) prepared esters of the aliphatic alcohols with antimony trioxide, using anhydrous copper sulphate as a dehydrating agent. The boiling-point of methyl antimonite is given as 65° C.

Some esterification appears therefore to take place when arsenic trioxide and methyl alcohol are heated together, the amount of ester formed being increased in the presence of a desiccating substance such as anhydrous copper sulphate. However, under the conditions which prevailed during these estimations no evidence has been obtained for the formation of an arsenious ester. I propose to further examine the possibility of ester formation involved in the separation described in this communication.

In conclusion, I desire to express my thanks to Dr. W. H. Willcox and Mr. John Webster for their practical interest and help, and to Mr. A. Chaston Chapman for the help he has afforded me throughout the course of this work.

CHEMICAL DEPARTMENT, KING'S COLLEGE, LONDON.

DISCUSSION.

The PRESIDENT, having invited discussion,

Mr. CHASTON CHAPMAN suggested that the function of the sulphuric acid might be not only to retain the more basic antimony, but also to assist esterification. He did not quite know upon what evidence Mr. Collins based his opinion that no formation of ester occurred, and he (Mr. Chapman) could not help feeling that the separation was in reality dependent on the formation of a methyl arsenious ester. With the comparatively small quantities of arsenic used in Mr. Collins' experiments, the detection in the distillate of such an ester would not be easy; but it was quite clear that its formation would be favourably influenced by the presence of the sulphuric acid.

Mr. C. REVIS said that this process seemed to be a great advance on that of Clark. He had had occasion to use Clark's process a good deal some years ago, but had not been able to obtain very satisfactory results with it, finding that antimony was carried over during the distillation, especially when the antimony was large in quantity as compared with the arsenic. When, however, no other metal but arsenic was present, the results were fairly good.

Dr. WILLCOX said the process was itself an old one, and he (Dr. Willcox) believed that Taylor had claimed to be the originator of a modification of it for toxicological purposes. The process in that form, however, involved considerable risk of explosion, and it was not reliable for the separation of arsenic from small quantities of antimony and tin. Mr. Collins had tested his form of the process very thoroughly, and he (Dr. Willcox) believed that, if carried out under the conditions which Mr. Collins laid down, it would be found to be reliable for the separation of arsenic from antimony, mercury, bismuth, etc. It would be very useful for toxicological work, especially in criminal cases of arsenical poisoning, because in such cases doses of bismuth were frequently given, and there was considerable difficulty in the analysis of viscera containing arsenic accompanied by large quantities of bismuth when the usual method of precipitation as sulphides was employed. Apart from the question of the separation of arsenic from antimony, etc., this process would be valuable in dealing with arsenic alone, as was shown by the results that had been obtained in the case of salvarsan-poisoning referred to.

Mr. T. MACARA said that the process devised by the late Dr. Clark was intended for use in connection with white metals, bronzes, and similar materials, and for such purposes it gave very good results when properly applied. It was essential to use strong hydrochloric acid, and not to concentrate the solution too much and so unduly raise its boiling-point. The one fault of the process was that it necessitated two or three distillations, but that difficulty might be overcome by passing hydrochloric acid gas into the distilling flask, as suggested by Mr. Collins, which would enable good results to be obtained at a comparatively low temperature.

The PRESIDENT said that it seemed to him that Mr. Collins' process was essentially different from that of Dr. Clark. Of course, in a toxicological investigation it would not be proper to assume that a volatile product was arsenic without weighing it as a definite arsenical compound; but for many purposes it would probably be sufficient to boil the sulphide of arsenic with water, and titrate the arsenious oxide with iodine.

Mr. COLLINS, in reply, said that the statement of Frankheim and Michaelis was that the method depended on the formation of a methyl arsenious ester, but so far as his own work had gone he had not been able to obtain any evidence of the formation of such an ester. He had, however, only as yet been able to make one experiment as to this, which showed that the boiling-point of the distillate was not higher than that of methyl alcohol, whereas the boiling-point of pure methyl arsenite was 128° C. In this experiment dehydrated methyl alcohol and sulphuric acid were heated with arsenic trioxide, and hydrochloric acid gas was passed through; on fractional distillation it was found that the boiling-point did not rise appreciably above that of methyl alcohol. He hoped later on to make further experiments by carrying out the fractional distillation under reduced pressure, under which conditions some esterification might possibly take place.

THE ANALYSIS OF LITHOPONE.*

BY W. L. AUSTIN AND CHARLES A. KEANE, D.Sc., PH.D., F.I.C.

(*Read at the Meeting, May* 1, 1912.)

THE chief estimations required for the technical valuation of lithopone comprise the determination of the zinc sulphide, zinc oxide, and barium sulphate. Several other zinc compounds have been shown to be present, in varying amounts, in the mixture, such as the carbonate, normal sulphate, and basic sulphate. Coffignier (*Bull. Soc. Chim.*, 1902, **27**, 829, 943) has also drawn attention to the occurrence of soluble salts of zinc and of the hydroxy-sulphide $Zn\langle\begin{smallmatrix}OH\\SH\end{smallmatrix}$ in cases where the product has been imperfectly calcined; but such constituents are to be regarded as abnormal, and should not be present in lithopones that have been properly prepared and washed. In addition, lithopone sometimes contains a small proportion of barium carbonate, and traces of impurities, including ferric oxide, alumina, lime, and magnesia. Whilst the determination of these secondary products is seldom required, their presence is of importance in selecting a method of analysis. This is especially the case in regard to the influence of the iron and calcium on the estimation of the zinc, and also in regard to the possible presence of zinc compounds, other than the sulphide and oxide, as any soluble salts of zinc are, of course, of no value as a pigment. The presence of barium carbonate can be readily determined by a separate estimation if required.

The numerous methods that have been proposed for the analysis of lithopone consist in the determination of the total zinc, the total sulphide, and the barium sulphate. By calculating the total sulphide to zinc sulphide, and subtracting its equivalent in zinc from the total zinc found, the proportion of zinc other than sulphide is calculated and generally expressed as oxide. As a check on this last factor, the zinc oxide and carbonate can be extracted either with dilute acetic acid or with a mixture of sodium acetate and acetic acid, and estimated separately.

---

* This work was carried out under the provisions of the Analytical Investigation Scheme.

These determinations have involved simply a combination of ordinary methods of analysis, of which the following may serve as examples:

P. Drawe (*Zeitsch. angew. Chem.*, 1902, **15**, 174, 229, 297) estimates the total zinc by precipitation as carbonate and the zinc present as sulphide by treating the sample with 1 per cent. acetic acid, to remove the oxide and carbonate, and precipitating the remaining zinc again as carbonate. Kochs and Seyfert (*Zeitsch. angew. Chem.*, 1902, **15**, 802) precipitate the total zinc as sulphide, and estimate the oxide and carbonate by solution in 5 per cent. acetic acid and precipitation as sulphide. Amsel (*Zeitsch. angew. Chem.*, 1902, **15**, 174) also extracts the oxide with 5 per cent. acetic acid, and estimates both it and the total zinc volumetrically by titration with calcium ferrocyanide. For the estimation of the sulphide-sulphur as an indirect means of determining the content of zinc sulphide, J. F. Sacher (*Farbenzeitung*, 1910, **15**, 1810) recommends treatment with metallic tin and hydrochloric acid, passing the evolved sulphuretted hydrogen into an ammoniacal solution of hydrogen peroxide, and precipitating the ammonium sulphate formed with barium chloride, whilst H. Wolff (*Farbenzeitung*, 1910, **15**, 1859) estimates the sulphuretted hydrogen volumetrically by absorbing it in iodine solution, and titrating back the excess of the latter with thiosulphate. J. S. Remington and C. Smith (*Caoutchouc and Gutta-Percha*, 1909, **6**, 3259) estimate the sulphide-sulphur by oxidation with bromine and precipitation as sulphate, and the total zinc as carbonate, or, if salts of iron, calcium, or barium (soluble in hydrochloric acid) are present, as sulphide.

The alternative to these many proposals that we recommend is to estimate the total zinc volumetrically and the zinc sulphide indirectly by oxidising the sulphide-sulphur to sulphate. The gravimetric estimation of the zinc as carbonate is inaccurate in presence of calcium and iron, both of which are usually present, and precipitation as sulphide is a tedious determination. A direct estimation of the sulphide-sulphur is especially desirable, as the value of the pigment is chiefly dependent on the proportion of zinc sulphide present, and of the various methods available oxidation followed by precipitation is simpler and easier to carry out than the determination of the sulphuretted hydrogen evolved on decomposition.

For the volumetric estimation of the zinc we have employed a method devised by A. Voigt (*Zeitsch. angew. Chem.*, 1889, **2**, 307) for the analysis of zinc ores and products which is sufficiently accurate for the estimation, and which has the advantage that the results are not affected by the presence of iron or calcium. For the oxidation of the sulphide-sulphur either bromine or nitric acid may be used; we have found the former preferable, and carry out the estimation on the same lines as proposed by Remington and Smith (*loc. cit.*). Whilst, therefore, there is no claim to originality in the methods employed, we have found the combination adopted more rapid and adaptable than previous proposals, and sufficiently accurate for technical purposes.

The method of analysis is as follows: 5 grms. of the finely-ground sample are treated with concentrated hydrochloric acid and a little potassium chlorate, the whole evaporated to a small bulk on the water-bath, taken up with boiling water, and the residual barium sulphate filtered off and thoroughly washed. The filtrate is collected in a 250 c.c. graduated flask, made up to the mark, and aliquot portions taken for the estimation of the total zinc by Voigt's method. The potassium ferrocyanide solution is made up by dissolving 46 grms. of the crystallised salt in a litre of water, and is standardised by a solution of zinc chloride containing 12·4476 grms. of pure zinc oxide per litre; 1 c.c. of this solution is equivalent to 0·01 grm. of zinc. For the estimation, 50 c.c. of the above filtrate are taken, 10 c.c. of a solution of tartaric acid (200 grms. per litre) and 10 c.c. of a solution of ferric chloride (60 grms. per litre) added, the whole diluted to about 200 c.c., made just alkaline with ammonia, and titrated; the completion of the reaction is determined by adding a drop of the solution to dilute acetic acid (1:3) on a pitted porcelain plate until a permanent blue colour is produced. After a preliminary estimation a sharp end-reaction is easily secured, and it is not affected by the presence of an excess of ammonia. In a series of tests made, in which the quantity of ammonia added was increased up to twice the amount necessary for neutralisation, the maximum difference in the titrations did not exceed 0·15 c.c.

For the estimation of the sulphide-sulphur, 0·5 grm. of the sample is oxidised with bromine, after the addition of water, hydrochloric acid added, the residual barium sulphate filtered off, and the sulphuric acid in the filtrate precipitated by barium chloride. By calculating the sulphur thus found to zinc sulphide, and subtracting its equivalent of zinc from the total zinc estimated volumetrically, the content of zinc, other than sulphide, is obtained by difference, as stated above.

The following results were obtained by this method with three different samples of lithopone; the zinc, other than that present as sulphide, is calculated as oxide:

	I.	II.	III.
$BaSO_4$	64·36	67·59	72·80
ZnS	30·98	27·82	24·14
ZnO	0·55	1·82	0·88
CaO, Fe_2O_3, $BaCO_3$, Moisture, etc.	4·11	2·77	2·18
	100·00	100·00	100·00

As a check upon the volumetric estimation of the zinc, that in Sample No. 1 was also estimated by precipitation as sulphide, the result obtained being 21·44 per cent. zinc as against 21·20 per cent. by titration. The indirect determination of the zinc oxide was also checked by treating 2 grms. of each sample with 5 per cent. acetic acid at the ordinary temperature for one hour, with occasional agitation, the dissolved zinc filtered off, precipitated as sulphide, and finally estimated as oxide in the usual manner. The results obtained were as follows:

	I.	II.	III.
ZnO (calculated)	0·55	1·82	0·88
ZnO (estimated by precipitation) ...	0·75	1·70	0·90

These data confirm the reliability of the indirect method of estimation, and also show that the zinc, other than sulphide, in the samples analysed is practically all present as oxide.

CHEMISTRY DEPARTMENT,
THE SIR JOHN CASS TECHNICAL INSTITUTE, ALDGATE.

Discussion.

The President said that the specimens of lithopone that passed through his hands were usually ground in oil. Those who were experienced in work of this kind would know that it was never possible to extract the oil completely; some oxidised oil always remained unextracted, and this caused difficulty in the estimation of the sulphide sulphur by oxidation with bromine in an acid solution. His practice was first of all to add some caustic soda to the extracted lithopone, and then pour in the liquid bromine and acidify. Under those conditions no globules of sulphur or sulphur bromide escaped oxidation. With regard to the estimation of the zinc, he could understand that, in laboratories where such estimations were made very frequently, it would be worth while to use a volumetric process; but, when it was only necessary to make such estimations occasionally, a gravimetric process was, perhaps, equally expeditious. He should like to ask whether the authors had tried precipitating the zinc in a solution containing a minute trace of free mineral acid. Under those conditions the zinc was completely precipitated, and in a granular form. Of course, during the precipitation more acid was set free, and one must be careful to neutralise all but the very faintest trace. In the analyses given by the authors the proportions of what might be called impurities were larger than he had been accustomed to find.

Mr. T. Macara asked whether the authors had tried the phosphate method of estimating zinc in the case of such a compound as lithopone. He thought that this method, which was proposed by the late Dr. Clark for the estimation of zinc in alloys, etc., would probably work well in such a case as this.

Dr. H. P. Stevens asked whether the lime shown as CaO in the authors' analyses referred to caustic lime. Lithopone was used in rubber mixings, in which the presence of caustic lime was very undesirable.

The President added that a certain amount of soluble SO_3 was always present, and it was his practice to determine this, calculating it as calcium sulphate; and perhaps if that were done in these cases, some, at any rate, of the lime would appear as calcium sulphate. In many cases the quantities of CaO and of soluble SO_3 found were just equivalent to one another, showing that all the lime was present as calcium sulphate.

Mr. J. H. B. Jenkins asked whether the oxide of iron referred to in the analyses amounted to anything appreciable. One of the advantages of lithopone paint was its dead whiteness, and one would not expect this if any sensible quantity of iron were present. The majority of the samples of lithopone that he had examined contained more barium sulphate relatively to the sulphide of zinc than was shown in the authors' analyses. He believed that in the trade the proportions were supposed to be about 3 parts of barium sulphate to 1 part of zinc sulphide.

Dr. Dyer incidentally observed—although, of course, the remark did not apply to genuine "lithopone"—that mixed pigments containing barium sulphate in the form of barytes sometimes contained considerable quantities of calcium fluoride, owing to admixture of fluor spar with the heavy spar from which the barytes was ground. He mentioned this because he had seen no published reference to it, and it was at first puzzling to find a considerable quantity of calcium present in a form other than the familiar carbonate or sulphate.

Dr. Keane, in reply, agreed that the method of estimating zinc as phosphate was an excellent one, but they wished to employ a volumetric rather than a gravimetric method, in order that the process might be as useful as possible for works purposes. He also agreed with the President as to the advantages of precipitating the zinc in the presence of a trace of mineral acid. Up to the present they had not had occasion to deal with small quantities of organic matter, such as would be derived from oil, but, in another connection, he had found that organic matter could be effectively got rid of by electrolysing the solution in presence of dilute nitric acid. In that way, even in the case of animal products containing a good deal of organic matter, a crystal-clear solution could be obtained containing no trace of organic matter. With regard to the lime, this undoubtedly was not present as such, but probably to some extent as sulphate, and as sulphide and carbonate. Of course, by estimating the soluble constituents one could always, if it were desired to do so, calculate the lime to calcium sulphate, as suggested by the President. The quantity of iron present was small, usually no more than a trace. The moisture was occasionally rather high, sometimes as much as 1 per cent. Of the samples analysed, the first was made in Germany, the other two being English products; there are, of course, considerable variations in the relative proportions of barium sulphate and zinc sulphide in lithopones.

✣ ✣ ✣ ✣ ✣

ON THE EFFECT OF LIME ON THE AMMONIUM MOLYBDATE METHOD OF LEAD ASSAY.*

By C. O. BANNISTER, A.R.S.M., and W. McNAMARA.

(*Read at the Meeting*, *May* 1, 1912.)

During the analytical portion of the experimental work in connection with a recent research on the "Theory of Blast Roasting of Galena" (*Bull. Inst. Min. and Met.*, 1912, No. 89), the necessity arose for ascertaining the effect of lime on the ammonium molybdate method of lead assay. On referring to published results on this point, a great divergence of opinion was found to exist, some writers stating that the presence of lime had no influence, and others that the results obtained for lead in the presence of lime were too high.

I. C. Bull (*School of Mines Quart.*, 1902, **23**, 348), who examined the effect of calcium, barium, strontium, antimony, and bismuth on the assay, came to the conclusion that calcium, bismuth, and antimony had no effect on the result, and that barium and strontium caused low results. In this work, however, Bull added the impurities to the solution of lead sulphate in a form in which they could not ordinarily exist in the course of assays, for the calcium, barium, strontium, and antimony were added as chlorides and the bismuth as nitrate.

---

* This work was carried out under the provisions of the Analytical Investigation Scheme.

On following out the method as originally devised by H. H. Alexander (*Eng. and Min. J.*, 1893, 55, 298), it is obvious that only insoluble sulphates can be left with the sulphate of lead, and also that the impurities most likely to interfere are calcium, barium, and strontium.

H. A. Guess (*Amer. Inst. Min. Eng.*, 1904, 35, 359) points out that the molybdate method cannot be used with safety in dealing with poor lead ores containing large quantities of lime. W. H. Seamon ("A Manual for Assayers and Chemists," Chapman and Hall, 1910, p. 91) also states that the molybdate method is not reliable on low-grade ores containing much lime, and that it frequently fails when there is iron in the ores, all the sulphate of iron failing to go into solution, and obscuring the end-point with tannin. To overcome these difficulties, Seamon separates the lead by precipitation on aluminium. A. H. Low ("Technical Methods of Ore Analysis," Chapman and Hall, fifth edition, p. 152) states that Alexander's original method did not sufficiently provide for the presence of calcium, which is a frequent constituent of lead ores. Calcium forms a molybdate which is more or less insoluble under the conditions of titration, and tends to raise the results in a rather irregular manner. To overcome this, Low recommends a longer method, involving the separation of the lead from the ammonium acetate solution by means of ammonium sulphide.

In a recent paper on "Quick Combination Methods in Smelter Assays" (*Bull. Inst. Min. and Met.*, 1912, No. 89), A. F. French gives results showing that lime does not interfere with the molybdate assay as ordinarily carried out, and these results are confirmed by F. C. Robinson (*ibid.*, 1912, No. 90), who, in a written contribution to the discussion of French's paper, states that when lime is known to be present the assay, after evaporation to the point at which SO_3 fumes are liberated, is not diluted, cooled, and allowed to stand overnight, but is diluted only when it can be proceeded with at once after cooling, as calcium sulphate crystallises out and is difficult to redissolve. By washing by decantation twice with 30 c.c. of cold dilute sulphuric acid (1 per cent. by volume) and once with water, calcium sulphate is sufficiently well removed.

From the foregoing it is evident that the effect of lime on the assay is by no means clearly understood, and it is also evident that in order to correctly interpret the action of lime on the titration a solution of calcium sulphate in ammonium acetate should be used.

Preliminary experiments showed that a solution of calcium sulphate in ammonium acetate does not form an insoluble molybdate with ammonium molybdate in the absence of lead, neither does it react with the lead molybdate formed during an ordinary lead assay; for if the assay be carried out to a satisfactory end-point, and then a quantity of solution of calcium sulphate in ammonium acetate be added, the end-point is found to be permanent, no more ammonium molybdate being required to react with the lime. If, however, a solution containing sulphates of lead and lime in ammonium acetate be titrated with ammonium molybdate solution, then the lime causes a larger amount to be required, thus giving high results, the excess necessary increasing with the lime added to a certain point, after which additional lime makes no difference.

The following tables indicate the effect of the addition of increasing amounts of calcium sulphate:

TABLE I.—*Effect of Small Quantities of Calcium Sulphate on the Ammonium Molybdate Titration for Lead.*

Weight of Pb taken.	Weight of $CaSO_4$ added.	c.c. Molybdate Solution required.	Lead calculated, per Cent.
0·3415 grm. ...	nil	29·0	100·0
" " ...	0·0036	29·1	100·3
" " ...	0·0073	29·2	100·7
" " ...	0·0109	29·5	101·7
" " ...	0·0146	29·8	102·7
" " ...	0·0183	29·8	102·7
" " ...	0·0256	29·8	102·7
" " ...	0·0292	29·9	103·1
" " ...	0·0327	29·9	103·1
" " ...	0·0366	30·0	103·4
" " ...	0·0402	30·2	104·1
" " ...	0·0439	30·7	105·8
" " ...	0·0475	30·7	105·8
" " ...	0·0512	30·7	105·8

On slightly altering the conditions of the experiments—as, for example, by using more dilute solutions or by varying the amounts of reagents used—the results obtained were found to vary considerably. The following table will illustrate this point; the determinations were carried out in exactly the same manner as the previous set, but a smaller quantity of lead was taken.

TABLE II.—*Effect of Larger Quantities of* $CaSO_4$ *on the Ammonium Molybdate Titration for Lead.*

Weight of Pb taken.	Weight of $CaSO_4$ added.	c.c. Molybdate Solution required.	Lead calculated, per Cent.
0·2005 grm. ...	nil	18·7	100·0
" " ...	0·0549	19·4	103·7
" " ...	0·0612	19·6	104·8
" " ...	0·0658	19·6	104·8
" " ...	0·0695	19·6	104·8
" " ...	0·0732	19·6	104·8
" " ...	0·0805	19·6	104·8
" " ...	0·0842	19·7	105·3
" " ...	0·0915	19·7	105·3
" " ...	0·0951	19·8	105·9
" " ...	0·1134	19·9	106·4
" " ...	0·1317	19·9	106·4
" " ...	0·1500	20·0	106·9
" " ...	0·1685	20·0	106·9
" " ...	0·1866	20·0	106·9
" " ...	0·2049	20·2	108·0
" " ...	0·2232	20·2	108·0
" " ...	0·2415	20·4	109·1

It will be seen, on comparing these tables, that mass action plays a considerable part in these reactions; for in the case of Table II., in which the lead solution is more dilute, 0·0915 grm. calcium sulphate (45·6 per cent.) interferes to a less extent than 0·0512 grm. calcium sulphate (15 per cent.) does in the results given in Table I.

The table given below shows the effect of larger quantities of calcium sulphate on the assay. In this case separate weights of the sulphate and of the calcium sulphate were taken, the same amount of ammonium acetate was used in each case, and the whole conditions of the experiment were kept identical.

TABLE III.

Weight of Pb taken.	$CaSO_4$ taken. Grms.	$CaSO_4$ per Cent. of $PbSO_4$ present.	c.c. Ammonium Molybdate required.	Lead calculated, per Cent.
0·25 grm. ...	—	—	23·7	100·0
,, ,, ...	0·055	15	25·1	105·9
,, ,, ...	0·110	30	26·1	110·1
,, ,, ...	0·183	50	26·7	112·6
,, ,, ...	0·256	70	27·1	114·3

,, ,, ...	0·366	100	27·1	114·3
,, ,, ...	0·549	150	27·1	114·3

From the results given it will be seen that calcium sulphate, even in small quantities, causes high results to be obtained for lead; but from Table III. it will also be seen that the range of this interference is limited to a certain amount, above which no further increase in the lead results is obtained.

When the conditions of the experiments are not kept absolutely constant, the presence of calcium sulphate raises the results in an irregular manner, as stated by Low (*loc. cit.*); but when the conditions are kept the same, then additions of calcium sulphate cause systematic increases in the calculated amount of lead present. There are indications that double molybdates are precipitated when calcium sulphate is present; for on calculating from the molybdate used the composition of the precipitate formed in the case of the results given in Table III., the following results are found:

$CaSO_4$ present.	Calculated Formula of Precipitate.
15 per cent. of the $PbSO_4$ present.	17 $PbMoO_4$, $CaMoO_4$.

50 ,, ,, ,,	8 ,, ,,
70 to 150 ,, ,, ,,	7 ,, ,,

The results of similar experiments in which a solution of lime in ammonium acetate was used in place of the calcium sulphate solution are given in Table IV., and in this case a more dilute solution of ammonium molybdate was used, to insure greater accuracy, the first 100 c.c. in each case being added by means of a Stas pipette.

TABLE IV.—*Effect of Lime on the Ammonium Molybdate Titration for Lead.*

From these figures it is seen that lime acts in a similar manner to calcium sulphate in causing high results to be obtained for lead when the lime is present in the ammonium acetate solution of the lead sulphate. On carrying out a large number of experiments with lime, under somewhat varying conditions as to strength of solution, etc., the same irregularities as to the amount of interference introduced were noticed.

Similar experiments carried out with barium and strontium sulphates show that these act in quite a different manner; for by boiling mixtures of these sulphates with sulphate of lead in ammonium acetate solution somewhat low results were obtained in every case, owing to these insoluble sulphates holding small quantities of lead sulphate, and thus preventing the complete solution of the lead.

From this work the following conclusions may be drawn: (1) That lime or calcium sulphate in solution in ammonium acetate does not form an insoluble molybdate when boiled with ammonium molybdate solution. (2) That lime or calcium sulphate in ammonium acetate solution does not react with precipitated lead molybdate. (3) That when lime or calcium sulphate is present with lead sulphate in ammonium acetate solution, then, on boiling with ammonium molybdate solution, the insoluble molybdate formed contains both lead and lime. (4) From conclusion (3) it follows that it is impossible to determine lead sulphate direct by solution in ammonium acetate when lime or calcium sulphate is present; and (5) in the ordinary lead assay for materials containing lime, etc., it is necessary to separate the lead, or else to take special precautions to wash the lead sulphate free from calcium sulphate before proceeding with the solution of the lead sulphate. (6) Barium and strontium sulphates do not act in the same manner as calcium sulphate, and tend to give low results instead of high results.

METALLURGY DEPARTMENT,
SIR JOHN CASS TECHNICAL INSTITUTE, ALDGATE.

DISCUSSION.

Mr. RICHMOND asked whether the authors had any further data as to the composition of these double molybdates beyond the excess of molybdate used. Had the double molybdate been actually separated, and its composition determined? Looking at the figures, it seemed to him that by no means all the calcium had been precipitated, and that the proportion that was precipitated was not the same in every case. He should like also to ask whether the authors could give the reason why there was no further increase in the percentage of lead found when the calcium sulphate exceeded 70 per cent. Was it due to the fact that the solution was saturated, and that the excess of calcium sulphate was not in solution? Or was it due to the fact that under the conditions of mass action an equilibrium was approached at the point where the maximum figure was obtained?

Mr. RAYMOND ROSS asked whether any of the impurities referred to were likely to be found in the finished lead—*i.e.*, in ordinary commercial lead.

Mr. BANNISTER, in reply, said that the actual composition of the double molybdates had not been ascertained; it would be seen from the paper that the readings obtained were merely considered to be an indication that double molybdates were formed. It was, however, curious that the results of a whole set of experiments should calculate out almost exactly in molecular proportions. They could not explain why the increase in the figures for lead stopped when 70 per cent. of calcium sulphate was reached. The saturation-point, however, was certainly not reached there, for even with as much as 150 per cent. of calcium sulphate the whole of this went into solution before the titration was commenced. These impurities were present in many lead ores, and also in lead slags and other furnace products, and it was important that the possibility of interference should be recognised in commercial work.

THE DETECTION OF HEAVY PETROLEUM IN PAINTS AND VEGETABLE OILS.

BY W. B. POLLARD.

(*Read at the Meeting, May* 1, 1912.)

OWING to the present extensive use of turpentine substitutes, petroleum is now frequently found in mixed paints. Whatever views are held with regard to the value of light petroleum as a turpentine substitute, there is no doubt that heavy petroleum should never be present in paints. As the drying property of such paints can never be satisfactory, it is important to be able to detect the presence of this substance. Light petroleum can be readily separated by steam distillation; and by the action of sulphuric acid, this may further be separated from any turpentine present. Heavy petroleum is not so readily detected, though it can be found by the method described in Allen's "Commercial Organic Analysis." This method, though satisfactory for quantitative work, requires far too much time and manipulation to be of much use as a qualitative test for petroleum. Experiments were therefore made to find in what way it could be modified, in order to give rapid results. It was noticed that when linseed oil is poured into an excess of molten caustic soda and stirred with an iron rod, complete saponification takes place in a few seconds; the soap thus obtained, after cooling, can be extracted with petroleum ether without any passing into the solution and without any emulsion being formed. The petroleum ether extract, which can easily be filtered, will then contain the unsaponifiable oil. Should heavy petroleum be present, it will often betray its presence by the strong fluorescence imparted to the solution.

On evaporating the petroleum ether, petroleum is left behind, and a further examination can be made. In the case of normal linseed oils, a small residue of unsaponifiable oil, rarely exceeding 2 per cent., is always left after extraction; it was noticed that this unsaponifiable oil could further be removed by boiling with a good excess of strong nitric acid, only the minutest trace, if any, remaining after this treatment. Should, however, heavy petroleum be present in the linseed oil, this will reveal itself by the large amount of unsaponifiable matter, and will remain unattacked by the treatment with nitric acid. It was found that as little as 0·5 per cent. of heavy petroleum, when present in linseed oil, could be detected by this means. It is most conspicuous when the nitric acid is warmed, as the oil tends to creep up the side of the tube. Light petroleum or turpentine is not detected in this way, as they volatilise at the temperature at which the saponification takes place; as previously mentioned, they would be detected by steam distillation.

The actual method of conducting the test is as follows:—About 10 grms. of caustic soda are placed in a nickel crucible of 60 to 100 c.c. capacity, and fused over a Bunsen burner. When all the soda has just melted, the crucible is removed from the flame, and about 5 c.c. of the oil or paint quickly poured in. The contents are well stirred with an iron rod, and the crucible allowed to stand in a little water to cool. When cool, about 50 c.c. of petroleum ether are poured into the crucible, and the contents well stirred with the iron rod. By this method the soap forms a powder which settles at the bottom of the crucible, and an emulsion is never produced.

The petroleum ether solution is decanted through a filter-paper and received in a test-tube. It is then boiled off, the vapour being conducted away through a glass tube fixed by means of a cork in the mouth of the test-tube. The residue can now be further examined; this is done by boiling with about 3 c.c. of nitric acid, when any residue beyond a minute trace will be petroleum. Should a paint be found by this method to contain petroleum, it must be absolutely condemned, as its drying properties can never be satisfactory.

It is sometimes stated that resin oil is added to paints. Should this occur, it would be detected by the large amount of unsaponifiable matter, but would be distinguished from petroleum by the fact that it is oxidised by boiling with nitric acid. It might be thought that the Zeiss butyro-refractometer reading of the unsaponifiable matter would afford an indication of the presence of petroleum; this, however, is not the case, as both the heavy petroleum and the unsaponifiable matter normally present in linseed oil give readings which are outside the scale of the instrument.

This method may be used in examining other kinds of saponifiable oils for petroleum adulteration. A small quantity of unsaponifiable oil is left in nearly every case, but on boiling this with an excess of nitric acid, it is invariably destroyed.

The method can also be applied in the examination of stearine candles, which, when they contain paraffin, soften at a temperature considerably below their melting-point.

No claim is made that the method is quantitative, but it affords a ready means for the detection of heavy petroleums when mixed with saponifiable oil, and should not take more than about ten minutes to perform.

Survey Department Laboratories, Cairo.

Discussion.

Mr. **Raymond Ross** said that a determination of the factor $\frac{\mu-1}{d}$ in the residue would nearly always indicate whether it consisted of petroleum, and would in many cases show to what class of petroleum it belonged. In the case of nearly all petroleum oils this value was quite definite, varying from 0·557 to 0·543, while the figure for fatty oils was much different.

The **President** agreed that it seemed improbable that so little as 1 per cent. of mineral oil would be used as an actual adulterant, unless it were added to mask some other addition. Small quantities of mineral oil were, however, sometimes met with in fatty oils obtained by extraction with a solvent, owing to incomplete evaporation of the solvent. This had the effect of considerably lowering the flash-point of the oil, and also, to some extent, the viscosity.

Mr. **E. Richards Bolton** said that it was now unusual to find any trace of solvent in extracted oil, because in most modern extraction plants arrangements were made for blowing steam through the oil in order to remove the last traces of solvent, and manufacturers, for reasons of economy, were usually careful to carry out this operation as thoroughly as possible.

The **President** said that, although it might occur but rarely, it certainly was occasionally the case that the manufacturer did not succeed in removing the last traces of volatile solvent. A sample of extracted rape oil that he had lately examined lost 0·36 per cent. when 1 grm. was heated for an hour in the water-oven, and its flash-point (close test) was only 286° F., whereas the flash-point of rape oil obtained by pressure from the seed would not be below 400° F.

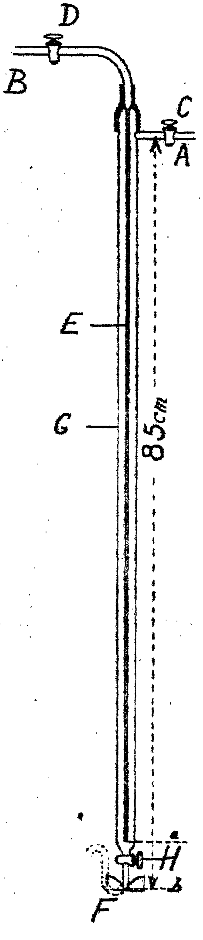
A CONVENIENT APPARATUS FOR OBTAINING AN AVERAGE SAMPLE OF GAS, AND FOR REGULATING THE FLOW OF A GAS INTO AN EVACUATED VESSEL.

By FRANK STURDY SINNATT.

(*Read at the Meeting, April 3, 1912.*)

The apparatus was devised to permit of the accurate regulation of the flow of gas into an evacuated vessel. The rate at which the gas is collected in the exhausted vessel is uniform within certain limits, and the pressure at which the gas is removed from any source is constant, but may be altered if required. After a preliminary adjustment little attention is necessary.



The figure shows a form of the apparatus constructed of glass, and the dimensions mentioned are those used for an apparatus for small volumes of gas (about 1 litre). A long burette makes a convenient main tube *G*, but the diameter may be less than that of the usual burette, if the volume of gas to be obtained is small. By this means an economy in the mercury necessary for the apparatus may be effected. The capillary tube *E* should be about 1 to 1·5 mm. in bore, and the walls should be of stout glass, in order to withstand the vibration which takes place in the tube. The volume of the capillary tube depends upon the diameter of the main tube. The end of the capillary tube is brought as close to the bottom of the main tube as possible, providing the flow of mercury from the latter is not interfered with. The exit of the main tube should be short, or bent into a seal, as indicated by the broken line. The reservoir *F* may be replaced by a levelling bottle during the evacuation of the apparatus, but this must be removed before the actual working of the apparatus is started. The vessel in which the gas is to be collected—*e.g.*, an ordinary gas sampler—is attached at *A* by pressure tubing, and by a second opening connected to a vacuum pump. The apparatus may be used in the following manner: The tap *D* is closed, and the whole exhausted, mercury being allowed to enter the main tube from the reservoir *F*. When the mercury level has reached the required point in the main tube, the sampling vessel is closed to the vacuum pump, and then disconnected. The tap *H* is then closed. The sample of gas is obtained by connecting the gas supply to *B*, and opening the tap *D* slowly; owing to the difference in pressure between the gas vessel and the capillary tube, gas is drawn down the capillary tube, and passes through the column of mercury into the gas vessel. If the distance between *a* and *b* be great, the tap should be opened cautiously; the less this distance the better, so long as the diminished pressure is sufficient to overcome that of the gas to be sampled. When the diminished pressure in the gas vessel has reached that represented by the height of the mercury column from *a* to the surface of the mercury in the main tube, gas no longer enters the gas vessel. The tap *D* may now be opened fully. Mercury is then allowed to flow from the main tube, drop by drop, into the reservoir. As the mercury leaves the tube, gas enters the gas vessel. The rate at which the mercury is allowed to flow determines the rate of entry of the gas into the gas-sampling vessel. When the tap is set, the rate at which the mercury falls into the reservoir is constant, as it depends upon the height of the column of mercury *a* to *b*; this flow is constant until the end of the capillary tube no longer dips into mercury. The distance *a* to *b* may be altered by moving the capillary tube, and consequently the gas may be drawn from a source at any diminished pressure required. By arranging for the mercury to run from the tube in a certain time, a representative sample of the gas throughout that period is collected in the gas vessel. It will be seen that the volume of the sample of gas collected is independent of the size of the apparatus itself. The condition of the gas is comparable with that of gas which has been collected in vessels previously filled with dry mercury.

The use of mercury in aspirators of more than 1 litre capacity is generally considered to be expensive, and too cumbersome for practical purposes. In this respect it is hoped the apparatus may be of some practical use.

An efficient water-pump serves for many purposes for exhausting the apparatus, and by washing the whole apparatus through with the gas to be sampled, the error due to the presence of air may be eliminated. If the pressure in the apparatus be noted, and the volume of the sampling vessel is known, the volume of gas entering the vessel may be calculated.

It is essential that the temperature of the vessel in which the gas is being collected should be as constant as possible throughout the period of sampling, in order to prevent any variation in pressure from that cause. It will be found advantageous to arrange the capillary tube to touch the wall of the main tube throughout its whole length. Instead of the gas passing through the column of mercury in irregular bubbles, and splashing at the surface, it passes up the canal formed at the two glass surfaces in a continuous and regular stream. The passage of the gas through the column of mercury is then scarcely perceptible, being accompanied by a slight vibration in the tube and mercury column.

An alternative way of using the apparatus is to fill the main tube, connections, and capillary tube with mercury, by means of a levelling tube, and then attach a gas vessel which has been previously evacuated at *A*, and proceed in the manner described for admitting the gas.

THE USE OF METHYLENE BLUE AS AN INDICATOR IN IODIMETRIC TITRATIONS.

BY FRANK STURDY SINNATT.

(*Read at the Meeting, June* 5, 1912.)

IN a previous publication (ANALYST, 1910, 35, 309) it was shown that a dilute aqueous solution of methylene blue may be used in place of starch as an indicator in iodimetric titrations. The determinations quoted in that publication were made with a solution of methylene blue prepared by dissolving pure methylene blue in water. It has since been found that the usual commercial forms of methylene blue may also be used without the delicacy of the colour change at the completion of the titration being interfered with. The solutions should be of a similar concentration to that suggested for the pure methylene blue—viz., 0·05 grm. per litre, and about 1 c.c. be taken for a titration. The following observations may be added to the previous note:

It will be found that the compound of iodine and methylene blue frequently separates from the solution as a precipitate. This occurs when an excessive amount of methylene blue has been added, but it will be found not to interfere with the observance of the colour change. There are no objections, such as hold in the case of starch, to the introduction of the methylene blue at the beginning of the titration, and no retardation of the change in colour has been observed.

Titrations have been made in order to determine the influence of inorganic compounds upon the behaviour of the indicator, and neutral salts and the following acids —acetic, hydrochloric, or sulphuric—have been found not to affect the colour change.

When a solution of iodine in alcohol or in aqueous potassium iodide solution is added to methylene blue dissolved in alcohol, the formation of the iodine compound of methylene blue is accompanied by the production of a green-coloured solution. The change in colour is delicate, and, although not very pronounced, is more easily observed than when no indicator at all is used. The addition of a reducing agent such as sodium thiosulphate to the green solution restores the colour of the methylene blue. It is suggested that methylene blue may be of use for the determination of iodine in the presence of alcohol, where it would be impossible to use another indicator.

It has been shown by Harrison (*Koll. Zeit.*, 1911, 9, 5) that the formation of the blue coloration when iodine solution is added to starch solution is interfered with by the introduction of ethyl alcohol. The volume of ethyl alcohol which prevents the formation of the blue coloration varies with the concentrations of the solutions, and in the experiments quoted the blue coloration was not definitely produced when 30 per cent. of alcohol by volume was present in the liquid. Before this percentage of alcohol is reached the formation of the blue compound is too indefinite to be of value as an indicator.

In order to test the value of methylene blue as an indicator in the presence of alcohol, the following determinations were carried out. The solutions used were sodium thiosulphate solution (1 c.c. = 0·01309 grm. iodine) made according to the usual directions, and starch solution made from pure potato starch. The ethyl alcohol contained 96 per cent. of alcohol by volume. In carrying out the check titrations with starch solution, sufficient water was added to lower the percentage of alcohol present to about 2 per cent. Generally three titrations were made for each experiment.

$\frac{N}{10}$ iodine solution (potassium iodide) was mixed with alcohol, 1 c.c. of methylene blue in alcoholic solution added, and the liquid titrated with sodium thiosulphate solution.

Indicator.	$\frac{N}{10}$ Iodine Solution.	Alcohol.	$\frac{N}{10}$ Sodium Thiosulphate required.
	c.c.	c.c.	c.c.
Methylene blue ...	10	20	9·7
" " ...	10	50	9·7
" " ...	10	100	9·7
Starch	10	—	9·7

The introduction of chloroform or carbon tetrachloride does not affect the titration if the percentage of alcohol present is sufficient to prevent the organic solvent separating from the solution.

Indicator.	$\frac{N}{10}$ Iodine.	Carbon Tetrachloride.	Chloroform.	Alcohol.	$\frac{N}{10}$ Sodium Thiosulphate required.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

ANALYSIS OF FOOD AND DRUGS.

Amounts of Arsenic in Vegetable Foods. F. Jadin and A. Astruc. (*Comptes. rend.*, 1912, **154**, 893-896.)—Estimations were made, by a modification of Marsh's method, of the amounts of arsenic in thirty-six samples of fresh and dried vegetables and fruits, typical of all those of most common occurrence. In the fresh vegetables the proportion of arsenic ranged from 0·004 mgrm. (peas) to 0·023 mgrm. (lettuce) per 100 grms. The edible portion of apples contained 0·005, and that of oranges 0·011 mgrm. per 100 grms.; whilst in the case of dried fruits and vegetables the amounts varied from 0·007 (rice) to 0·025 (almonds and red haricot beans) mgrm.

C. A. M.

Detection of Small Quantities of Chloral in Presence of Chloroform. T. Jona. (*Giorn. Farm. Chim.*, 1912, **61**, 57; through *Chem. Zentralbl.*, 1912, I., 1148.)—Chloral is usually detected by the reducing action of the formic acid into which it is first converted. This method is inapplicable in presence of compounds containing the group CCl_3, such as chloroform and trichloracetic acid, whilst bromoform and iodoform may also give rise to illusive results. Chloral cannot be separated from chloroform by distillation. The following method is recommended: In a flask closed by a plug of cotton-wool, the substance, dissolved in water and slightly acidulated with sulphuric acid, is allowed to stand, without warming, in contact with zinc until the evolution of hydrogen has ceased; a strip of filter-paper, soaked in a fresh solution of sodium nitroprusside and 5 per cent. piperidine solution, is hung in the neck of the flask, and the liquid warmed, but not allowed to reach the paper. The acetaldehyde formed by reduction of the chloral colours the paper blue. In this manner 1 part of chloral hydrate in 20,000 can be detected. O. E. M.

Method for the Determination of the "Gasoline Colour Value" of Flour. A. L. Winton.

(*Bull.* 137, *Bureau of Chem., U.S. Dept. of Agriculture.*)—Winton and Shanley (*U.S. Dept. of Agriculture, Bull.* 122, p. 217) have suggested a qualitative gasoline test for bleaching, which corroborates the nitrite test, but it does not give quantitative results. The method described is of value in the comparison of patent or other high-grade flours which owe their colour to the kind of wheat, not to mechanical impurities, as a means of detecting bleaching. Only the colour soluble in oil is measured, and not the total colour, or the colour due to mechanical impurities. Twenty grms. of the flour are placed in a wide-mouthed glass-stoppered bottle, and 100 c.c. of colourless gasoline are added. The bottle is shaken vigorously for five minutes, and is then allowed to stand for sixteen hours, when it is again shaken, and the contents filtered through a dry paper into an Erlenmeyer flask, keeping the funnel covered with a watch-glass. The colour value of the clear solution is determined in a Schreiner colorimeter, using for comparison a 0·005 per cent. aqueous solution of potassium chromate; this solution corresponds to a gasoline number of 1. The colorimeter tube containing the gasoline solution should be adjusted so as to read 50 mm., and the tube containing the standard chromate solution is raised or lowered until the shades of yellow in both tubes match. The reading of the chromate solution, divided by that of the gasoline solution, gives the gasoline colour value. If desired, the colour value may be determined in Nessler tubes, using for comparison chromate solutions of various dilutions, and filling the tubes in all cases to the height of 50 mm. A number of determinations are given, showing the effect of variety, grade, ageing, and bleaching, on the gasoline value. Bleaching with nitrogen peroxide (2 parts of nitrous nitrogen per million) immediately produced about the same degree of whitening as ageing for thirty weeks. Ageing of the bleached flour brought about further bleaching, so that after thirty weeks hardly any colour remained. If the flour is known to have been milled within ten weeks, the gasoline colour value may be depended upon to corroborate the determination of nitrous nitrogen as a means of detecting bleaching. H. F. E. H.

Composition of Hare Fat. J. Klimont.

(*Monatsh. Chem.*, 1912, **33**, 441-446.)—A specimen of this fat yielded the following chemical and physical constants:

Sp. gr. at 50° C.	0·9134
Melting-point	35° C.
Solidifying-point	29° C.
Acid value	15·3
Saponification value	204·9
Iodine value	107·0

The fat was found to consist principally of tripalmitin mixed with glycerides of unsaturated, fluid fatty acids; the latter, however, did not contain linoleic acid to any great extent. W. P. S.

Saponificaton of Fats by Sulphuric Acid. A. Grün and O. Corelli. (*Zeitsch. angew. Chem.*, 1912, **25**, 665-670.)—All the experiments carried out by the authors on the action of sulphuric acid on pure triglycerides of the higher fatty acids yielded the same result—namely, the formation of diglycerides. On treating tripalmitin for several hours at 70° C. with a tenfold molecular quantity of sulphuric acid of sp. gr. 1·845, the resulting mixture contained 56·5 per cent. of free palmitic acid and 43·5 per cent. of neutral fat, the latter consisting of 30 per cent. of unaltered tripalmitin and 70 per cent. of dipalmitin. On doubling the quantity of sulphuric acid, the product consisted of 65 per cent. of free acid and 35 per cent. of neutral glyceride, the latter being 25 per cent. unaltered glyceride and 75 per cent. dipalmitin. Tristearin yielded approximately similar results. The reaction appears to proceed beyond the diglyceride stage, as is shown by the proportion of free fatty acid to neutral fat, and, although monoglycerides could not be detected at any stage of the reaction, it is possible that monoglycerides are formed and immediately split up into fatty acids and glycerol or glycerol esters of sulphuric acid. W. P. S.

Mkonga Oil. W. Arnold. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 391-392.)—The seeds of the Mkonga-tree (*Balamites ægyptica*), which grows in German East Africa, yield a yellow oil having a nutty taste and odour. A specimen of the oil yielded the following figures on analysis:

	Oil.	Non-Volatile Fatty Acids.
Sp. gr. at 15° C.	0·9173	—
$[N]_D$ 40° C.	55·9	—
Saponification value	195·6	206·1
Reichert-Meissl value	0·55	—
Polenske value	0·40	0·50
Iodine value	77·2	82·9
Acid value	8·5	—
Solidifying-point	Turbid at 8·8° C.	—
Stearic acid	2·4 per cent.	2·6 per cent.
Unsaponifiable matter	0·07 ,, ,,	—

The oil yielded negative reactions when tested for cottonseed and sesame oils. W. P. S.

Sources of Error in the Estimation of the Polenske Value of Fats. W. Arnold. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 389-391.)—From the results of analyses of fats which have been published from time to time, it is evident that incorrect results are sometimes obtained in the estimation of the Polenske value, and the author draws attention to the errors in manipulation which tend to cause these discrepancies. Many of these points have been mentioned already (*cf.* ANALYST, 1904, **29**, 154; 1909, **34**, 223, etc.). The distillation flask should be of 300 c.c. capacity, and all the dimensions of the apparatus described originally by Polenske should be adhered to; the use of wire gauze under the flask should be avoided, but the flask should rest on an asbestos ring, the hole in which is 6·5 cm. in diameter. The flame of the burner should be sufficiently large to cover the bottom of the flask, but should not make the edges of the asbestos ring incandescent. Powdered pumice must be employed instead of pieces of pumice to prevent "bumping," and the distillate should measure exactly 110 c.c. As the Polenske value varies with the quantity of glycerol used in the saponification of the fat, care should be taken that exactly 20 grms. of glycerol be used for each estimation. In the author's opinion, the correct working of any apparatus is ascertained by making an estimation of the Polenske value of a specimen of pure, fresh lard; the value found should be approximately 0·5, and should never exceed 0·65. W. P. S.

Influence of the Concentration of Hydrogen Ions on the Baking Qualities of Flour. H. Jessen-Hansen. (*Comptes rend. Trav. Lab. de Carlsberg*, 1911, **10**, 170-206.)—Determinations of the concentration of hydrogen ions were made with the object of ascertaining the effect of the addition of acid substances to flour, the methods employed for the measurement being the conductivity and colorimetric processes described previously by the author (ANALYST, 1909, **34**, 498). It was found that for dough prepared from wheaten flour there is a certain definite concentration of hydrogen ions at which the best baking results are obtained, and that this concentration is higher than in dough prepared from freshly milled flour and distilled water or fresh milk. The optimum concentration corresponds approximately with the exponent $p_{\text{H}}^{+} = 5$; in the case of the best qualities of flour it may be a little higher, and for ordinary flours slightly lower. The flour from the central portion of the wheat grains has a greater acidity—that is, a higher concentration—than the outer portion, the bran having the least. The addition of "improvers" to flour has scarcely any other effect than to increase the concentration of the hydrogen ions. Processes for the estimation of the gluten, which depend on the separation of the gluten by washing the flour, do not afford trustworthy data as to the baking qualities of flours. W. P. S.

Incineration of Food-Stuffs and other Organic Substances prior to the Determination of their Phosphorus-Content. A. Vozárik. (*Zeitsch. physiol. Chem.*, 1912, **76**, 426-432; through *J. Soc. Chem. Ind.*, 1912, **31**, 250.)—The phosphorus in food-stuffs is in part present in the form of phosphatides, which are more or less volatile below 100° C. For the incineration of such products, as a first step in the determination of the phosphorus, the author proposes the following modification of Eschka's method: One grm. of the finely-ground sample if of animal origin, or 3 grms. if vegetable, is well mixed with 0·2 grm. of magnesia in a platinum crucible. The magnesia employed should be as light and voluminous as possible, and free from lumps. The open crucible is laid obliquely, and at first warmed carefully near the edge until all volatile matters have been expelled. The burner is then moved towards the base of the crucible, the cover is placed obliquely in the mouth, and the heating is continued until incineration is complete. The whole operation may require half an hour to two hours in the case of animal matters, and two to three and a half hours with vegetable matters. The ash is obtained as a powder, which does not adhere to the inside of the crucible.

Determination of Phosphorus in Food-Stuffs and other Organic Substances by Titration with Uranyl Solutions. A. Vozárik. (*Zeitsch. physiol. Chem.*, 1912, **76**, 433-456; through *J. Soc. Chem. Ind.*, 1912, **31**, 250.)—In the determination of phosphorus in incinerated organic products (see preceding abstract) by titration with uranyl nitrate solutions, errors may arise from the presence of mineral acids, large quantities of acetic acid, various dissolved salts, especially the acetates of the alkali and alkaline earth-metals, and the phosphates of iron and aluminium. The liquid to be titrated should contain no phosphates acid towards phenolphthaleïn and no aluminium or iron phosphate. The disturbing influence of free acetic acid begins to be appreciable at a concentration of 0·36 per cent. when cochineal is used as indicator, and 0·6 per cent. when potassium ferrocyanide is used. Errors are introduced by sodium, ammonium, and magnesium acetates at concentrations exceeding 4, 2, and 0·75 per cent. respectively. The presence of strong acids leads to high results with cochineal as indicator, but to low results with ferrocyanide. If both are used at the same time, the divergence of the results gives an indication of the magnitude of the error. When the liquid titrated contains a large quantity of foreign salts, the influence of the latter on the result must be determined and a corresponding correction made. A certain small volume of uranyl solution is required to produce the indicator reaction. If allowance is made for this, there is strict proportionality between the volume of uranyl solution required and the quantity of phosphorus present, irrespective of the concentration of the latter. The author gives full details for carrying out the determination of phosphorus in incinerated organic substances by this method. The results obtained agree well with those found by the gravimetric citrate method.

Formic Acid in Honey. H. Fincke. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 255-267.)—That formic acid is not invariably present in honey is shown by the results of analyses of numerous samples of honey recorded by the author. Many of the samples were free from formic acid, but the majority contained traces of a reducing volatile acid (as estimated by the mercuric chloride method; *cf.* ANALYST, 1911, **36**, 103), the quantity of which did not generally exceed 0·003 per cent.; in a few cases the quantity amounted to 0·02 per cent., calculated as formic acid. The volatile acid was present partly in the free state and partly in the form of salts; esters of the acid could not be detected. In the course of the investigation it was found that invert sugar, prepared by heating cane sugar with acids, yields small quantities of formic acid when submitted to steam distillation; invert sugar prepared with invertase does not yield formic acid. W. P. S.

Kola Nuts from British West Africa. (*Bull. Imp. Inst.*, 1912, **10**, 34-37.)—The samples of "kola nuts" received during 1909-10 from the Gold Coast were found on examination to have the following composition:

	Moisture, per Cent.		Caffeine.			
			In Nuts as received, per Cent.		In Nuts after Drying at 100° C., per Cent.	
	1.	2.	1.	2.	1.	2.
Cola acuminata (genuine kola nuts)	50·16	15·2	0·73	1·7	1·5	2·1
C. Johnsoni (false kola nuts)...	49·32	14·8	0·67	0·7	1·3	0·8
C. verticillata „ „ ...	52·60	14·2	0·55	0·7	1·1	0·8

The so-called "bitter kola seeds" contain no caffeine, and are the product of *Garcinia Conrauana.* A. R. T.

Estimation of Dry Matter in Potatoes and the Applicability of the Ordinary Tables. H. Björn-Andersen. (*Zeitsch. anal. Chem.*, 1912, **51**, 341-359.)—From experiments of his own, as well as from consideration of the data on which Maercker and others have founded their tables, the author concludes that the sp. gr. of potatoes, however carefully determined, is a most uncertain guide to their content of dry matter. In at least one experiment in ten the error will exceed ± 1 per cent., which is far too large an error where the number to be estimated is 22·5 ± 3 per cent., which limits for dry substance would include most potatoes grown for their starch. If a table is to be used, it should rather be one connecting dry substance as determined by the most exact methods with the number obtained by some empirical, and not too slow or complicated, method of drying. The author disintegrates 4 or 5 kgrms. of potatoes in a mincing-machine with holes 0·9 cm. in diameter, and 2 kgrms. of the resulting paste is put through the machine twice more, using plates with holes 0·45 and 0·3 cm. in diameter. A 10-grm. sample is then dried for eight days at 99° to 100° C. If the drying be discontinued after twenty-four hours, the results are 0·4 ± 0·04 per cent. too high, and it is suggested that drying in a vigorously boiling, well-ventilated steam oven for twenty-four hours, with a deduction of 0·4 per cent. from the value found, would afford a good empirical method. G. C. J.

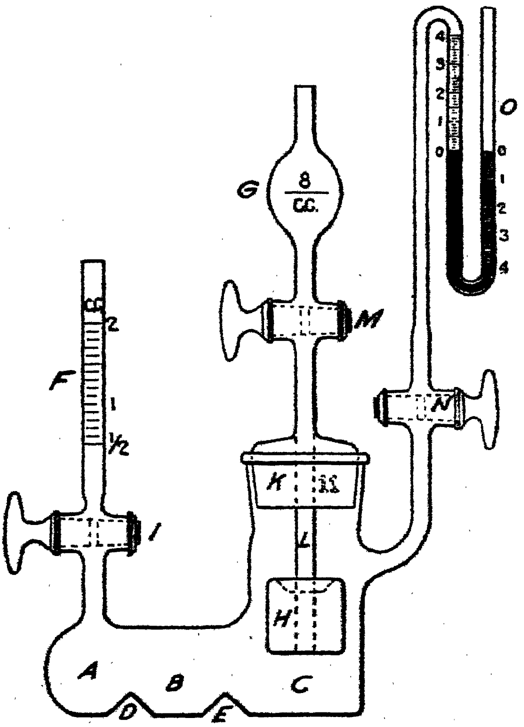
Detection of Adulteration of Cayenne Pepper. A. von Sigmond and M. Vuk. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 387-388.)—The authors have endeavoured to find a method for the detection of added oil in this condiment, but without success. As they have mentioned previously (*cf.* ANALYST, 1912, 56), the added foreign oil would remain on the surface of the particles, but attempts to separate this "surface" oil by pressing the pepper between filter-paper and extracting the oil absorbed by the latter by shaking the pepper with water and separating the oil by centrifugal action, etc., did not yield results which were of any use. The iodine value of the separated oil afforded no evidence of the presence of a foreign oil. W. P. S.

Estimation of the Total Solids of Vinegar. P. Lehmann and J. Gerum. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 267-274.)—Windisch and others have shown that the total solids of vinegar may be estimated correctly by evaporating the vinegar, treating the residue three times with water, and weighing the final residue; the latter may then be dissolved in a definite volume of water and the sp. gr. of the solution determined, a reference to tables giving the amount of total solids corresponding with the sp. gr. found. The authors now give an indirect method of estimating the total solids, which consists in estimating the quantity of acetic acid in the vinegar, multiplying the percentage quantity of this constituent by 0·0015, and subtracting the product from the sp. gr. of the vinegar. The difference is the sp. gr. of the solution of the total solids, and the quantity of the latter is then found by reference to tables. In case traces of alcohol or other substances lighter than water are present, 50 c.c. of the vinegar should be evaporated to 15 c.c., diluted to 50 c.c., and the sp. gr. determined. The solution is then titrated with $\frac{N}{1}$ potassium hydroxide solution, and the number of c.c. required for neutralisation is multiplied by 0·00018. The result, subtracted from the sp. gr., gives the sp. gr. of the solution of the total solids. W. P. S.

Estimation of Glycerol in Wine. S. Rothenfusser. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 332-337.)—In the method proposed the glycerol is converted into oxalic acid after the wine has been treated with stannous chloride to precipitate organic acids, and with ammoniacal basic lead acetate to remove sugars (*cf.* ANALYST, 1910, **35**, 208). When only a small quantity of sucrose is present in the wine, the addition of a somewhat large amount of the lead reagent effects its removal, provided that the casein solution is not employed; but if more than 1 per cent. of sucrose is present, the wine should be subjected to a preliminary heating with an acid in order to invert this sugar. The estimation is carried out as follows: A quantity of the wine is treated with an excess of sodium carbonate, and crystallised stannous chloride is then added until the mixture exhibits an acid reaction. The precipitated lactic and other organic acids are now removed by filtration, and the filtrate is diluted to a definite volume after the addition of ammoniacal basic lead acetate solution. The mixture is filtered, and an aliquot portion of the filtrate is treated with a small quantity of sodium phosphate and potassium carbonate, and evaporated to about one-third its volume. Powdered potassium permanganate is then added to the cold solution in excess, and after the lapse of thirty minutes the excess is destroyed by the addition of hydrogen peroxide. The oxalic acid formed by the oxidation of the glycerol is now precipitated as its calcium salt, which is collected, dissolved in diluted sulphuric acid, and titrated with permanganate solution in the usual way. Estimations of glycerol in artificial wines containing from 0·26 to 0·64 per cent. of glycerol yielded results which did not differ by more than 0·02 per cent. from the quantity present. W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Measurement of the Oxidase Content of Plant Juices. H. H. Bunzel. (*J. Amer. Chem. Soc.*, 1912, **34**, 303.)—The oxidising enzymes in plants are of importance in connection with respiration and in many diseases; and in special cases they are concerned with the darkening of tea and of bread during its making, as well as with the hardening of the black Japanese lacquer prepared from the tree *Rhus vernicifera*. The author has elaborated a quantitative method involving the measurement of the amount of oxidation of pyrogallol by oxygen in the presence of the plant juice. Only fresh unfiltered juice was used. The apparatus (see Fig.) is clamped on the carriage of a shaking machine in a thermostat. Eight c.c. of fresh 1 per cent. pyrogallol solution are measured into the compartment *C* by means of the bulb *G*. Two c.c. of plant juice are measured into the compartment *A* from the burette *F*. The basket *H* is charged with 1 c.c. $\frac{N}{1}$ caustic soda solution. Only the stopcock *I* is left closed, and the interior of the thermostat is heated to the desired temperature. About 30 minutes later the windows of the thermostat are opened enough to allow the introduction of the arm, and the stopcock end closed. The shaking machine is then brought into action at an approximate rate of 5 complete movements in 3·3 seconds. At 15-minute intervals the shaking is interrupted long enough to read the manometers. The experiment is considered completed when successive readings are identical. The carbonic acid liberated can be approximately determined by lifting off the basket *H* at the ground joint *K*, adding a drop of phenolphthalein, and placing the whole in a special titration flask. In the experiments described, the pressure readings on the manometer are given, and the values reduced to the arbitrary volume of 150 c.c., this being about the capacity of the apparatus used. The absorption of oxygen comes to an end in about 2 hours, and the concentration of pyrogallol solution has no appreciable effect on the end result, provided it is over 0·2 and under 16 per cent. A certain quantity of potato juice is capable of bringing about the oxidation of a definite quantity of pyrogallol, any excess of which



remains unoxidised. The total oxygen absorption is at least approximately proportional to the quantity of potato juice present. Excess of caustic soda is necessary in the basket *H* to insure complete removal of the carbonic acid formed during the experiment. Care must be taken not to splash any pyrogallol into the alkali, or no satisfactory end result is obtained. Previous workers have shown that many enzymes lose their activity on vigorous shaking, and experiment showed that if the potato juice was shaken for 15 to 30 minutes before the addition of the oxidisable substance, its oxidising power was reduced to about half the original value; further shaking produces no effect. This indicates that two phases of the process are concerned, each of which may be measured separately, and to obtain the total oxidising effect of the plant juice measurements must be taken from the moment that shaking begins.

The author has applied his method to the investigation of the curly-top disease of sugar beets, and finds that the oxidase content is markedly greater in the diseased leaves, and shows wide variations, while normal leaves appear to be fairly constant. The deviation in oxidase content of the pathological leaves runs parallel with the appearance of the leaves. The main source of error in using the apparatus lies in the rise of pressure within it as soon as shaking is begun; but by allowing the apparatus and its contents to stay at the chosen temperature for at least half an hour, this may be almost entirely overcome. Within the limits of the experiments the amount of the chemical change is directly proportional to the concentration of the oxidase present, all other factors remaining the same. It thus appears that the behaviour of plant oxidase is contrary to the usual conception of enzyme action in general, since it would have been expected that small quantities of juice would bring about the oxidation of relatively large quantities of pyrogallol, and that the action would continue so long as pyrogallol and free oxygen are present; whereas the process comes to completion when only a small definite portion of the pyrogallol is oxidised, and while there is still an abundance of oxygen. It therefore seems that the oxidase in potato juice which accelerates the absorption of oxygen by pyrogallol is not an enzyme in the customary sense of the word, but is a substance entering directly into the reaction, and destroyed in the course of the same. As it is desirable to express the strength of the juice in terms of some standard, the author proposes as a unit for future experiments an oxidase solution of such strength that 1 litre of it will be capable of bringing about the consumption by pyrogallol of 8 grms. of oxygen. This unit of strength may not have any relation to the rate of the absorption, as it refers only to the total amount absorbed. It is left to future investigation to determine whether the strength of an oxidase solution, as expressed by this standard, is proportional to the rate at which the absorption takes place. The apparatus may be obtained from Machlett and Son, 143, East Twenty-third Street, New York City.

Copper Fungicides. S. U. Pickering. (*J. Agric. Sci.*, 1912, **4**, 273-281.)—Gimingham and Barker (ANALYST, 1911, **36**, 351) questioned the validity of the principle that solubility of the copper compound is essential in order that it may exert its fungicidal action, and doubt that such solubility is brought about by the action of carbon dioxide, suggesting that mere contact between the fungus and an insoluble copper compound is sufficient to account for its action. It is doubtful whether the carbon dioxide in air can render soluble more than mere traces of copper in ordinary Bordeaux mixture. The author controverts these opinions, and cites further experimental work in support of his view that the efficacy of such fungicides depends upon the proportion of copper in them which is rendered soluble by the carbon dioxide of the air. The amount of copper rendered soluble may be estimated by immersing clean iron rods in the solution, removing them at intervals, wiping them free from copper, and noting their loss in weight. Solutions too dilute to show copper by the ferrocyanide method (unless previously concentrated) can thus be shown to contain copper. The greater the excess of lime present, the longer is the interval before the solution of copper commences; but in practical spraying this time is shortened, since the deposit dries up and isolates the particles of basic sulphate from those of lime. In spite of the small solubility of $10CuO,SO_3$, the greater part of the copper in it will pass into solution in a short time if any body be present, such as iron, to react with it and remove it from the solution; and this will occur to a much greater degree in the presence of such a large reacting surface as fungus spores or plant leaves. If fungicidal action depended, as Gimingham and Barker hold, on a solvent material exuded from the fungus, all copper compounds, or, at any rate, all the basic sulphates and carbonates, would be equally efficacious for a given weight of copper present, a proposition which is contrary to all experience. Ordinary Bordeaux mixture should be more effective than other compounds of the same copper content, for the lime itself appears to have a conspicuous fungicidal action, which action, the author claims, accounts for the results obtained by Gimingham and Barker (*loc. cit.*), when they found that ordinary Bordeaux mixture was affected in an atmosphere free from carbonic acid—a result which they accepted as proving that carbonic acid does not bring the copper of such a mixture into solution.

H. F. E. H.

Estimation of Sugar in Blood. E. Herzfeld. (*Zeitsch. physiol. Chem.*, 1912, 77, 420-424.)—The blood, or blood-serum, is treated with metaphosphoric acid to precipitate proteins; these are removed by filtration, and the filtrate, after the addition of potassium hydroxide, is titrated with a standardised methylene-blue solution. The latter is decolorised by aldoses, ketoses, and dextrins, in alkaline solution, and also by proteins, cholesterol, and bilirubin—hence the necessity of removing these by treatment with metaphosphoric acid; urea does not decolorise the methylene-blue solution. The standardisation of the methylene-blue solution is carried out by adding 0·5 c.c. of a 20 per cent. potassium hydroxide solution to an exactly measured quantity of a 0·1 per cent. dextrose solution, and heating the mixture nearly to boiling. When the hot solution begins to turn yellow in colour, a 0·001 per cent. aqueous methylene-blue solution is run in, drop by drop, until the colour is no longer discharged. Experiments carried out by the author show that 1 c.c. of the methylene-blue solution is equivalent to 0·00062 grm. of dextrose. In the case of blood, 5 c.c. of the sample are mixed with 15 c.c. of a 10 per cent. metaphosphoric acid solution, filtered after the lapse of ten minutes, and the precipitate washed with a small quantity of the metaphosphoric acid solution. The filtrate is then neutralised with potassium hydroxide, an excess of 0·5 c.c. of 20 per cent. potassium hydroxide solution is added, and the titration carried out as described above. The method yields concordant results. W. P. S.

Copper-Reducing Power of Normal Urine. N. Schulz. (*Zeitsch. physiol. Chem.*, 1912, **67**, 121-128.)—When normal urine, free from sugar, is treated with copper sulphate solution, and then rendered alkaline with an excess of sodium hydroxide solution, a clear blue solution is obtained, provided that too much copper has not been added; on heating the solution for some minutes, reduction of the copper takes place. If, however, the urine be rendered alkaline before the addition of the copper solution, a turbid solution is produced, and the copper is not reduced (Trommer's test for sugar). Creatinine solutions behave in a similar manner, the solution of the copper hydroxide or otherwise, depending on the order in which the reagents are added; as creatinine is converted into creatine by the action of alkalis, it is probable that this is the explanation of the reaction. W. P. S.

Method of Testing Water. Determination of the Power of Bacteria to Decompose Proteins. W. Spät. (*Arch. Hyg.*, 1912, **74**, 237-288; through *Chem. Zentralbl.*, 1912, I., 1332-1333.)—The method proposed consists in mixing quantities of the water under examination with varying amounts of a 2 per cent. sterilised peptone solution, maintaining the mixtures at 37° C., and estimating the ammonia formed. The activity of the bacteria as regards the production of ammonia is expressed in c.c. of $\frac{N}{100}$ solution. In the case of sterile waters, ammonia is not formed; with waters containing but few bacteria the production of ammonia is very small, but impure waters loaded with bacteria produce considerable quantities. The amount of ammonia formed is not always proportional to the number of bacteria present, as the true water bacteria are capable of producing but very small traces of ammonia, and practically the same may be said of pathogenic organisms and *B. coli*; but soil bacteria produce large quantities of ammonia, and the method mainly serves the purpose of detecting the presence of surface water in a supply, the introduction of which water indicates that other contaminating matters may find an entrance. At ordinary temperatures the production of ammonia is negligible, even in the case of contaminated waters, and samples may therefore be transported without being packed in ice. When a water-supply is examined periodically, any sudden increase in the quantity of ammonia obtained almost certainly points to the introduction of surface water. Sewage produces large quantities of ammonia, the decomposition of the peptone being accompanied by the formation of an extremely offensive odour, and, although there is a certain relation between the amount of ammonia produced and the quality of the sewage, some of the ammonia is lost during the incubation of the mixtures. The method will readily detect as little as 0·0005 c.c. sewage.

W. P. S.

ORGANIC ANALYSIS.

Aromatic Grass Oils. Part III. (*Bull. Imp. Inst.*, 1912, 10, 27-34—*cf.* ANALYST, 1912, 61; 197.)—New essential oils from species of *Cymbopogon* and from vetiver roots were found to give the following analytical results on examination:

	Cymbopogon Coloratus (Fiji). 3 Samples.	*Cymbopogon Polyneuros* (Ceylon). 4 Samples.	*Cymbopogon Sennaarensis* (Soudan). 1 Sample.
Sp. gr. 15°/15° C. ...	0·915 to 0·920	0·936 to 0·951	0·9383
Opt. rotation, 100 mm. at 20° C.	−7·7° (at 22° C.) to −8·7°	+30·9° to +55·25°	+34·25°
Aldehydes by sodium bisulphite, per cent.	42·0 to 43·5	—	(or ketones) 27
Citronellal, ,,	45·7; 49·5	—	—
Geraniol, ,,	15·6; 15·6	Total alcohols, 38·7 to 51·8	Total alcohols, 17·3
Solubility in—			
80 per cent. alcohol	1 : 1 or more vols.	1 : 1	—
70 ,, ,,	1 : 3; more alcohol gives cloudy solution.	Opalescence to turbidity with 1 : 10	—
Odour	Varying between citronella and lemon-grass oils.	Unlike citronella or lemon-grass oil.	Pennyroyal oil (pulegone present).

	Vetiver Oil (Fiji).	Oil from Seychelles Vetiver Roots.	Oil from Indian Vetiver Roots.
Sp. gr. 15°/15° C. ...	1·0298	1·0282	1·015 to 1·030
Opt. rotation, 100 mm. at 20° C.	—	+27·0°	+27·7°
Acid value	—	55·9	—
Saponification value	35·3	67·3	60 to 80
Solubility in 80 per cent. alcohol.	1 : $2\frac{1}{2}$; more alcohol gives cloudy solution.	1 : 1 or more.	1 : $1\frac{1}{2}$ or 2; more alcohol gives cloudy solution.

A. R. T.

Estimation of Acetaldehyde in Paraldehyde. **R. Richter.** (*Pharm. Zeit.*, 1912, 57, 125; through *Chem. Zentralbl.*, 1912, 1, 1148.)—The sulphite method given in the German Pharmacopœia for the estimation of formaldehyde was used. A solution of 10 grms. paraldehyde in 100 c.c. water is neutralised with $\frac{N}{1}$ potassium hydroxide solution, 2 drops of phenolphthaleïn solution being used as indicator, 20 c.c. of an aqueous solution containing 25 grms. crystallised sodium sulphite solution in 100 c.c. added, and $\frac{N}{1}$ hydrochloric acid to decoloration. From the quantity of hydrochloric acid used is subtracted the quantity required to decolorise a mixture of 100 c.c. water, 20 c.c. of the sulphite solution, and 2 drops of phenolphthalein solution. The difference must not exceed 9·1 (or 1·15, as the case may be) c.c. $\frac{N}{1}$ hydrochloric acid, corresponding to a maximum acetaldehyde content of 4 (or 0·5) per cent. acetaldehyde; 1 c.c. $\frac{N}{1}$ hydrochloric acid corresponds to 0·044 grm. acetaldehyde. Estimations of a number of commercial samples showed that paraldehyde with only a few tenths per cent. is easily obtainable. The author considers that paraldehyde of sp. gr. 0·998 to 1·00 may be required to show a solidification-point of 10° to 11° C., and not more than 0·3 per cent. acid, 0·5 per cent. acetaldehyde, and 0·1 to 0·2 per cent. metaldehyde, determined by evaporating 10 grms. of paraldehyde at 50° C. O. E. M.

Method of Distinguishing between Aldoses and Ketoses. M. Betti. (*Gazz. Chim. Ital.*, 1912, **42**, 288-294.)—The method is based upon the fact that β-naphthol-benzylamine forms crystalline compounds of amino-aldehydic character with aldoses, but does not react with ketoses. With *d*-mannose the reagent forms a compound, $C_{17}H_{13}ON : C_6H_{12}O_5$, which crystallises in white needles melting (with decomposition) at 207° to 208° C.; with *d*-galactose it yields small prisms melting at 206° C. (with decomposition); with *d*-glucose, white silky needles melting (with decomposition) at 192° C., and being more soluble in alcohol than the preceding compounds; and with rhamnose, white crystals melting (with decomposition) at 192° C. In using the reagent for the separation of dextrose and lævulose, a solution of 0·90 grm. of each of the sugars in dilute alcohol was added to a warm alcoholic solution of 2·5 grms. of the base, and the mixture left for twenty-four hours, and then allowed to evaporate spontaneously. The crystalline mass was triturated with a little water and filtered, and then washed on the filter. The filtrate and washings contained the lævulose. The residue, after being washed with petroleum spirit and crystallised from a large volume of alcohol, melted at 192° C., and by treatment with dilute hydrochloric acid yielded the dextrose again.

C. A. M.

Examination of Bituminous Materials. F. C. Garrett. (*J. Soc. Chem. Ind.*, 1912, 31, 314-317.)—The following methods of analysis were adopted: *Water* is determined by heating for five to six hours at 40° to 50° C., or by desiccation *in vacuo* over sulphuric acid for several days. The two methods give similar results, and a slight loss of organic matter takes place, but this is not important except in the case of pitches containing much water. *Sulphur* is determined by a modification of Eschka's method (ANALYST, 1906, 31, 52), the following results being obtained (the figures in brackets show the percentage amount of sulphur calculated on the organic matter only of the sample): Sulphur per cent. in petroleum, 1·39 (1·39); liquid pitch, 2·66 (2·66); soft pitch from Hatley's hole, Lot C, 2·88 (3·13); soft lake pitch, 3·62 (5·54); lake pitch, 3·81 (5·98); lake pitch dried by steam, 4·12 (6·52); land pitch, 3·55 (6·17); cheese pitch, 3·84 (6·38); iron pitch, 3·86 (6·27); impure pitch, seashore, 3·20 (7·67); manjak (Grahamite), 2·96 to 3·57 (3·13 to 3·74) in three samples; glance pitch, 5·12 (5·17); Barbados manjak, 0·86 (0·89); Cuban hard pitch (Grahamite), 8·47 (8·59); elaterite (elastic), 1·14 (1·16).

Proximate Analysis by Heating.—About 2 grms. of the sample are placed in a platinum crucible and heated with the lid on by the tip of a Bunsen-flame for half a minute after the disappearance of flames round the crucible lid. The time required is two and a half minutes, the bottom of the crucible being faintly red during the last half minute. The crucible is then heated to bright redness for two minutes in the flame of a blast Bunsen, cooled without removing the lid, weighed, and the loss of weight (less moisture) noted as "volatile hydrocarbons." The coke is next heated to redness till burnt off, the loss of weight being "fixed carbon" and the residue "ash." In the case of pitches which melt and froth over, smaller quantities are heated in a larger platinum crucible, and the first heating is spread over five minutes. The method allows of distinctions being made between, say, lake pitch and land pitch. The amount of volatile matter, divided by the fixed carbon, gives the "volatility factor," which in the lake pitches is above 5, and in the land pitches between 4 and 5. The following are typical of the results obtained :

PETROLEUM AND THE "PITCHES."

	Petroleum (Sp.Gr.,0·9226; Flash-point, 27° C.).	Liquid Pitch (Sp. Gr., 0·926).	Lake Pitch.	Land Pitch.	Iron Pitch.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Moisture	nil	nil	1·20	8·60	0·60

Ash	1·45	3·90	3·00	1·00	2·20
Volatility factor ...	1·19	1·62	2·00	3·09	87·90

Proximate Analysis by Extraction with Solvents.—A piece of filter-paper, 9 by 6 inches, is dried at 100° C. and weighed, folded lengthwise, about 2 grms. of the pitch, accurately weighed, placed on the central portion of the paper and spread in a very thin layer, the sides of the paper turned over, and the whole rolled from each end towards the centre. The cylinder thus prepared is tied with a weighed platinum wire and introduced into a Soxhlet tube, and extracted with acetone till the pitch, on two successive weighings, after draining and drying for two hours at 100° C., loses less than 10 mgrms. during twelve hours extraction. The loss is recorded as "petrolene," and the extraction then continued with chloroform, which similarly extracts the "asphaltene." The residue is ignited and the mineral matter weighed, the difference between 100, and the sum of the petrolene, asphaltene, and the mineral matter being the "organic matter not bitumen." This usually consists of plant remains. The following are some of the results obtained:

ANALYSES BY SOLVENTS.

		Liquid Pitch.	Lake Pitch.	Land Pitch.	Iron Pitch.	Manjak (Grahamite).	Barbados Manjak.	Glance Pitch.
		Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.

A. R. T.

Estimation of Cellulose in Woods and Textile Fibres. J. König and F. Hühn. (*Zeitsch. Farb. Ind.*, 1911-1912. Series of ten articles.)—The authors have reinvestigated the various analytical methods proposed or adopted for cellulose estimation, and give their preference to *acid* methods of digestion, especially for elimination of unsaturated and oxidisable groups (lignone). They have particularly studied the methods of König (digestion with glycerolin sulphuric acid at 137° C., followed by alkaline oxidation) and Tollens-Dmochowski (digestion of "crude fibre" with strong nitric acid). The weights obtained in either case show a considerable deficiency (10 to 12 per cent.) from those of the generally adopted methods. The discrepancy in the former case (König) is explained as due to removal of "hemihexosanes" from celluloses reputed as "normal." In the latter case Tollens "corrects" the figures obtained by multiplying by the factor 1.1, and the present authors see no ground of criticism of such a "correction."

These two methods are selected and commended, and the methods of ordinary practice are adversely criticised.

C. F. C.

NOTE.—Either process leads to a product of degradation of doubtful relationship to the original cellulose. The process of chlorination (following *alkaline* hydrolysis) depends upon specific constitutional (and quantitative) relationships, has been therefore generally adopted, and must be still commended.

Modification of the Sulphonation Test for Creosote. E. Bateman. (*U.S. Dept. Agricult., Forest Service*, Circular 191, December 9, 1911; through *J. Soc. Chem. Ind.*, 1912, **31**, 425.)—The following modification of the sulphonation test is claimed to give more accurate results in a shorter time than the old method: Ten c.c. of the fraction of creosote under examination are treated with four successive portions of 10 c.c. each of $\frac{N}{37}$ sulphuric acid in a Babcock's milk-bottle, which is shaken for two minutes after each addition. It is then kept for an hour at 98° to 100° C., being meanwhile thoroughly shaken every ten minutes, and is subsequently cooled, filled to the mark with ordinary sulphuric acid, and whirled for five minutes in a Babcock's separator, after which the amount of unsulphonated residue is read upon the graduated scale. The reading, multiplied by two, gives directly the percentage of unsulphonated oil by volume. The size of the steam-bath used to maintain a constant high temperature during the sulphonation is immaterial, provided it be large enough to contain completely the bottle beneath its cover.

Estimation of Formaldehyde. E. Rimini and T. Jona. (*Giorn. Farm. Chim.*, 1912, **61**, 49; through *Chem. Zentralbl.*, 1912, I., 1147.)—The usual methods are examined, especially that of Riegler (*Zeitsch. anal. Chem.*, 1901, **40**, 92), depending on the conversion of formaldehyde into formalazine by hydrazine:

$$2CH_2O + H_2N.NH_2 = C_2H_4N_2 + 2H_2O.$$

The excess of hydrazine is determined gasometrically in the sense of the equation:

$$\begin{gathered}15N_2H_4.H_2SO_4 + 10HIO_3 = 15N_2 + 3H_2O + 15H_2SO_4 + 10HI \\ 10HI + 2HIO_3 = 6H_2O + 12I.\end{gathered}$$

Formalazine is slowly attacked by iodic acid, and low values may result. Rimini has simplified the method by working in an alkaline solution, when the reduction does not go beyond the formation of iodide:

$$3N_2H_4.H_2SO_4 + 2KIO_3 + 6KOH = 3N_2 + 2KI + 3K_2SO_4 + 24H_2O.$$

Formalazine is stable in alkaline solution, and nitrogen from the excess of hydrazine only is measured. The method has been further simplified by the substitution of mercuric chloride for hydriodic acid:

$$N_2H_4.H_2SO_4 + 6KOH + 2HgCl_2 = K_2SO_4 + 4KCl + 2Hg + N_2 + 6H_2O.$$

The formalin found by the Riegler method is shown to decrease with the duration of reaction—from 39·00 per cent. after two minutes to 28·40 per cent. after thirty-nine. Tables showing the satisfactory agreement of results by the standard methods with those by the authors' method are given. The estimation is carried out as follows: The volume of nitrogen evolved from 20 c.c. of 1·1 per cent. hydrazine sulphate solution by mercuric chloride is first determined in a Lunge nitrometer; 20 c.c. of the solution are then added to 5 c.c. of the formaldehyde solution (about 1·1 per cent.) and the excess of nitrogen with mercuric chloride measured. The results of the examination of commercial disinfectants containing formaldehyde are given.

O. E. M.

Estimation of Formic Acid in the Presence of other Acids by Means of Potassium Permanganate. A. Fouchet. (*Bull. Soc. Chim.*, 1912, 11, 325-328.)—Small quantities of formic acid (1 to 5 mgrms.) may be estimated in the presence of large amounts of acetic, propionic, butyric acids, etc., by the following method: A solution of 0·05 grm. of the sample in a little water, is added to a mixture of 40 c.c. of crystalline sodium carbonate (50 grms. per litre) and 20 c.c. of potassium permanganate (5 grms. per litre), whilst simultaneously a blank test is made with water instead of the solution. In the case of very dilute solutions of formic acid, the permanganate solution should be diluted (1 : 10), and the other reagents also diluted. The two flasks are immersed for exactly three minutes in boiling water, after which 20 c.c. of dilute (1 : 1) sulphuric acid and 50 c.c. of ferrous ammonium sulphate solution (20 grms. of the salt and 30 grms. of sulphuric acid per litre) are introduced, and the excess of the iron salt estimated by titration with 0·5 per cent. permanganate solution. The difference between the results obtained with each flask gives the amount of oxygen corresponding to the oxidised formic acid, each c.c. of the permanganate solution being equivalent to 1·25 mgrms. of oxygen and 3·51 mgrms. of formic acid. The test analyses quoted in detail show that the method gives accurate results.

C. A. M.

Estimation of Glucose in Leather. J. G. Parker and J. R. Blockey. (*J. Soc. Chem. Ind.*, 1912, 31, 268-269.)—The authors show that in the estimation of glucose in leather, higher results are obtained when normal lead acetate is used for precipitating the tanning matters, etc., than when basic lead acetate is employed. For instance, in one sample 8·7 per cent. of glucose was found with normal lead acetate as against 7·8 per cent. with basic lead acetate. The discrepancy is due to the fact that certain cupric reducing matters—*e.g.*, gallic acid, are not completely precipitated in the presence of acid. The aqueous extract from leather contains some free organic acid, acetic or lactic; consequently the precipitation of the gallic acid would be incomplete when normal lead acetate is used to an extent depending on the free acidity; on the other hand, basic lead acetate would neutralise the free acid, giving a more complete precipitation of the gallic acid, and a lower but more accurate value for the glucose. Lower results are also obtained if the acidity of the aqueous extract be neutralised with potassium hydroxide, using phenolphthaleïn as an external indicator, care being taken not to allow the neutralised solution to stand long before removing the tannins with the lead solution. Previous neutralisation lowers the results for glucose not only with normal, but also with basic lead acetate. It has also been shown that the acidity of the solution affects the precipitation not only of the gallic acid, but also of certain of the tannins—viz., the group of catechol tannins. This is an additional argument against the use of normal lead acetate. J. F. B.

Notes on the Gum Resins. H. Ingle. (*J. Soc. Chem. Ind.*, 1912, 31, 272-273.)—On the question of the "weathering" of kauri and copal gums, the author is inclined to think that the "weathered" gum is probably quite as useful to the varnish-maker as the "bold" gum, and that the varnish prepared from it is less likely to deteriorate by further oxidation. The effect of "weathering" on the gums is shown by a decrease in the iodine value and an increase in the acid value.

Estimation of Kauri, Manila Copal, and Dammar, in a Mixture.—As the acid values of these three gums are so different (kauri = 50 to 70, manila = 107 to 156, and dammar herrol = 30 to 32), it was thought that a separation might be effected by means of sodium carbonate solution. Ten grms. of gum were finely ground, and treated with 300 to 400 c.c. of a 5 per cent. solution of sodium carbonate, boiled, filtered, and washed with the carbonate solution; the filtrate was acidified, and the precipitate collected on a tared filter-paper. The results showed: Kauri gum, 6·1 per cent.; manila, 92·9 per cent.; dammar, 2·5 per cent.

Estimation of Dammar.—The author describes a method based on solubility, which may be used in combination with the above method. The sample is ground to powder, and one or more grams are treated in a beaker or flask with a mixture of 3 parts of alcohol and 1 part of benzene; the residue is filtered off, washed with the same mixture, and then dissolved in carbon bisulphide, the filter being washed three times with this solvent, and the solution collected in a tared flask; the solvent is evaporated, and the extract dried and weighed. After the extraction with alcohol and benzene, kauri and manila gums leave no residue soluble in carbon bisulphide. Dammar herrol gives from 36 to 44 per cent. of matter insoluble in alcohol-benzene, but soluble in carbon bisulphide. If the mixture of gums is in lumps, some of the dammar may be picked out, and the actual solubility value of the particular sample employed may be determined. In a mixture of the three gums the dammar may be estimated by this carbon bisulphide method, and the kauri and manila by the acid value and matter soluble in sodium carbonate; very satisfactory results are obtainable.

SOLUBILITY TABLE OF GUM RESINS.

Solvent.	Kauri.	Manila.	Dammar.
Acetone	Insoluble	Partially soluble	Insoluble
Alcohol	Partially soluble	Soluble	Insoluble
Alcohol and American turpentine	Soluble	Soluble	Partially soluble
Benzene	Insoluble	Insoluble	Partially soluble
American turpentine	95·5 per cent. insoluble	104·0 per cent. insoluble*	—
Amyl acetate ...	5·3 per cent. insoluble	11·5 per cent. insoluble	26·7 per cent. insoluble
Ethyl acetate ...	Soluble	Nearly soluble	Insoluble
Petroleum ether ...	18·6 per cent. soluble	12·1 per cent. soluble	—

J. F. B.

* Result attributable to the oxidation of the solvent.

Separation of Liquids, the Boiling-Points of which lie close together, or which form Mixtures of Minimum Boiling-Point. A. Golodetz. (*Chem. Zeit.*, 1912, **36**, 273-274, 297-298, 302-304.)—Young (*J. Chem. Soc.*, 1902, **81**, 709) effected the dehydration of ethyl alcohol by taking advantage of the fact that ethyl alcohol, benzene (or hexane), and water formed a ternary mixture, which boiled constantly at a temperature lower than the boiling-points of the single constituents, or of the mixtures of minimum boiling-point which alcohol forms with benzene and with water separately. No similar ternary mixture of minimum boiling-point has since been described, but many separations, otherwise difficult or impossible, may be effected by adding a suitable third liquid to the mixture it is desired to resolve, and then distilling. For example, toluene and acetic acid form a mixture of minimum b.-pt. (104° C.), the mixture containing 30 per cent. of acetic acid. Since benzene also forms with acetic acid a mixture of minimum b.-pt. (80° C.), pure toluene remains as the residue in the still when the toluene-acetic acid mixture is distilled with a small excess of benzene. Since a mixture of toluene and water in the proportions 4 : 1 boils constantly at 84° C., the toluene-acetic acid mixture may also be resolved by distilling with water. In this case it is the acid which is separated in a pure condition, and if only a small excess of water be employed, as much as half the acid may be recovered of 99·9 per cent. strength. Similar methods serve for the separation of liquids which do not form mixtures of minimum b.-pt., but which boil at temperatures so nearly the same that separation by ordinary fractional distillation is impossible. For example, the last case may be reversed, and toluene made use of to prepare acetic acid of high strength from more dilute aqueous solutions. Another example of the resolution of mixtures of minimum b.-pt. is that of benzene and methyl alcohol by the agency of carbon bisulphide, which forms with methyl alcohol a mixture of still lower b.-pt.; whilst among mixtures of liquids with b.-pts. lying very close together, the most striking separation is that of amyl bromide (b.-pt. 118·5° to 119° C.) and ethyl butyrate (b.-pt. 119·9° C.) by distillation with propyl alcohol, which forms a mixture of minimum b.-pt. with amyl bromide.

G. C. J.

Ester Method for the Detection of Mono-Amino-Acids together with Polypeptides. E. Abderhalden and R. Hanslian. (*Zeitsch. physiol. Chem.*, 1912, **77**, 283-288.)—The ester method of separating amino-acids resulting from the cleavage of polypeptides, etc., the esters being formed by saturating the alcoholic solution of the acids with dry hydrochloric acid gas, yields trustworthy results, and there is no risk of producing further quantities of amino-acids during the esterification. It is usual to cool the mixture during the latter operation, but experiments with polypeptides of high molecular weight showed that further decomposition does not take place when the mixture is not cooled. Silk fibroin yields no soluble nitrogenous product when esterified, but when the alcoholic solution is saturated with hydrochloric acid and boiled for six hours, considerable quantities of amino-compounds are formed. In the case of casein, boiling the esterified mixture results in only a very small increase of the amino-compounds.

W. P. S.

Estimation of Mercury in Smokeless Powder. J. D. Berkhout. (*Zeitsch. ges. Schiess- u. Sprengstoffwesen*, 1912, 7, 6[illegible].)—In a 50 c.c. wide-mouthed stoppered bottle 2·5 grms. nitrocellulose or nitroglycerine powder are covered with 20 c.c. acetone and kneaded with a glass rod. The sample is sufficiently softened in eighteen hours, and is then transferred to a layer of fine copper oxide in a mortar; the bottle is rinsed out with copper oxide into the mortar. The powder and copper oxide are mixed with a spatula until they form a fine-grained dry mass, most of the acetone having evaporated; this is transferred to a soft-glass tube of 50 cm. length and 14 mm. bore, closed at one end. Ignited asbestos fibre, rinsings of copper oxide from the mortar, asbestos, 15 cm. of coarse copper oxide, and asbestos, are successively introduced, and the tube drawn out into five constrictions, 2 mm. in diameter and 5 cm. long, and four bulbs. The tube is closed with a rubber stopper and bent tube dipping into water. The tube and one bulb are encased in asbestos-lined sheet-iron; the three outer bulbs, projecting through an asbestos card, are water cooled. Heat is applied first to the coarse copper oxide, and gradually extended to the rest of the tube at such a rate that not more than two bubbles per second are given off. When gas evolution has nearly ceased, the capillary is sealed off between the tube and the first bulb, filled up with concentrated hydrochloric alcohol and alcohol, heated in the water-bath, and inverted upon a watchglass containing water. The globule of mercury is measured under the microscope or weighed. O. E. M.

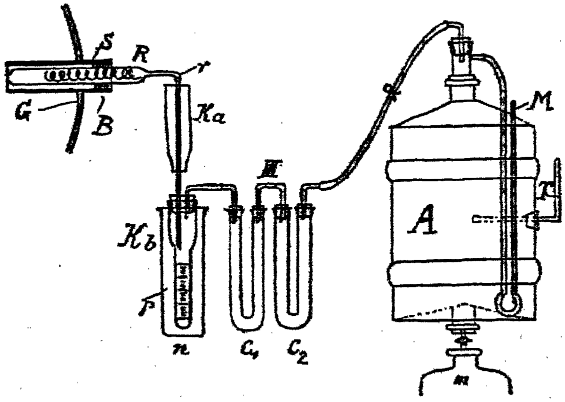
Estimation of Sulphur in Nitrocellulose. C. Kullgren. (*Zeitsch. ges. Schiess- u. Sprengstoffwesen*, 1912, 7, 89.)—The sulphur is present, as a sulphuric acid ester, in combination with nitrocellulose. After several of the known methods for the estimation of sulphur in nitrocellulose had been investigated and rejected, the sample was denitrated by heating it with 10 c.c. of concentrated hydrochloric acid for thirty minutes on the water bath, dried in a large porcelain boat, and burnt in a current of oxygen. The sulphuric acid was arrested by sodium carbonate on granulated quartz. A small quantity of sodium peroxide was added to the solution before the precipitation with barium chloride, to insure that all sulphur is present as sulphuric acid. Nitrocellulose boiled for one-quarter of the usual time showed 27·8 mgrms. of barium sulphate per grm. of substance, unboiled about the same, boiled for one-half the usual time, 17·2, and completely boiled, 14·4. O. E. M.

Influence of Lucidol (Benzoyl Peroxide) on Certain Qualitative Tests for Oils. Atz. (*Chem. Rev. Fett- u. Harz. Ind.*, 1912, 19, 70-72.)—If excessive quantities of the new bleaching agent, "lucidol," have been applied to olive or cottonseed oils, colorations may be obtained with Baudouin's or Soltsien's reagents, which have some resemblance to those given by sesamé oil. On the other hand, in certain tests for other oils—*e.g.*, Becchi's reaction for cottonseed oil—the coloration is produced with the same intensity in the presence of "lucidol," but the occurrence of the reaction is retarded. In the case of some other colour reactions, the intensity of the coloration is sometimes reduced, as, for instance, in the reactions for cottonseed and sesamé oils. It is, therefore, necessary to take the possibility of the presence of "lucidol" into account in testing oils, such as olive oil, for the presence of small quantities of other oils. C. A. M.

Estimation of Petroleum Spirit and Benzene Hydrocarbons in Turpentine Oil. J. Marcusson. (*Chem. Zeit.*, 1912, **36**, 413-414; 421-422.)—In Burton's method of estimating petroleum spirit in turpentine oil the sample is treated under specified conditions with fuming nitric acid, in which turpentine oil is completely soluble, whereas in the presence of petroleum spirit one portion of the latter (naphthenes and paraffin hydrocarbons) is undissolved, whilst another part (aromatic hydrocarbons) is dissolved, but may be separated from the nitro-derivatives of the turpentine oil by means of its insolubility in water. Criticisms have been brought against this method by Herzfeld (*Chem. Zeit.*, 1910, **34**, 885) and others, but the author shows that it gives good results, which are independent of the nature of the petroleum spirit, which may contain but little benzene hydrocarbons (as in the case of Russian and Pennsylvanian products) or be rich in those hydrocarbons (Indian and Galician petroleum spirits). The method is, therefore, to be preferred to that of Eibner and Hue (ANALYST, 1910, **35**, 358), which, as its originators showed, is not applicable to the heavy Indian petroleum spirits, such as Sanga oil, which at the present time are extensively used in the preparation of substitutes for turpentine oil. In testing a mixture 10 c.c. of the sample are introduced, little by little, during the course of thirty minutes, into 30 c.c. of fuming nitric acid (sp. gr., 1·52) chilled to − 10° C. The mixture is left for fifteen minutes, and then treated with 75 to 80 c.c. of concentrated nitric acid (sp. gr., 1·4); and should no oily layer appear upon the surface of the liquid, the absence of petroleum spirit is indicated. For the detection of benzene hydrocarbons, the solution is poured into 150 c.c. of water in a 500 c.c. flask with a neck graduated in $\frac{1}{10}$ths c.c., and heated for fifteen minutes on the water-bath, after which the flask is allowed to stand for some hours. The separation of heavy reddish-brown oily drops (not merely slight resinous masses) denotes the presence of benzene hydrocarbons. For an approximate estimation of these hydrocarbons, the product of the reaction is treated with sulphuric acid (sp. gr., 1·6) until the oily nitro-derivatives are driven into the graduated neck of the flask, where their volume may be read. In test estimations with mixtures containing from 10 to 50 per cent. of benzene, toluene, or xylene, the results agreed within 4·5 per cent. of the theoretical amount, whilst with technical benzene preparations ("solvent naphthas") the maximum difference was 3 per cent. If the presence of more than 50 per cent. of benzene hydrocarbons be suspected from the bromine value, etc., the heating of the diluted nitric acid solution should be omitted, since, in the absence of sufficient turpentine oil, the hydrocarbons in these solvent naphthas are attacked under these conditions. On the other hand, omission of the heating causes the proportion of nitro-derivatives to be too high, and to correct this the result should be divided by the factor 1·15. The figures will then correspond within about 4 per cent. with the theoretical amounts. C. A. M.

Application of the Formolite Reaction to the Analysis of Paraffin Wax. F. Sommer. (*Petroleum*, 1912, 7, 409; through *Chem. Zentralbl.*, 1912, I., 1151.)—The oils contained in commercial paraffin wax determine its tendency to turn yellow and its transparency, both important factors in a valuation. Drainings from the paraffin sweating process were repeatedly sweated, cooled to below 0° C., and pressed in filter-cloths. The resulting oil contained only small quantities of saturated hydrocarbons; its iodine value was 444; three-quarters of it dissolved in concentrated sulphuric acid, and it gave 63 per cent. of formolite. To represent the transparency in figures, the liquid hydrocarbons must be determined; the yellowing tendency is, however, a function of the formolite number, as the table of results shows. This is determined as follows: To 20 grms. of the molten paraffin in 20 c.c. of concentrated sulphuric acid are gradually added 20 c.c. of formaldehyde. The dark red mixture is heated on the water-bath for twenty minutes, poured into a porcelain dish, left on the water-bath until paraffin and reaction-mixture separate, and cooled; the cake of paraffin is removed, and the liquid beneath diluted and shaken out with chloroform. The chloroform extract is evaporated, the residue dried at 105° C., and the formolite weighed. All samples examined were exposed to diffused daylight. The formolite number is suggested as a criterion of the quality of paraffins; factories having a uniform supply of paraffin oil can compare colorimetrically the chloroform solution with a normal colour. The authors state that a paraffin wax with more than 0·75 per cent. oil is always opaque. O. E. M.

Estimation of Tar in Producer Gas. A. Gwiggner. (*Chem. Zeit.*, 1912, **36**, 461-462.)—The apparatus of Tieftrunk is useless for the estimation of tar in hot-producer gas. The apparatus now figured serves well for this purpose. A wrought iron tube, *S*, is screwed into the gas main, *G*, to support the tar-filter, *R*, which is formed from combustion tube 30 to 35 mm. in diameter, packed with slag wool, and drawn out at one end and constricted at the other. Its wide portion is about 40 cm. long. The condenser tube, *r*, carries a removable condenser, *Ka*, and leads into the measuring tube, *P*. *Ka* and *Kb*, the beaker in which *P* stands, are filled with ice water. C_1 and C_2 are tubes containing calcium chloride, and *A* is an aspirator of at least 10 litre content. Before use *R* is weighed separately; *r* and *P*, disconnected from the condenser, *Ka*, are weighed together; and C_1 and C_2 are weighed separately. Even with a very brisk stream of gas, no visible fog reached C_1, and the increase in the weight of this tube is due to moisture alone. The increase in weight of the system $r+P$ is due to light oil and moisture, and the latter can be separately estimated by washing down *r* with benzene or light petroleum, diluting the contents of *P* somewhat with the same solvent, and reading off the water by means of the graduations on *P*. The increase in the weight of *R* is due to soot, tar, and some moisture. To determine these separately, *R* is



connected to apparatus similar to the system $r+P+C_1$, and a current of hot dry air is led through the whole train of apparatus. The moisture finds its way to the graduated tube and calcium chloride tube. Usually a little light oil finds its way into the graduated tube, and is separated from the water in the manner already described. The tube R is next weighed, its contents washed with benzene so long as the escaping benzene is discoloured, and is finally dried and weighed. The loss of weight on treatment with benzene gives the content of tar, and the increase of weight as compared with the weight at the commencement of the test gives the content of soot. Some ten weighings in all are necessary, but it is said that no simpler method will give results of any value where the gas to be sampled is producer gas at temperatures in the neighbourhood of 600° C. G. C. J.

New Uric Acid Reaction. D. Vitali. (*Boll. Chim. Farm.*, 1911, **50**, 799; through *Chem. Zentralbl.*, 1912, I., 1252.)—Ganassini (*Boll. Chim. Farm.*, 1908, **47**, 715) has stated that uric acid in alcoholic solution gives, with various oxidising agents an oxidation product which forms a characteristic blue basic salt with zinc salts. The author finds that the oxidation may be effected with sodium peroxide, and that as little as $\frac{1}{10}$ c.c. of freshly prepared alkaline uric acid solution then gives a positive reaction. A reaction is not obtained with other oxidising agents, such as hydrogen peroxide, turpentine, turpentine + blood, pus, and copper sulphate + hydrocyanic acid. Permanganate solution produces a yellow coloration, and, on the addition of zinc sulphate, a white precipitate insoluble on warming. If copper sulphate is substituted for zinc sulphate, a green precipitate, or with a larger quantity, a blue precipitate, is formed; cobalt chloride, and a nickel salt give respectively blue-violet and yellow-green precipitates, reactions which are very sensitive, and can be used to distinguish between nickel and cobalt salts. The precipitate with neutral antimony acetate is brown-red; with mercuric chloride white, or on warming, vermilion; with silver nitrate metallic silver is obtained. The blue colour of the basic zinc urate is destroyed by the addition of sulphur or of hydrocyanic acid. The reducing action of zinc or of sodium hydrogen sulphite in the alkaline reaction mixture does not cause decoloration. O. E. M.

INORGANIC ANALYSIS.

Volumetric Estimation of Beryllium. B. Bleyer and A. Moormann. (*Zeitsch. anal. Chem.*, 1912, **50**, 360-367.)—Normal beryllium salts are so far hydrolysed in aqueous solution that their solutions have a fairly strong acid reaction, and will set free iodine from a solution of potassium iodide and iodate. If sufficient of this solution be added, the hydrolysis is quantitative and the beryllium may be estimated from the iodine set free—$BeCl_2 = I_2$. If the iodine be distilled over into potassium iodide solution, using a curent of hydrogen to drive the last of the iodine vapour out of the apparatus, the results, as determined by titration of the iodine with thiosulphate, will be constantly 1 per cent. below those indicated by theory. Omission of the current of hydrogen doubles the error, which in such circumstances is also less constant.

In pure aqueous solution, salts of beryllium may be estimated by titration with standard caustic alkali, using phenolpthaleïn as indicator. Beryllium sulphate must be converted into chloride by addition of barium chloride before it can be titrated in this way. In the ordinary course of analysis the beryllium salt most often presents itself in solutions containing excess of acid. In such cases concentrated caustic soda, free from carbonate, is added to the solution drop by drop until the precipitate of beryllium hydroxide first formed has re-dissolved as beryllate, and the alkaline solution is made up to known bulk. Aliquot portions are then titrated with standard acid, using phenolpthaleïn and methyl orange as indicators. The difference between the two titrations is the measure of the beryllium—Be = 2HCl. The solution should not contain much more than 0·03 per cent. of beryllium, as otherwise the end point of the phenolphthaleïn titration is a little difficult to determine. The titration should be made at a temperature of 30° to 40° C., and it has to be remembered that towards the end of the methyl orange titration the reaction proceeds somewhat slowly. The test numbers which accompany the paper are all almost exactly 1 per cent. low.

G. C. J.

Estimation of Boric Acid in Nickel Baths. A. Wogrinz and J. Kittel. (*Chem. Zeit.*, 1912, **36**, 433-434.)—Experiments are described which show that the amount of boric acid in nickel-plating baths cannot be estimated with any approach to accuracy by the method of Rose, or by that of Marignac. Methods depending on the titration of the boric acid in presence of a large quantity of some polyhydric alcohol give sufficiently accurate results, but only after removal of the ammonium salts, the concentration of which in nickel-baths may be considerable. The sample (100 c.c.) is first electrolysed to throw out nickel and decompose citric acid, which is nearly always present in such baths. The solution is then made strongly alkaline by addition of 10 grms. of caustic soda and evaporated in a nickel dish to decompose ammonium salts. The residue is made acid with hydrochloric acid and the solution diluted to 25 or 30 c.c., and heated to expel carbon dioxide. After allowing to cool, the solution is exactly neutralised to methyl orange, 100 c.c. of a 10 per cent. solution of mannitol is added, and the boric acid titrated in the usual manner with $\frac{N}{5}$ caustic alkali, using a considerable quantity of phenolphthaleïn as indicator. The results are from 0·5 to 1 per cent. high, calculated on the boric acid. G. C. J.

Sources of Error and the Electrolytic Standardisation of the Conditions of the Iodide Method of Copper Analysis. A. W. Peters. (*J. Amer. Chem. Soc.*, 1912, **34**, 422-454.)—The various methods for the standardisation of sodium thiosulphate may be classified by groups, and the differences between the values found by the different groups far exceed the limits of error of the methods of the same group. Thus, for the estimation of copper, the thiosulphate must be standardised against a copper solution, and accurate results cannot be expected by employing a factor based on an iodine standard. The author has worked out a rapid electrolytic method for standardising a copper solution for this purpose. An alkaline electrolyte is employed, the reagent containing 35 grms. of Rochelle salt and 25 grms. of purified potassium hydroxide per 100 c.c.; 10 c.c. of the copper solution are mixed with 10 to 20 c.c. of this reagent, and a quantity of a saturated solution of potassium cyanide, ranging from 0·4 to 1·0 c.c. is added. The cyanide controls the rate of deposition and the hardness of the deposit, but if too large a quantity be employed, the time required for complete precipitation is lengthened. Rapid deposition is obtained by using a high voltage, high current density, and keeping the temperature near the boiling-point. For preparing solutions of copper for titration by the iodide method, the copper is heated in an Erlenmeyer flask with the smallest necessary quantity of slightly diluted nitric acid. The solution is diluted, powdered talc is added, and the mixture is boiled vigorously for five to ten minutes. The rapid ebullition quickly removes nitrous acid, and the liquid is then cooled and diluted. Sulphuric acid may be added to the nitric acid solution when a solution of the sulphate is desired. The accuracy of the results obtained by the iodide method is influenced by varying concentrations of mineral acids, and by the presence of large amounts of salts. In the latter case, as, for instance, when the alkaline copper solutions from sugar analyses have to be titrated, sulphuric acid must be used instead of acetic acid in order to obtain good results. For instance, when the total volume of reduction-liquor was 60 c.c., consisting of 20 c.c. of Ahlin's alkaline tartrate solution, 20 c.c. of Fehling's copper sulphate, and 20 c.c. of water, the precipitated cuprous oxide could be filtered off and washed, giving a total volume of 70 to 75 c.c. of filtrate. The addition of 3·45 to 5·0 c.c. (best 4 c.c.) of concentrated sulphuric acid to this volume of liquid gave good results on titration, but smaller amounts were unsatisfactory. In working with ordinary solutions of copper (*i.e.* where no alkali has to be neutralised), normal results are obtained with 1 c.c. of concentrated sulphuric acid in 60 of the final liquid, or with 1 c.c. of strong acetic acid in 6 of the solution. A further essential factor for success is the presence of a sufficiently large quantity of potassium iodide; this is best employed in the form of a saturated solution containing about 1·1 grm. of the salt per 1 c.c. In titrations completed at a total volume of 60 c.c., 5 c.c. of the iodide solution are required; for titrations at a final volume of 120 c.c., 6 to 10 c.c. of iodide are used. Lastly, the question of the end-point requires careful attention, since it is not readily observed in presence of the cuprous iodide. So long as a drop of thiosulphate falling into the solution produces a white area, the end-point is not reached. It is best to have a burette containing standard iodine always at hand, and to verify the end-point by titrating back again immediately. Provided the above precautions be taken, the results of the iodide method are quite unaffected by the concentration of the copper. J. F. B.

Relation of the Refractive Index of Soda Lime Glasses to their Chemical Composition. E. W. Tillotson, Jun. (*J. Ind. Eng. Chem.*, 1912, **4**, 246-249.)—A number of batches of glass of known chemical composition were prepared, and the density and refractive index of each was determined, and the specific refractivities calculated by the formula of Lorenz and Lorentz (*Wied. Ann.*, 1880, **9**, 641; 1882, **11**, 70) $\frac{n^2-1}{n^2+2} \times \frac{1}{d} = K$. On plotting the values of K thus obtained as abscissæ in a system in which the ordinates represented the chemical composition of the glasses, which ranged from $Na_2O.3\ SiO_2$ to $CaO.SiO_2$, K was found to be a linear function of the chemical composition, at any rate until the molecular ratio of lime to soda reaches 3 : 2. At this point there is a slight change in the direction of the curve, but in very few glasses does the ratio of lime to soda exceed this limit. Since the specific refractivity is linear, it may be computed by means of the following equation $K = \frac{P_1K_1}{100} + \frac{P_2K_2}{100} + \frac{P_3K_3}{100}$, etc., in which P_1, P_2, P_3, etc., are the percentages of the oxides and, K_1, K_2, K_3, etc., the empirically determined specific refractivities of the oxides. For soda lime glasses these are as follows:

SiO_2 . . . 0.1220, CaO . . . 0.1210, Na_2O . . . 0.1302.

G. C. J.

Use of the Mercury Cathode, particularly in the Electro-Analytical Separation of Metals. P. Baumann. (*Zeitsch. anorg. Chem.*, 1912, **74**, 315-350.) The author has applied his apparatus (ANALYST, 1911, **36**, 529) to the separation of mercury from bismuth, mercury from copper, and silver from bismuth, all of which separations may be made rapidly at ordinary temperatures. For the reasonably rapid separation of copper from antimony, copper from cadmium, and bismuth from cadmium, a temperature of about 70° C. is necessary. It is probable that cadmium could be separated from zinc by means of the mercury cathode; but the separation is so slow, and requires so much of the analyst's attention, that the method could serve no useful purpose. One difficulty in the use of a mercury cathode is the need of considerable quantities of ether which shall be without action on mercury. Simple distillation of the ether does not get over the difficulty, as, within a few days, it re-acquires the faculty of giving rise to a black film on the surface of mercury with which it is brought in contact. If the ether be stored in a large distilling flask over caustic potash, and distilled in small quantities as wanted, the trouble is overcome, and the distillate remains for three or four weeks without action on mercury.

G. C. J.

Perchloric Acid in Electrochemical Analysis. W. S. Hendrixson. (*J. Amer. Chem. Soc.*, 1912, **34**, 389-392.)—In a recent paper by H. Golblum (*Zeitsch. anal. Chem.*, 1911, **50**, 741) on the electrolytic decomposition of nickel and cobalt perchlorates, it was shown that perchloric acid is remarkably stable, and therefore suitable for general purposes in electrolytic work. The only reducing agents which decompose perchloric acid in solution appear to be freshly precipitated ferrous oxide, sodium thiosulphate, and, to a small extent, some oxides of nitrogen; in fact, in aqueous solutions perchloric acid exhibits only the properties due to its primary ions, and there are no side reactions due to the decomposition of its negative ion. Besides being stable, it is also a "strong" acid—*i.e.*, highly dissociated, and metals may easily be converted into their perchlorates for electrolysis. Perchloric acid readily dissolves many oxides of the heavy metals, and in other cases the nitrates may be converted almost quantitatively into perchlorates by evaporation with an excess of perchloric acid. From potassium nitrate 94 per cent. of the nitric acid was expelled, and from copper nitrate 98 per cent. The author describes the electrolytic deposition of copper, silver, and cadmium from perchloric acid solutions. Pure copper oxide was dissolved in a small excess of perchloric acid, and subjected to electrolysis in a platinum dish with a rotating anode; the results were perfectly satisfactory. Silver was dissolved in nitric acid, and the resulting silver nitrate evaporated twice on the water-bath with water and perchloric acid, a trace only of nitric acid being left in the perchlorate. In the subsequent electrolysis silver oxide tended to collect on the anode, but was redissolved, especially on warming, long before the current was stopped. With cadmium also a satisfactory deposit was obtained from a solution of the oxide in perchloric acid. The acidity in all these experiments ranged from 0·03 to 0·4 normal, mostly round about 0·1 normal. J. F. B.

Standardisation of Potassium Permanganate Solution by Sodium Oxalate. R. S. McBride. (*J. Amer. Chem. Soc.*, 1912, **34**, 393-416.)—On behalf of the Bureau of Standards, the author has subjected the process of standardising permanganate solution by means of sodium oxalate to a complete revision, studying the effect of every conceivable variation and source of error separately—viz., temperature, acidity, volume of solution, rate of addition of the permanganate, access of air, and presence of added manganous sulphate. In connection with the question of the excess of permanganate present when the end-point is determined, the author has confirmed the accuracy of Bray's method, according to which the titrated solution is cooled, treated with potassium iodide, and the iodine liberated is titrated back with 0·02 N thiosulphate. He found that the residual oxidising power of the small excess of permanganate required to establish an end-point remains unchanged for at least half an hour, and consequently the lapse of five to ten minutes required for cooling the solution is quite negligible. Using this control, the author found that if the end-point be approached slowly in a solution at a temperature above 60° C., the depth of colour is proportional to the excess of permanganate present. The chief possible source of error is the continued existence of manganese in the higher stages of oxidation, resulting in an apparent loss of oxygen, due to low temperature, large bulk of the solution, too rapid addition of permanganate (especially at the start or just before the end-point), and insufficient stirring. On the other hand, the addition of manganous sulphate decreases the consumption of permanganate. The author finally recommends the following procedure: In a 400 c.c. beaker dissolve 0·25 to 0·3 grm. of sodium oxalate in 200 to 250 c.c. of hot water (80° to 90° C.), and add 10 c.c. of dilute (1 : 1) sulphuric acid. Titrate at once with $\frac{N}{10}$ potassium permanganate solution, being very careful to stir the liquid vigorously and continuously. The permanganate must not be added more rapidly than at the rate of 10 to 15 c.c. per minute, and the last 1 to 0·5 c.c. must be added drop-wise, with particular care to allow each drop to be fully decolorised before the next is introduced. The excess of permanganate used to cause an end-point colour must be estimated by matching the colour in another beaker containing the same bulk of acid and hot water. The solution should not be below 60° C. by the time the end-point is reached; more rapid cooling may be prevented by standing the beaker on a hot plate during titration. The use of a small thermometer as a stirring-rod is recommended. The author employed a weight burette delivering a drop of 0·03 c.c. for his titrations; the influence of temperature changes due to the steam rising from the hot liquid is thereby avoided.

The accuracy of the above method is claimed to be within 0·1 per cent.; probably the error does not exceed 0·05 per cent. J. F. B.

Direct Determination of Small Amounts of Platinum in Ores and Bullion. F. P. Dewey. (*J. Ind. Eng. Chem.*, 1912, 4, 257-258.)—The old method of parting by means of sulphuric acid, re-alloying with silver, and parting with nitric acid, is quite useless for the determination of small amounts of platinum. The second weighing may possibly exceed the first, even when traces of platinum are present, and other members of the platinum group may go into solution in nitric acid and be estimated as platinum. Small amounts of platinum (and gold) may be estimated accurately and conveniently as follows: The silver alloy first obtained in the regular course of assay is parted with nitric acid in the usual way, platinum, if present in small amount, passing into solution with the silver. The solution is evaporated, if strongly acid, and then diluted, and about 1 or 2 c.c. of strong hydrogen sulphide solution diluted to 15 to 30 c.c. is added. After three or four hours, or, better, after standing overnight, the precipitate of silver sulphide containing all the platinum metals, if these were present in small amount, is filtered off, dried, and ignited. The resulting metallic sponge is wrapped in lead-foil, cupelled, and parted by means of strong sulphuric acid. If the amount of fine metal is considerable, the actual platinum may be determined by the double chloride method. In the examination of fine silver for traces of platinum and gold, 100 grms. or more of the silver is dissolved in nitric acid, the bulk of the acid evaporated, and the gold and platinum, with some silver, precipitated in the diluted solution (250 c.c.) by 5 c.c. of strong hydrogen sulphide diluted to 50 c.c. The sulphide precipitate is filtered off, ignited, and cupelled, the lead parted with nitric acid, and the gold weighed. The platinum in solution is then precipitated with hydrogen sulphide in the manner already described, and parted from silver by means of sulphuric acid. In this way two purchases of fine silver were found to contain, in each 100 grms., 0·23 and 0·10 mgrm. of gold, and 0·55 and 0·14 mgrm. of platinum, respectively.

In the case of material containing a considerable amount of platinum, the well-known fact that platinum alloyed with silver is not entirely soluble in nitric acid must be considered. In such a case the gold must be realloyed with silver, and reparted two or three times.

The possibility of the application of the method to the estimation of noble metals in copper and similar materials is indicated, but no experiments in this direction are described. G. C. J.

Estimation of Gold, Silver, and Platinum. Trenkner. (*Metallurgie*, 1912, 9, 103.)—The assay of platinum by cupellation with lead requires an excessive temperature, and the bead formed contains lead and is brittle. Gold and platinum may be estimated to 0·05 per cent. by the following method. For the preliminary assay 500 parts by weight (500 mgrms. = 1,000 parts by weight for alloys with more than 25 per cent. gold + platinum; 1,000 mgrms. = 1,000 parts by weight for poorer alloys) are cupelled at 900° to 950° C. with 3 to 15 grms. lead, according to the amount of base metal present; from the more or less grey, flat, and rough appearance of the bead, the content of gold and platinum is judged, or is roughly determined by weighing the residue after dissolving in concentrated sulphuric acid. For the assay itself 500 parts by weight, with ten times as much silver (*cf.* Sharwood, *J. Soc. Chem. Ind.*, 1904, **23**, 412) as the platinum and gold found by the preliminary determination, are cupelled with lead; the bead, less the silver added, gives the weight of gold, platinum, and silver. The amount of silver lost is found by cupelling a known similar alloy. The bead is dissolved in 25 to 30 minutes in 25 c.c. of sulphuric acid of sp. gr. 1·84, which is heated, but not boiled; decanted and washed three times with water; the residue gently ignited and dissolved in a minimum quantity of *aqua regia*, most of which is then driven off; the liquid is diluted with water, and the silver chloride removed by filtration; 15 c.c. of hydrochloric acid of sp. gr. 1·19 are added to the filtrate, the volume of which is about 150 c.c., and the gold precipitated with 1 grm. of hydrazine hydrochloride, allowed to stand with occasional stirring for one hour, filtered, ignited, and weighed. To remove any platinum it is fused on a cupel with a small quantity of lead and five to eight times its weight of silver, and the platinum and silver dissolved out by boiling with nitric acid. The platinum is precipitated from the gold filtrate by ammonia (Jannasch, *Ber.* 1903, **37**, 1980) or with potassium hydroxide. O. E. M.

Estimation of Sulphates in Solution by the Physico-Chemical Volumetric Method. A. Bruno and P. T. d'Auzay. (*Comptes rend.*, 1912, **154**, 984-986.)—Dutoit and Duboux (ANALYST, 1908, **33**, 90) proposed a method for the estimation of sulphates, notably in wines, by adding to the liquid $\frac{N}{4}$ baryta water, and measuring the electrical conductivity after each addition, plotting the values in the form of a curve. Theoretically, such a curve should show a minimum point corresponding to the total precipitation of the sulphates. On applying this method to a number of French wines, however, the authors found that the results were inaccurate in about three-quarters of the cases. They have therefore tested the method on aqueous solutions containing sulphuric acid, potassium sulphate, potassium bitartrate, tartaric acid, and malic acid, alone or in the form of mixtures.

The results in the case of solutions containing sulphates were classified in the following manner: 1. The curve shows no minimum point. This is the case with a pure solution of neutral potassium sulphate, where the end of the precipitation is shown by the intersection of two ascending straight lines. 2. The curve shows a minimum point. This is the case with all the other solutions in which sulphates were present, and the results are subdivided as follows: (1) The minimum corresponds actually and exclusively to the total precipitation of the barium sulphate with (*a*) sulphuric acid alone; (*b*) sulphuric acid in presence of potassium bitartrate, in which case the curve consists of three straight lines, one of them descending. (2) The minimum point never corresponds to the end of the precipitation with (*c*) potassium bisulphate alone; (*d*) sulphuric acid in presence of tartaric or malic acid. In the case of (*c*) the minimum point coincides with the precipitation of half of the total sulphuric acid. In the case of (*d*) the minimum point always occurs after the total precipitation of the sulphate, and the neutralisation of the organic acid only takes place after that of the sulphuric acid. (3) Lastly, the minimum point may coincide with the total precipitation in the case of potassium sulphate, neutral or acid, in presence of bitartrate or organic acids; but the phenomenon is quite fortuitous and unreliable, depending on complex equilibria which may become established. This case corresponds to wines. Similar conclusions were arrived at in the case of dilute alcoholic solutions, and the proposed method, therefore, cannot be used for the estimation of sulphates in wines. J. F. B.

Modification of the Method of Arnold and Hardy for the Rapid Estimation of Sulphur in Siderurgical Products. F. Giolitti and M. Marantonio. (*Rassegna Mineraria, Metallurgica e Chimica*, 1911, 35; through *Chem. Zentralbl.*, 1912, 1, 1250.)—The method of Arnold and Hardy (*Chem. News*, 1888, **58**, 41) consists in converting the sulphur into sulphuretted hydrogen, and observing how far the precipitation of lead sulphide progresses in a series of vessels containing lead acetate solution of known strength. The authors suggest (1) an improved form of vessel, more easily cleaned than the original one; and (2) the passage of the gas through a heated tube, to decompose organic sulphur compounds incapable of reaction with lead acetate, before it reaches the vessels. Sample analyses, with controls in which the sulphur is determined independently, show the utility of the method.

O. E. M.

Estimation of Sulphur in Insoluble Sulphides. T. S. Warunis. (*Ber.*, 1912, **45**, 869-870.)—The method previously described for the estimation of sulphur in coal (ANALYST, 1911, **36**, 375) has been extended, with slight modification, to the estimation of sulphur in insoluble sulphides. The substance (0·5 grm.) is heated in a porcelain crucible with a mixture of 4 parts sodium carbonate and 3 parts copper oxide, at first at a low heat, but finally with the full flame of a Bunsen burner. The mixture is frequently stirred during the heating, which should be continued for two hours. The contents of the crucible, when cool, are boiled out successively with water, sodium carbonate solution, and again with water, and the solution is filtered and acidified with hydrochloric acid. In absence of metals which form insoluble sulphates the contents of the crucible may be dissolved at once in hydrochloric acid. After separation of silica, if present, by evaporation, the hydrochloric acid solution of the sulphate is precipitated hot with barium chloride, and the precipitate treated in the usual manner. An analysis of pyrites gave 53·16 per cent. sulphur against 53·04 by Fresenius's method; and an analysis of mercuric sulphide gave 13·75 per cent. sulphur, as compared with 13·65 per cent. obtained after oxidation by means of potassium chlorate and concentrated nitric acid. G. C. J.

Rapid Determination of Vanadium in Steel. F. Garratt. (*J. Ind. Eng. Chem.*, 1912, **4**, 256-257.)—The following modification of Johnson's method ("Chemical Analysis of Special Steels," p. 8) is found by the author to be preferable to any other for routine work. The steel (2 grms.) is dissolved in 50 c.c. of dilute sulphuric acid, and 5 c.c. of nitric acid is then added to oxidise the iron and any tungsten which may be present. The solution is boiled until nitrous fumes are no longer evolved, or, in the case of tungsten steels, until the separated tungstic acid is of a pure yellow colour. The solution is next diluted to about 150 c.c., filtered from tungstic acid, if this is present, and cooled to room temperature. It is then further diluted to about 350 c.c., ferrous sulphate is added, and then dilute permanganate from a burette until a permanent pink tint is just reached. Potassium ferricyanide is added as indicator, and the vanadium titrated with standard ferrous ammonium sulphate. Blanks must be run on steels of similar composition, and consistent end-points adhered to in titrations. The author agrees that for umpire work, and in any case where a sample concerning which nothing is known has to be analysed, a method of more general application, such as that of Cain (ANALYST, 1911, 36, 475), must be used; but he considers that in routine work these more exact methods give no more useful information, whilst they consume more time.

G. C. J.

Rapid Method for Determination of Vanadium in Steels, Ores, etc., based on its Quantitative Inclusion by the Phosphomolybdate Precipitate. J. R. Cain and J. C. Hostetter. (*J. Ind. Eng. Chem.*, 1912, 4, 250.)—For steels containing vanadium, chromium, nickel, titanium, manganese, molybdenum, singly or in combination, an amount of drillings estimated to contain from 2 to 10 mgrms. of vanadium is dissolved in nitric acid (sp. gr. 1·135), of which about 20 to 25 c.c. is taken for each grm. of drillings. The solution is boiled until free from fumes, oxidised with permanganate solution ($1\frac{1}{2}$ per cent.), the manganese peroxide is dissolved by addition of sulphurous acid, and the solution again boiled until free from fumes. It is then nearly neutralised with ammonia (1 : 2), and a solution of sodium phosphate is added in such amount that there is at least ten times as much phosphorus as there is vanadium present. The solution is heated to boiling, and, after removal from the hot plate, ordinary molybdate reagent (0·05 to 0·06 grm. MoO_3 per c.c.) is added at the rate of at least 2 c.c. for each mgrm. of phosphorus present, and in no case less than 50 c.c. The mixture is agitated for a minute or so, the supernatant liquid decanted through an asbestos filter, and the precipitate washed three times by decantation with a hot solution of acid ammonium sulphate, made by adding 15 c.c. of ammonia (sp. gr. 0·9) and 25 c.c. of strong sulphuric acid to 1,000 c.c. of water. The last wash liquor is decanted off as completely as possible from the precipitate in the flask, and the filter is sucked dry. The filter is now connected to a small dry pump flask, and the small amount of precipitate on it is dissolved in hot concentrated sulphuric acid, which is then sucked through the filter and transferred to the flask containing the bulk of the precipitate, and the pump flask is rinsed out once with sulphuric acid. The total amount of acid used should be from 5 to 8 c.c. for every 10 mgrms. of phosphorus present. The contents of the flask are heated until solution takes place, a few drops of nitric acid (1 : 25) are added, and the solution is heated until it fumes strongly. It is then removed from the hot plate, and successive small additions of hydrogen peroxide solution are made, with vigorous shaking after each addition, until the solution assumes a deep brown colour, due to action on the molybdate. The flask is replaced on the hot plate and kept fuming for four or five minutes, when the brown colour gives place to a green or blue. The flask is covered and its contents cooled, and then poured into four times its volume of cold water and titrated at 70° to 80° C. against $\frac{N}{100}$ permanganate.

The function of the hydrogen peroxide is to reduce vanadium to the tetravalent state.

With steels containing tungsten, the only change necessary is to dissolve in *aqua regia*, dilute with hot water, filter off the tungstic acid, nearly neutralise with ammonia, and add 10 grms. of ammonium nitrate for every 100 c.c. of the final volume before precipitating as above described.

The behaviour towards solvents of a phosphomolybdate precipitate containing vanadium is very different from that of pure ammonium phosphomolybdate, and the choice of an acid solution of ammonium sulphate as wash liquor is based on experiments which are described in the paper, and which have some bearing on the estimation of phosphorus in steels containing vanadium.

The method can be extended to the estimation of as much as 30 mgrms. of vanadium, but the manipulation in such cases becomes inconvenient. From 2 to 10 mgrms. can be estimated with an error not exceeding 2 per cent., and the method permits of the concentration of the vanadium from 50 or 100 grms. of steel of low vanadium content, so that extremely small percentages can be determined with ease. A method is described whereby the vanadium may be separated as pentoxide in cases where there could be the slightest doubt of its being present at all. G. C. J.

New Method for Determination of Vanadium in Steel. D. J. Demorest. (*J. Ind. Eng. Chem.*, 1912, 4, 249-250.)—The method depends on the selective oxidation of ferrous sulphate in the presence of vanadyl sulphate by means of manganese dioxide. The vanadyl sulphate is then titrated by adding excess of permanganate, the excess permanganate being determined by means of sodium arsenite. The manganese dioxide should be sufficiently fine to pass through a 200-mesh sieve, and yet should settle in a beaker of water in thirty seconds (see next abstract). The borings (2 grms.) are dissolved in a mixture of 30 c.c. water and 12 c.c. sulphuric acid contained in a 500 c.c. flask. The iron is oxidised by addition of 1 c.c. of nitric acid, and the solution is boiled for a few minutes to remove nitrous fumes. It is then diluted with 30 c.c. of water, and excess of strong permanganate solution is added, and the solution boiled to completely oxidise all carbon. Ferrous sulphate is next added to reduce manganese dioxide, permanganate, chromate, and vanadate, and the solution again boiled to expel any possible nitrous fumes. The solution is diluted to about 250 c.c., and, after addition of $\frac{N}{10}$ permanganate until a pink colour persists, it is cooled. Ferrous sulphate is now added in amount at least sufficient to reduce all the chromic and vanadic acid, and any other reducible compound which may be present, but a large excess should be avoided. The solution is next shaken vigorously with about 1 grm. of manganese dioxide, and after two minutes a drop is tested with ferricyanide. The test is repeated at intervals of a minute, shaking all the while, until, usually in about five minutes, ferrous iron is found to be absent, when the shaking is continued for about another half minute, and the solution is then filtered through asbestos, using suction. The reduction of the iron is complete when the drop withdrawn does not instantly develop a blue colour when added to a drop of ferricyanide. A blue colour always develops in the course of a few seconds, due to the reduction of ferricyanide to ferrocyanide by the vanadyl sulphate. To the filtered solution standard permanganate is added from a burette until a pink tinge persists; 1 c.c. more is then added, and the excess of permanganate is titrated with sodium arsenite solution. The standard solutions employed correspond to 0·001 grm. vanadium per c.c. A blank determination must be run on a vanadium-free steel, the blank being generally about 0·7 mgrm. vanadium. Quantities of vanadium up to 7 mgrms. in 2 grms. of steel may be determined with an error not exceeding 0·1 mgrm., and the presence of ten times as much chromium is without influence on the results.

G. C. J.

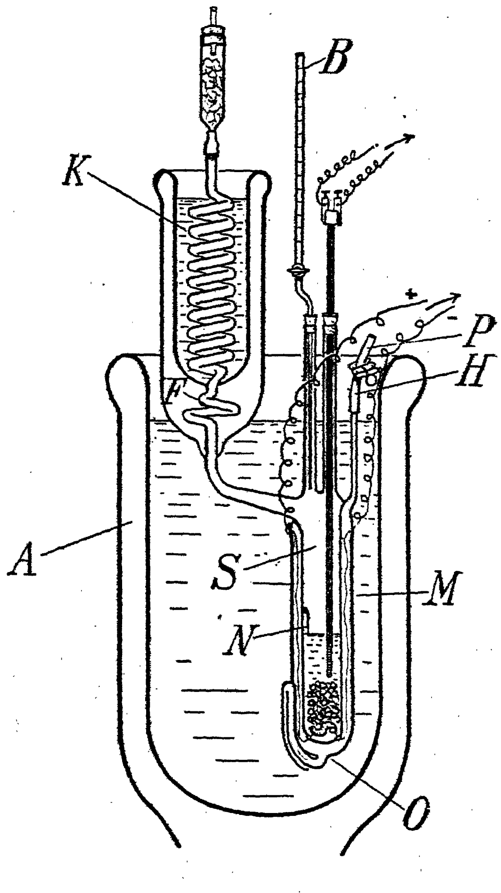
New Method for Determination of Vanadium. J. R. Cain and D. J. Demorest. (*J. Ind. Eng. Chem.*, 1912, 4, 256.)—J. R. Cain has found (*J. Ind. Eng. Chem.*, 1911, 3, 476) that manganese dioxide oxidises vanadyl compounds as well as ferrous compounds. This appears to conflict with the differential oxidation of iron by manganese dioxide on which Demorest's method of estimating vanadium (see preceding abstract) is based. Working together, the authors find that the difference in their results is solely due to the difference in grain of the dioxide each used. Very finely divided manganese dioxide oxidises vanadyl compounds completely, but when only of the fineness indicated in Demorest's paper, the velocity of this reaction is so small that its effect is inappreciable in the short time required for the quantitative oxidation of the iron. G. C. J.

APPARATUS, ETC.

Laboratory Centrifuge for Quantitative Separation and Estimation of Solids and Liquids. H. Zimmermann. (*Zeitsch. angew. Chem.* 1912, 25, 718-719.)—The centrifuge is arranged to carry four cylindrical copper beakers mounted on trunnions. The cylinders are of 100 to 150 c.c. capacity, and their height is about three times as great as their diameter. Their bottoms are cut away except for a narrow rim of metal which supports a removable perforated plate. In use a disc of felt is placed on the perforated plate, and a circular piece of wire gauze, mounted in a frame which exactly fits the cylinder, is placed on top of the felt. The apparatus has been specially constructed for determining the percentage of sugar crystals in raw sugars which contain syrup or molasses adhering to the crystals. Such raw sugar (50 grms.) is shaken with five times its weight of a saturated solution of cane-sugar in a pear-shaped bulb which is then connected by a rubber bung to one of the copper cylinders, and this to a filter pump flask. When the suction of the pump no longer extracts any liquid, the cylinder is capped with a rubber cap and whirled in the centrifuge for five minutes at 2,000 to 2,700 revolutions per minute. The contents of the cylinder are then pushed out, the perforated plate removed, and the sugar weighed with the felt and wire discs which have previously been tared. Usually a constant correction is made for syrup which persistently adheres to the crystals, but in any particular case the proper correction can be made by drying *in vacuo*, and assuming that for every part of moisture thus determined two parts of sugar were adhering to the crystals in the form of syrup. The whole centrifugal arrangement is surrounded by a case for safety and to avoid the projection of syrup, and when the apparatus is used for other purposes, where the liquor rather than the solid is the important constituent, the cylindrical beakers are provided with a collecting cup screwed on below the perforated false bottom. G. C. J.

Ebullioscopic Determinations at Low Temperatures (−36° to −83° C.).

E. Beckmann and W. Weber. (*Zeitsch. anorg. Chem.*, 1912, **74**, 297-309.)—The apparatus figured serves for ebullioscopic determinations with liquids such as hydrogen sulphide, chloride, bromide, and iodide as solvents. The greater part of the apparatus is seen immersed in a cooling liquid contained in a Weinhold-Dewar vessel of some 3 litres capacity. The central apparatus corresponds to the ordinary Beckmann apparatus, with arrangements for raising the temperature electrically and determining it by means of an electrical resistance thermometer. The boiling tube is surrounded by an air-jacket, which, however, is not sealed, but provided with an open syphon bend at the bottom, *O*, and a tube rising out of the bath, and adapted to be closed by a pinchcock, *P*, and rubber tube. When introducing the volatile solvent into the apparatus, suction is applied at *P*, so that the cooling liquid in the Dewar vessel may enter the air-bath and condense the solvent. When the level of the solvent reaches the glass point *N*, the liquid in the air-jacket is blown out by the use of a pressure ball. The bottom inch of the boiling tube is filled with garnets. *B* is a narrow burette for introduction of the second liquid—toluene in the authors' experiments. The temperature of the large cooling bath is maintained about 4° or 5° C. below the boiling-point of the solvent; that of the condenser, also contained in a Dewar vessel, about 10° to 15° C. below the boiling-point of the solvent. A lower temperature for the condenser is not permissible with hydrogen iodide, which solidifies some 16° below its boiling-point, and the boiling and freezing points of the other solvents also lie close together. In the case of hydrogen chloride, the cooling bath must consist of petroleum ether and liquid air, but for the other solvents a mixture of ether with carbon dioxide snow serves well, and with hydrogen sulphide a form of apparatus which dispenses with the 3-litre Dewar vessel may be



used. With the apparatus here figured, the authors have determined the molecular increase of the boiling-point of hydrogen sulphide as 6·3, hydrogen chloride 6·4, hydrogen bromide 15, and hydrogen iodide 26. These numbers are in good agreement with those deduced from the best attested values for the boiling-points and latent heats of vaporisation by the formula $K = \frac{0{\cdot}02\,T^2}{L}$. G. C. J.

Electrical Furnace for Studying the Course of Reactions under Great Pressure. F. Fischer and H. Ploetze. (*Zeitsch. anorg. Chem.*, 1912, 75, 1-9.)—A furnace is figured and described by means of which it is possible to heat substances to temperatures up to 900° C. under gas pressures as high as 100 atmospheres. The temperature at any particular point in the furnace can be determined within 20° C., but it is specially pointed out that other furnaces exist which give a larger area of uniform temperature. This furnace was specially designed to study the action on certain substances of oxygen at high temperatures and under high pressure. Essentially it consists of a porcelain tube, wound with platinum wire to conduct the heating current, and insulated by a considerable thickness of asbestos, etc., from an external casing constructed substantially of mild steel. The provision for the introduction of the current terminals, of the gas-leading tubes, etc., are necessarily somewhat elaborate, owing to the immense pressure, which tends to make all such connections leak. In use the whole apparatus is immersed in water, and one result of this is that there is a sharp temperature gradient between the middle and the ends of the tube. For certain purposes, however, this is an advantage, as it is possible to conduct simultaneously a number of experiments at different temperatures which may differ from one end to the other of a series by nearly 200° C. By means of this apparatus the authors have been able to prepare strontium peroxide, lead peroxide, and alkali peroxides by heating the corresponding oxides with oxygen under high pressures (*Zeitsch. anorg. Chem.*, 1912, 75, 10, 15, 30).
G. C. J.

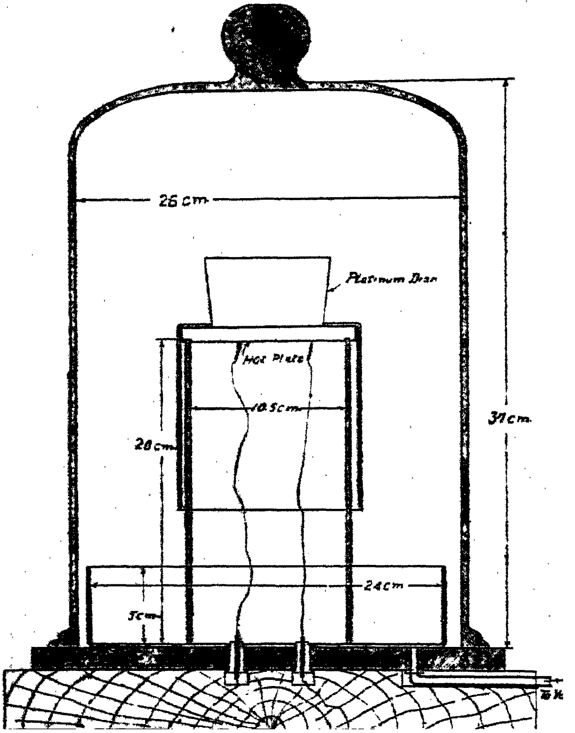
New Form of Extraction Thimble. P. A. Boeck. (*J. Ind. Eng. Chem.*, 1912, 4, 303-304.)—The thimbles are made of "alundum," the product of the fusion of bauxite in the electric furnace, in which process partial purification takes place, so that the resulting product is nearly pure fused alumina. In the manufacture of laboratory articles, the fused alumina is crushed, graded to uniform mesh, mixed with a suitable ceramic bonding material, moulded to the required shape, and fired in a porcelain kiln. The porosity of the bodies can be controlled by varying the size of the alundum grains or changing the kind or proportion of bonding material. Filtering thimbles and dishes of this material effect a great saving of time when substituted for paper thimbles, asbestos mats, and the like, in many laboratory operations. They are made by the Norton Company, Worcester, Mass., U.S.A. G. C. J.

New Forms of Gas Analysis Apparatus. G. A. Burrell. (*J. Ind. Eng. Chem.*, 1912, 4, 297-302.)—The author of this paper describes eleven pieces of apparatus in use by the U.S. Bureau of Mines. By means of one piece of apparatus it is possible to determine methane in mine air with an accuracy of 0·01 per cent. in ten minutes. After measuring, the gas is passed into a slow-combustion pipette containing an electrically heated platinum spiral and when combustion is complete—that is to say, after three or four minutes—the pipette is allowed to cool and the gas transferred back to the burette, and the contraction due to the burning of methane determined. The method, which is much quicker than Winkler's titration method, assumes the absence of other combustible gases in more than negligible traces, but this is often a safe assumption. A portable form of this apparatus is also figured, as well as one for the determination of methane and carbon dioxide. Another apparatus serves for the determination of small amounts of carbonic oxide by the iodic acid method. Considerable aid may be rendered in subduing mine fires by analysing samples of the atmosphere taken from behind stoppings, in order to determine whether the latter are sufficiently tight to exclude air, and a modified Orsat apparatus specially designed for this service is figured. Finally, there is a laboratory apparatus, and a portable modification of it, for the analysis of mixtures containing carbon dioxide, oxygen, ethylene, carbon monoxide, hydrogen, methane, and nitrogen. Special provision is made for the avoidance of the so-called capillary error which attaches to most ordinary forms of Orsat apparatus, and Babb's pipettes (*Eng. Soc. West. Pennsylvania*, 1904, **20**, 421) are used for cuprous chloride. G. C. J.

Marking of Porcelain Crucibles, etc. P. A. Yoder. (*Chem. Eng.*, 1912, **15**, 102-103.)—The author's platinum process for marking laboratory utensils of porcelain or silver-ware is as follows: The crucibles are cleaned by heating for half an hour with nitric acid and water (1 : 1). The parts of the apparatus to be marked are dipped into a hot gelatin size (5 per cent. solution of gelatin), and set aside to dry. When dried, the desired number is stamped on with rubber type with a solution of platinic chloride containing 12 to 15 per cent. of platinum. The pad may be made of six or eight folds of smooth linen or muslin a little larger than the type used, and is nearly saturated with a few drops of the platinum solution. After the numbers are dry, the crucibles are gently heated till reduction takes place, and the gelatin is burnt off, preferably in a muffle, and finally for one half-minute at the full temperature of a blast-lamp. The figures are made more prominent if burnished by means of a burnishing stone or of sea sand. The markings are resistant to single acids, but not to alkalis. Gold, and mixtures of gold and platinum, may be applied similarly. A. R. T.

New Silver Spiral for Use in Organic Elementary Analysis. A. H. Fiske. (*Ber.*, 1912, **45**, 870-871.)—In place of a spiral of silver foil or wire, the author recommends the use of a spiral of silver gauze, or better, because cheaper and equally efficient, a spiral of copper gauze plated with silver. After dipping in silver nitrate solution to give it a coating of silver, the gauze spiral is heated in a blowpipe-flame till the silver coating begins to show signs of melting. In certain cases it is convenient to plate the spiral only for half its length, thus obtaining a combined copper and silver spiral (*cf.* Zincke and Kegel, *Ber.*, 1890, **23**, 246). G. C. J.

New Apparatus for Vacuum Sublimation. G. W. Morey. (*J. Amer. Chem. Soc.*, 1912, **34**, 550-552.)—The apparatus for the sublimation of considerable quantities of organic compounds *in vacuo* consists of a bell-jar 26 cm. in diameter, accurately ground on a glass base, a large, shallow crystallising dish fitting inside the bell-jar and resting on the glass plate, and a glass cylinder, 10·5 cm. in diameter and 20 cm. high, cut from a piece of wide tubing, standing in the crystallising dish. This cylinder serves as a support for the electrical heating element of ordinary type, consisting of a heated iron plate; the top of the cylinder is loosely ground into the enamel on the bottom of the plate. The wires carrying the current enter through the bottom as shown, holes being bored in the crystallising dish, through which the rubber stoppers insulating the wires are inserted. It is best to have the wires in two parts, with connectors near the top to facilitate the removal of the heating element. The substance is contained in a flat-bottomed platinum dish or crystallising dish resting directly on the hot plate, and a deep crystallising dish with a hole cut out to receive the platinum dish is inverted over the hot plate to prevent the sublimed substance coming in contact with the iron. Most of the sublimed substance drops into the crystallising dish at the bottom, and the material comes in contact with nothing but glass and platinum. J. F. B.



REPORTS.

Investigations of Explosives used in Coal-Mines. C. Hall, W. O. Snelling, S. P. Howell, G. A. Burrell, C. E. Munroe. (*Bulletin* 15, *Bureau of Mines. Washington*, 1912.)—Numerous explosions of fire-damp in American coal-mines led to the foundation, in 1908, of the Pittsburgh testing station, where explosives could be examined, particularly for their behaviour in fiery mines. This volume contains: An introduction; a chapter on the nature of explosives; a simple treatment of thermochemistry, intended to enable manufacturers to control the explosion temperature—which is one of the factors of safety—of their products; remarks on the characteristics of the natural gas used in the testing gallery; and an account of the testing equipment of the station and modes of using it. This includes the ballistic pendulum, the gallery for gas, and coal-dust and gas; Mettegang recorder for determining rate of detonation; apparatus for determining photographically the flame length of explosives; apparatus for finding the length of air-gap over which explosion is communicated from one cartridge to another; impact machine, for sensitiveness; Bichel closed vessel, for explosion pressure and composition of explosive gases; calorimeter; and Trunzl lead block, for power. Results of tests on dynamites classed (by the Pittsburgh station) as "permissible" and black blasting powder are given; those on four samples of foreign "permitted" explosives show that the natural gas is more sensitive than the foreign pit gas used in test galleries, and would require dilution with air to give comparable results.

O. E. M.

Investigations of Fuse and Miners' Squibs. C. Hall and S. P. Howell. (*Technical Paper* 7, *Bureau of Mines. Washington,* 1912.)—Five classes of fuse are used in the United States, distinguished by their varying resistance to moisture. A standard rate of burning for all fuse should be established. Six samples were examined for nature of covering, quantity of powder per foot, size of grain and composition of powder, and two for gaseous products of combustion. An improved sample with a wrapper treated with silicate of soda, and containing 0·63 grm. of powder per foot, gave only one-third as much gas as an untreated fuse with 1·08 grms. per foot; it gave much less sulphuretted hydrogen and carbon monoxide—an important feature in confined spaces. A fuse containing 0·63 grm. per foot ignited black blasting powder with certainty, and was safe in gas mixtures. The safety in gas mixtures increased with diminishing size of powder core. A fuse suitable for use in fiery mines should have a uniform core, an envelope strong enough to prevent bursting, pliable, and waterproof, a safe and certain means of ignition, a certain action, and a uniform rate of burning. Miners' squibs are excluded from use in fiery mines on account of their spit. O. E. M.

REVIEWS.

CHURCH'S LABORATORY GUIDE. Revised by EDWARD KINCH. 9th Edition. Gurney and Jackson. London. Price 6s. 6d. net.

The demand for a new edition of this well-known work, five years after publication of the eighth, bears testimony to its popularity among those for whom it is written. The division into three parts, dealing with Chemical Manipulation, Qualitative Analysis, and Quantitative Analysis, respectively, is maintained, and is to be highly commended, the exercises comprised in the first part being so selected as to encourage the student, early in his course, to realise that the pursuit of chemistry will assist him to a better understanding of agricultural products and processes. The section which gives individuality to the book and which calls for most praise is that devoted to Quantitative Analysis, as it contains much information to which an elementary student has not ready access, and deals in a comprehensive manner with manures, soils, waters, and foods.

It is to be regretted, however, that an otherwise useful manual should be marred by some obvious blemishes of style and treatment. The violent fluctuations in mood and tense throughout the opening pages of Part I. set a poor example for the student to follow in his own notes. The expression to "syringe out" a solid from one vessel to another is so unfamiliar that one automatically searches for a syringe in the list of apparatus required for the experiment. Such barbarities as "arseniosum," "arsenicum," "antimoniosum" and "stannicum," jostling copper without a word of explanation, can only mystify a beginner, whilst the unvarnished empiricism of the "sugar test" is deplorable. Although the "sugar test" is used on pp. 53, 54, 55, 59, 292, 295, and 301, instructions for its preparation being given on p. 86, the name Fehling is first encountered in small print on p. 303, and the only index reference to Fehling's solution is p. 86, where the name does not occur, and its connection with the "sugar test" is consequently lost. M. O. FORSTER.

HUILES ET GRAISSES VÉGÉTALES COMESTIBLES. Par G. HALPHEN. Librairie Polytechnique Ch. Béranger. Paris et Liège. 1912. Price 8s. net.

Concerning this book (which forms one of a series of practical manuals of chemical analysis published under the direction of MM. Bordas and Roux) one can have nothing to add but praise, and, in fact, the expectations raised by the name of such a well-known investigator as Halphen are fully realised.

Ostensibly the book deals with seven vegetable oils which are most commonly met with—namely, olive, arachis, cotton, poppy-seed, walnut, sesame, and cocoanut oils—but, on account of the minute details of the various possible adulterants of these oils, a very wide field dealing with the characteristics and properties of many other oils is covered. The method of treatment of the subject, and particularly the details of official methods, are different in many ways to those with which the English analyst is likely to be familiar; but this is only to be expected in a book written particularly for those engaged in the subject as it presents itself in the country of publication. In spite of this, the work is full of suggestions to the analyst, and there are a number of methods detailed and discussed to which many will be quite strangers.

One of the leading features of the book is the stress laid by the author on the use of colour tests in the detection of adulteration, and he defends himself both ably and convincingly against the attacks which have often been made upon his position.

The only possible exception that can be taken to the manner of treatment is, after all, an exception which really redounds to the credit and knowledge of the author, and that is to the somewhat full treatment of the various subjects which might possibly leave the casual investigator in a rather undecided state of mind, but which to the expert will be a source of advantage and assistance. This is exemplified by the fact that, out of about 450 pages, nearly 230 are taken up with the discussion and description of the method of determination of the various constants, etc. The book requires close reading, as in quite an incidental manner most useful hints with regard to technical manipulation, such as, in particular, the method given for incinerating fats, on p. 38, and for the estimation of total foreign matter, on p. 34, and many others are inserted, and the author has again brought to the front and supported with all the weight of his authority several useful tests which have, on account of adverse criticism, been allowed to lapse into an obscurity which was certainly not deserved.

Though the work abounds in tables of figures, it is extremely free from manifest errors, and, in fact, the only one which has been noticed of sufficient seriousness to lead the analyst astray is the transposition of the words "cholestèrine" and "phytostèrine" throughout an entire section on p. 221.

The author has also included a useful and sensible section on the production of rancidity.

The last section of the book contains an appendix dealing with the regulations in force in the different countries, together with copies of the various circulars issued to the official chemists by the French Minister of Agriculture, as well as some definitions of oils as set forth in the findings of the First International Congress for the Suppression of Adulteration, Geneva, 1908.

In conclusion, it may be said that this book is well worthy of the attention of those engaged in the examination of edible oils and fats.

E. Richards Bolton.

NEW BOOKS.

CHEMICAL WORKS: THEIR DESIGN AND EQUIPMENT. By S. S. DYSON and S. S. CLARKSON. London: Scott, Greenwood and Son. 1912. Price 21s. net.

Octavo volume, containing 204 pages of subject matter, with 80 illustrations and 9 plates, and an alphabetical index. The text is classified under the following heads: I. Choice of Site. II. Materials used in Construction. III. First Principles in Laying Out of Works. IV. The Power-House. V. Sulphuric Acid Plant. VI. Hydrochloric Acid Plant. VII. Nitric Acid Plant. VIII. Notes on High Explosives Plant. IX. Sulphate of Ammonia Plant. X. Artificial Manure Plant. XI. General Plant. Appendixes: I. The Chemical Engineer. II. The Saw-Mill and Box-making Department. III. The Alkali, etc., Works Regulation Act. IV. "Welfare Work" or "Prosperity Sharing."

QUALITATIVE ORGANIC ANALYSIS. By F. B. THOLE. London: Methuen and Co. 1912. Price 1s. 6d. net.

The contents comprise—I. Common Operations in Practical Organic Chemistry. II. Determination of Melting and Boiling Points. III. Preliminary Tests. IV. Identification of Aliphatic Compounds. V. Identification of Carbocyclic and Heterocyclic Compounds. VI. Separation and Identification of Mixtures. Appendixes. Index.

INSTITUTE OF CHEMISTRY.

PASS LIST: APRIL EXAMINATIONS, 1912.

OF fifteen candidates who presented themselves for the Intermediate Examination, six passed: L. M. Clark, A. L. Davidson, F. C. Guthrie, B.A. (Cantab.), J. T. Janson, B.Sc. (Lond.), T. S. Jones, B.Sc. (Lond.), and D. A. Legg. Of twenty-five candidates who presented themselves for the Final Examination, fifteen passed. In the branch of Mineral Chemistry: A. M. Bailey, H. W. Gill, B.Sc. (Lond.), D. McDonald, B.Sc. (Lond.), A. H. Maude, and C. R. Robson; in the branch of Physical Chemistry: F. W. Atack, B.Sc. Tech. (Manc.); in the branch of Organic Chemistry: G. McL. Carruthers, R. B. Croad, J. R. Douglas, A.R.C.Sc.I., A. J. Hale, B.Sc. (Lond.), D. Hamilton, J. Porter, and A. Rayner, B.Sc. (Lond.); in the branch of the Chemistry of Food and Drugs, and of Water: L. E. Campbell, B.Sc. (Lond.), and E. Hill, A.R.C.Sc. (Lond.).

JULY, 1912. Vol. XXXVII., No. 436.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

The monthly meeting of the Society was held on Wednesday evening, June 5, in the Chemical Society's Rooms, Burlington House. The President, Mr. L. Archbutt, F.I.C., occupied the chair.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. S. W. Collins, B.Sc., F.I.C., and C. B. Lessner, were read for the second time.

Messrs. H. T. Cranfield, E. G. Jones, M.Sc., F.I.C., and W. H. Roberts, M.Sc., F.I.C., were elected members of the Society.

The following papers were read: "The Composition of Milk," by H. Droop Richmond, F.I.C.; "The Estimation of Dirt in Milk," by W. Foulkes Lowe, A.R.S.M., F.I.C.; "On the Application of Adsorption to the Detection and Separation of Certain Dyes," by A. Chaston Chapman, F.I.C., and Alfred Siebold, F.I.C.; "A New Method for the Detection and Estimation of Small Quantities of Nitrous Acid," by E. Holl Miller; "A Further Note on the Use of Methylene Blue as an Indicator in Iodimetric Titrations," by Frank Sturdy Sinnatt; and "The Estimation of Nitric and Nitrous Acids in Acetic Acid Solution—The Stability of Nitric Acid in Acetic Acid Solution," by Kennedy J. P. Orton, M.A., Ph.D., F.I.C.

THE CONSTITUENTS OF OIL OF SAVIN.

By J. WATSON AGNEW F.I.C., and ROBIN B. CROAD.

(*Read at the Meeting, May* 1, 1912.)

Several samples of oil of savin have been analysed with the object of obtaining pure sabinene, and the following paper is an account of the method used to obtain the terpene, with a description of the various fractions obtained from a pure specimen of oil of savin.*

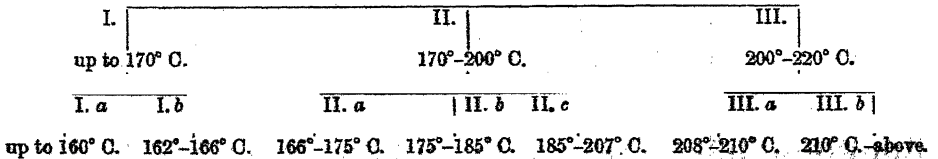
The oil was first of all hydrolysed by boiling under a reflux condenser with alcoholic potash for a week, the amount of caustic potash used being the theoretical quantity required to hydrolyse sabinol acetate (on the assumption that this ester were the sole constituent of the oil), since smaller quantities of potash always leave a large quantity of ester unhydrolysed. When the hydrolysis was finished, carbon dioxide was passed through the liquid until saturated. The solution was then filtered, and the filtrate distilled in a current of steam, the oily distillate separated and dried over anhydrous sodium sulphate. The dry oil was then fractionally distilled, using a six-bulb fractionating column. The flasks for each fraction should be closed, since the oil rapidly absorbs moisture from the air, and this interferes with the subsequent refractionation.

---

* This oil was obtained from Schimmel, who guaranteed it to be a genuine sample of oil of savin. The sample contained very little pinene, but other samples which we examined from other sources had evidently been mixed with oil of turpentine, as the amount of pinene was very high, while the sabinene was correspondingly low.

The oil was fractionated according to the following scheme:

Products of hydrolysis of savin oil.



Each of these fractions was then separately redistilled at a slow rate.

DESCRIPTION OF FRACTIONS OBTAINED.

I. *a*. In most of the samples examined this fraction was large in comparison to I. *b*, though in one case the amount of I. *b* was very large, whilst I. *a* was an exceedingly small fraction. This fraction was undoubtedly pinene, since on oxidation with mercuric acetate solution, a mixture of sobrerol and 8-hydroxycarvotanacetone was obtained. The presence of these two oxidation products of pinene was confirmed by the formation from the original sobrerol (m.-pt. 131° C.), of sobrerol dibromide (m.-pt. 131°–132° C.), and pinol dibromide (m.-pt. 94° C.). The sobrerol dibromide was analysed with the following result:

Br calculated for sobrerol dibromide = 48·48 per cent.
Br found ... ... = 48·27 „

The semicarbazone of the hydroxyketone was also prepared, and was found to melt at 175° C. This agrees with what already has been published (Henderson and Agnew, *J. Chem. Soc.*, 1908, **95**, 289), and the yields from pure pinene and from this fraction are comparable.

I. *b*. As already stated, this fraction was only obtained in large quantity in the case of one sample, and consisted of the terpene sabinene. That this fraction is sabinene was shown by shaking a small quantity with dilute sulphuric acid for about two weeks, when a terpin (m.-pt. 137° C.) and a terpineol (b.-pt. 209–212° C.) were isolated from the solution (Wallach, *Ber.*, 1907, **40**, 585). As these were obtained pure it is practically certain that no pinene was present, or crystals of a terpin hydrate (m.-pt. 120° C.) would have separated out. This was further confirmed by preparing the nitrosochloride according to the method used for pinene nitrosochloride (Wallach, *Annalen*, 1889, **253**, 250), the only resulting product being a sticky, green oil, with no trace of the solid pinene nitrosochloride. The formation of this green oil is in accordance with the observations of some other workers. The constants of the pure sabinene were as follows: b.-pt. 162° to 166° (chiefly 164° C.); sp. gr. 20° C. = 0·8468; $[\alpha]_{D\ 15^\circ\ C.} = -42{\cdot}5$.

It will be noticed that the oil was lævo-rotatory, which is contrary to the published results of other workers, who have only noted the dextro form. Semmler (*Ber.*, 1900, **33**, 1464) records a rotation +63°, and Wallach (*Ber.*, 1907, **40**, 587) a rotation of +67·5° $[\alpha]_D = 80{\cdot}17$. The sp. gr. is also somewhat higher than the figures usually given (Wallach = ·8420, and Semmler = ·840).

These two fractions, I. *a* and I. *b*, can be tested by adding 2 to 3 c.c. to a saturated solution of mercuric acetate in a Nessler tube. In the case of sabinene, oxidation commences at once, and there is a large precipitate of mercurous acetate at the end of fifteen minutes. In the case of pinene there is no oxidation until at least one hour has elapsed.

II. *a*. On careful refractionation this portion splits up into two fractions with the same boiling-points and properties as I. *b* and II. *b*.

II. *b*. This fraction, according to Fromm (*Ber.*, 1898, **31**, 2025), consists of terpinene, and this was confirmed by the ready formation of the nitrosite (m.-pt. 155° to 157° C.) in good quantity (Wallach, *Annalen*, 1887, **239**, 36).

II. *c*. This fraction was redistilled, and the lower and higher fractions were added to II. *b* and III. *a* respectively.

III. *a*. This fraction consisted of the alcohol sabinol, the constants of which were found to be as follows: b.-pt. 208° to 209° C.; sp. gr. 15° C. 0·9391; $[\alpha]_{D\ 15^\circ\ C.} = +17{\cdot}04$. The rotation of this sabinol is much higher than any we have observed in published results.

III. *b*. The residue from this fractionation consists chiefly of unhydrolysed esters.

The solution left in the flask after the original steam distillation contained the potassium salts of the acids, originally present in the esters. This solution was extracted with ether to remove resin and then evaporated down to dryness. The purified potassium salts thus obtained were acidified with dilute sulphuric acid and extracted with ether. The residue, after evaporating off the ether, was found to be a mixture of formic and acetic acids, with a small quantity of another acid, which melted at 85° C. This acid is saturated and is colourless when first isolated, but turns brown in the air. The presence of formic and acetic acids in oil of savin has been already noted, and the quantity of this third acid was too small to permit of our fully identifying it. The following is a table showing the percentage yields:

1. Resin from steam distillation	31·0
2. First runnings 150° to 160° C.	1·7
3. Sabinene 162° to 166° C.	16·0
4. Terpinene fraction 175° to 185° C.	5·3
5. Sabinol 208° to 209° C.	17·0
6. Residue 210° C. upwards	16·0
7. Acids—calculated from amount of sabinol ...	7·0

The percentage of resin is high owing to the difficulty of entirely freeing from water. According to Semmler (*Ber.*, 1900, **33**, 1463), a yield of 30 per cent. of sabinene was obtained by fractionating the crude oil. Altogether we have examined about 15 lbs. of oil of savin in different samples, and the above results are those of the best sample, which gives 16 per cent. In some cases the amount of sabinene was exceedingly low, and the amount of pinene correspondingly high.

In conclusion we desire to express our thanks to Professor G. G. Henderson for the interest he has shown in this work and for many valuable suggestions.

Department of Chemistry,
Royal Technical College, Glasgow.

Discussion.

Mr. H. E. Burgess said that he had examined a large number of samples of savin oil, and had never found any fraction that was not dextro-rotatory. It would seem that the sample worked upon by the authors must have been either inactive or lævo-rotatory, and therefore, as far as his experience went, abnormal.

Mr. Raymond Ross suggested that the authors might with advantage add to their communication the refractive indices of the various fractions. For the determination of the optical activity a considerable quantity of material was required, and the refractive index—which, as well as the boiling-point, could be determined with a few drops—would be more useful in actual practice, where the quantity of material available was often very small.

THE COMPOSITION OF MILK.

By H. DROOP RICHMOND, F.I.C.

(*Read at the Meeting, June* 5, 1912.)

The present communication deals with the results obtained during 1911 in the Aylesbury Dairy Company's Laboratory.

In Table I. the mean composition of 19,997 samples of milk as received from the farms is given. This series is selected, as it contains the largest number of samples, and is therefore the most nearly representative; the morning and evening milks are averaged separately. So far as the mean composition is concerned, it is confirmed by four other series, consisting of 11,269, 1,472, 2,908, and 1,836 samples respectively.

The average percentage of fat (3·71) is slightly below that found last year, and this was principally due to a falling off in the last months of the year. As is almost universally found, the lowest percentages of fat occurred in May and June and the highest in October and November. The evening milk is practically always richer than the morning milk, but the average difference found (0·30 per cent.) is slightly less than usual, and the slightly smaller amount of fat found in 1911 is due to that in the evening milk being less.

Average ...	1·0319	12·37	3·56	8·81	1·0315	12·64	3·86	8·78	1·0317	12·51	3·71	8·80

In continuation of the tables given in former years, I give the percentages of the morning milks falling below 3 per cent. in April, May, and June.

TABLE II.

Month.	2·9 to 3·0.	2·8 to 2·9.	2·7 to 2·8.	Below 2·7.
April	0·8	0·2	0·2	—
May	4·0	2·1	0·5	0·2
June	5·5	0·5	0·5	0·2

In the evening and morning milks during the other months of the year samples containing less than 3 per cent. of fat were practically absent.

The year 1911 was remarkable for the prolonged drought during the summer months, and not only was the quantity of milk influenced by the deficient herbage, but also the quality. It is usual to find that the solids-not-fat are lower in July, August, and September than during the other months, but during 1911 a greater deficiency than usual was observed.

The table below shows the percentages of the milks falling between the percentages of solids-not-fat given for these three months:

TABLE III.

Month.	8·4 to 8·5.	8·3 to 8·4.	8·2 to 8·3.	Below 8·2.	Total.
July	6·5	1·1	0·2	0·1	7·9
August ...	19·9	6·5	0·4	0·2	27·0
September ...	10·4	2·6	0·1	0·1	13·2

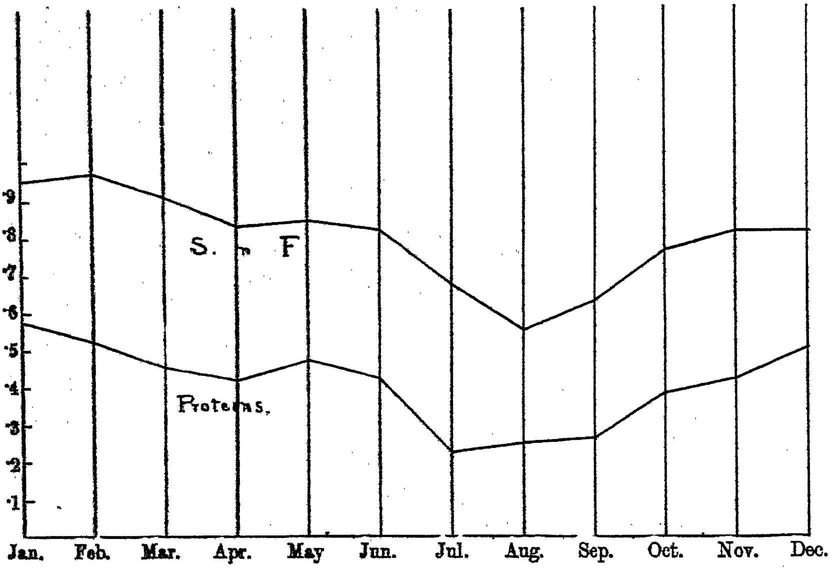
During the other months of the year very few samples fell below 8·5 per cent. of solids-not-fat.

In order to see to what constituent of the solids-not-fat the deficiency was due, the following table has been prepared. This gives the mean percentages of solids-not-fat, the mean percentage of proteins determined from the aldehyde figure, the percentage of ash determined directly, and the percentage of milk-sugar by difference. Although the number of protein and ash determinations is very much smaller than that of the solids-not-fat, the average figure is probably sufficiently close to the true value to render a comparison possible.

TABLE IV.

Month.	Solids-not-Fat.	Milk-Sugar.	Proteins.	Ash.
January	8·95	4·62	3·57	0·76
February	8·97	4·70	3·52	0·75
March	8·91	4·72	3·45	0·74
April	8·83	4·66	3·42	0·75
May	8·85	4·64	3·47	0·74
June	8·82	4·68	3·42	0·74
July	8·67	4·69	3·23	0·75
August	8·55	4·59	3·25	0·71
September ...	8·63	4·63	3·26	0·74
October	8·76	4·63	3·38	0·75
November ...	8·81	4·63	3·42	0·76
December ...	8·81	4·56	3·50	0·75

It is seen from the above figures that the deficiency in solids-not-fat during July, August, and September is due principally to a deficiency in proteins, and this is shown in the accompanying curve.



In conclusion, I wish to express my indebtedness to Mr. H. C. Huish, to whom the bulk of the above figures are due.

DISCUSSION.

Mr. R. Ross asked whether Mr. Richmond found the proportions of 13 : 9 : 2 for milk sugar, proteins, and ash respectively, still to hold good for normal milk. In the case of several recent samples taken under the Sale of Food and Drugs Act, he (Mr. Ross) had found deficiency in non-fatty solids to be due to deficiency in milk sugar, and he had accordingly reported the samples to be not adulterated, but abnormal. He should like to know what were the intervals between the times of milking.

Dr. VOELCKER expressed some surprise that, in an exceptionally dry year like 1911, the quality of the milk was lower, and not higher, than in the previous year. He referred incidentally to the unreliability of the results shown by cows when milked in the showyard for purposes of competition, instancing a recent case, which had been commented upon in the Press, in which a Jersey cow, under such conditions, had yielded milk containing only 2·75 per cent. of fat. From subsequent inquiries it appeared that the cow in question was of an unusually nervous temperament, and that the poorness of her milk on that particular occasion was due entirely to nervous disturbance caused by the strange conditions. He instanced this as showing how much better it was to rely upon such statistics as Mr. Richmond had put forward, than on "showyard" results.

Mr. C. REVIS said that the results of his own analyses during 1911 were similar to those obtained by Mr. Richmond, but he was not quite satisfied that an average of the results of such analyses exactly represented the state of the case. Some three or four years ago he had abandoned the calculation of such averages, and, instead, had adopted the plan of analysing samples drawn at intervals as the milk was being measured out from the mixing vessel, through which would pass some 4,000 gallons twice a day. In this way one eliminated such errors as would be incidental to calculations based on separate samples from about 250 different farmers which this represented. During the two months in question, the non-fatty solids in this quantity of milk were below 8·45 in eleven cases, being in one case as low as 8·34. He had never before met with such low figures in mixed milk, and he thought that Mr. Richmond had not laid sufficient stress on the profound effect of last year's drought. The effect of the drought was felt for some months, and the slightly lower average percentage of fat found in 1911 was no doubt attributable to the almost entire failure of proper feeding-stuffs towards the end of the year.

Mr. A. E. PARKES asked whether Mr. Richmond considered it to be possible, by determining the percentages of milk sugar and proteins, to ascertain whether a sample had been artificially prepared with milk powder, or was a mixture of fresh milk and this product. During last year's drought a considerable quantity of milk had been made up in this way, and he believed that in some districts the practice was still going on.

Mr. L. M. NASH said that, in a large butter factory, it was found that the quantity of milk required for the making of a given quantity of butter was almost exactly the same in 1911 as in 1910, while in a casein factory it was found that the percentage of casein obtained from the milk during 1911 was lower than usual, Mr. J. Evans asked whether any of Mr. Richmond's samples came from the North of England.

Mr. J. Connah said that he had been under the impression that the contracts under which farmers supplied the large dairy companies included a stipulation that the milk should not be below a certain minimum standard of composition, any milk below that standard being rejected. He should like to hear whether Mr. Richmond's averages included such rejected samples or not.

Mr. Richmond, in reply, said that the proportions of 13 : 9 : 2 for milk sugar, proteins, and ash (which were originally laid down by Dr. Vieth) still held good. This was, indeed, according to his experience, the closest approximation to the average that could be obtained in round figures, and he was still strongly of opinion that any wide departure from the proportions of 13 : 9 : 2 indicated that the milk was abnormal. As to the times of milking, these varied considerably in different districts, and were, practically speaking, determined by the train service. On going into this question some little time ago, he had found that on the average there was an interval of 13·2 hours from the evening milking to the morning milking, and of 10·8 hours from the morning milking to the evening milking. He did not quite understand why Dr. Voelcker expected the quality of the milk to be higher in a dry season, unless it was because of the smaller yield. When the quantity was checked by such a cause as a fall in temperature, the resulting decrease in the total metabolic change would not be accompanied by a corresponding decrease in the fat metabolism, and consequently the proportion of fat in the milk would be greater; but when the decrease in quantity was due to a decrease in the total amount of actual nourishment, one would expect a falling off in quality as well. He entirely agreed with Dr. Voelcker that results obtained at shows could not be regarded as representing the normal composition of milk. It was a very good plan to take average samples from large quantities of milk. He had followed it himself, and his experience had been similar to that of Mr. Revis, though the quantities sampled were not so large as in Mr. Revis's case. The question raised by Mr. Parkes was a very difficult one, more especially when the sample consisted only partially of milk made up with milk powder. At present he did not see how it was to be solved. The most northerly district represented among the samples was Cheshire. With regard to Mr. Connah's remarks, the practice was to name in the contract a certain standard of composition, to which the farmer was expected to conform as nearly as possible. As, however, the farmer had no real control over the percentages of fat and of non-fatty solids yielded by the cows, milk falling below the contract standard would not necessarily be rejected, unless the deficiency was very serious, and even then the milk that was rejected would be used for making cream, and the samples would be included in the average unless there was evidence of adulteration. As far as the non-fatty solids were concerned, very low percentages would of course be rejected, but not percentages between, say, 8·0 and 8·5, unless further examination indicated the presence of added water. Low percentages of fat would not lead to rejection unless there was some evidence—such, for example, as the arrival of the churn unsealed, with a deficiency in the quantity of milk—to show that cream had been removed.

THE DETERMINATION OF NITRIC AND NITROUS ACIDS IN ACETIC ACID SOLUTION. THE STABILITY OF NITRIC ACID IN ACETIC ACID SOLUTION.

By KENNEDY J. P. ORTON, M.A., Ph.D., F.I.C., and WILLIAM HERBERT GRAY.

Although numerous papers on the determination of nitric and nitrous acids and their salts have been published, the determination of these acids in acetic acid solution has not been investigated. The inquiry arose from the need of knowing, for the purpose of experiments on the nitration of aromatic compounds, whether nitric acid was reduced by acetic acid. For these experiments very dilute solutions—not greater than 1 per cent.—of nitric acid were required. This fact was the objection to the use of the Kjeldahl-Gunning-Jodlbauer method, which would be applicable to more concentrated solutions. For example, it was used with success by Pictet and Khotinsky (*Ber.*, 1910, **40**, 1163) in the analysis of acetyl nitrate.

The method here described is based on the fact that all the nitric acid in acetic acid solution is retained as potassium nitrate if the solution is evaporated to dryness on the water-bath with a slight excess of potassium carbonate; any nitrous acid is destroyed under this treatment. The potassium nitrate, which is mixed with some acetate, is determined by the Lunge process. The nitrous acid can be best determined by Raschig's permanganate method (*Ber.*, 1905, **35**, 3911). Nitric acid is remarkably stable in acetic acid solution, and can be kept of constant concentration for many weeks. If nitrous acid (oxides of nitrogen) is present, the major part is gradually oxidised to nitric acid, the solution becoming nearly colourless. Solutions in 50 per cent. acetic acid showed similar behaviour. Reduction of the nitric acid does not occur even after prolonged exposure to diffused light, but any colour due to oxides of nitrogen originally present gradually fades, the concentration of the nitric acid somewhat increasing. This remarkable behaviour will be further investigated.

Determination of Nitrous Acid in Acetic Acid Solution.

All the well-known methods of analysis were tested. The problem resolved itself into ascertaining which of these could be used in a medium containing about 10 per cent. acetic acid, as that was practically the maximum dilution attainable in any but the permanganate method on diluting the original glacial acetic acid medium. Further, the method should be accurate in the presence of the relatively very large excess of nitric acid.

(*a*) The tintometric method with *m*-phenylenediamine failed completely. Compared with aqueous solutions of nitrite, solutions in dilute acetic acid (5 to 40 per cent.) showed paler tints. The discrepancy is progressively greater as the proportion of acetic acid is increased. It should be noted that the mere addition of acetic acid after diazotisation does not in itself affect the tint.

(*b*) The Dunstan-Dymond method. In the presence of small quantities of acetic acid (5 to 10 per cent.) this method gives high results. Moreover, in the very dilute solutions which we required, the manipulative difficulties are excessive.

(*c*) The method devised by Maderna and Coffetti (*Gazetta*, 1907, **37**, 595), which is based on the reduction in a Lunge nitrometer of nitrous acid to nitric oxide by potassium ferrocyanide and citric or acetic acid—an environment in which nitric acid is stable—was found to give excellent results in the analysis of fuming nitric acid, which was neutralised before introduction into the nitrometer, with slight excess of sodium hydroxide. The solubility of the nitric oxide in the more concentrated acetic acids, which were unavoidable in this method, rendered it inaccurate.

(*d*) In Raschig's method we found a perfectly satisfactory means of estimating minute quantities of nitrous acid in acetic acid solution. The following procedure was finally adopted :

A given volume of the acetic acid solution, 10 to 30 c.c., was added drop by drop, over a period of four minutes, to a mixture of about 20 c.c. of $\frac{N}{10}$ permanganate, 5·5 c.c. of 10 per cent. sulphuric acid and 320 c.c. of water. The permanganate should be about double that required for the oxidation of the nitrous acid; the sulphuric acid is nearly the minimum quantity required for this dilution; the nitrous acid, when added to the mixture, should not be below a dilution of 1 in 20,000. The mixture is allowed to stand for fifteen minutes, and then excess (about 8 to 9 c.c. of a 2·5 per cent. solution) of potassium iodide introduced, and the iodine titrated with $\frac{N}{10}$ of thiosulphate. The time of addition of the acetic acid solution could be considerably shortened without materially affecting the accuracy, but the fifteen minutes' standing is a minimum. The following numbers illustrate the results of determinations of nitrous acid in fuming nitric acids :

Percentage of Acetic Acid in the Permanganate Mixture.	C.c. of $\frac{N}{10}$ $KMnO_4$ used in oxidising Nitrous Acid.	Grms. of HNO_2 in 100 c.c. of fuming Nitric Acid.
5	8·38	1·97
5	8·48	1·99
10	8·44	1·98
10	8·50	1·99

THE DETERMINATION OF NITRIC ACID IN ACETIC ACID SOLUTION.

The procedure we adopted is as follows : To an aliquot part of the acetic acid solution, which is placed in a glass dish, covered by a clock-glass, a slight excess (5 to 25 per cent.) of $\frac{N}{1}$ potassium carbonate solution is cautiously added. The liquid is then evaporated on the water-bath until no odour of acetic acid remains, the clock-glass being left on the dish. The slightly moist solid is then transferred by a spatula to the cup of a Lunge nitrometer. The spatula is then washed with 0·3 c.c. of water into the cup, and the liquid drawn into the tube. Five c.c. of pure concentrated sulphuric acid (96·6 per cent.) are poured into the glass dish, when the all but negligible residue is dissolved, and then introduced into the nitrometer. It was found by trial that 4·5 c.c. of the 5 c.c. of the sulphuric acid used reached the nitrometer tube. This proportion of water and acid gave a concentration of 93·2 per cent. in the nitrometer. In shaking, etc., we followed the directions which Marqueyrol and Florentin ANALYST, 1911, 36, 243) recommend in their recent critical study of the Lunge method. It was found that, after two of the shakings described by these authors, occupying one minute each, the maximum volume of gas was obtained. In calculating the results, the nitric oxide absorbed by the sulphuric acid, as given by Lunge, was allowed for, namely, 0·15 c.c. for 5 c.c. of sulphuric acid.

This method was tested by blank experiments (*a*) with potassium nitrate, (*b*) with mixtures of potassium nitrate and nitrite.

(*a*) On evaporating pure potassium nitrate with acetic acid on the water-bath, no nitric acid was lost, since no acetic acid was recognisable in the residue by any of the usual qualitative tests. The following numbers illustrate the results:

C.c. of Acetic Acid.	KNO_3 used.	C.c. of NO.	KNO_3 found.	Percentage Error.
5	0·1188	25·81	0·1180	0·7
5	0·1192	25·94	0·1181	0·95
5	0·1185	25·84	0·1175	0·80

(*b*) Mixtures of potassium nitrate and nitrite were evaporated with glacial acetic acid. The residue gave no trace of the reactions of nitrous acid. Quantitative determinations of the nitrate showed that no nitrite had been oxidised to nitrate.

C.c. of Acetic Acid.	Potassium Nitrite as a Percentage of Nitrate.	KNO_3 used.	KNO_3 found.	Percentage Error.
5	2·5	0·1160	0·1147	1·1
5	2·5	0·1160	0·1156	0·36
5	9·48	0·1160	0·1147	1·1

A comparison of determinations of the concentrations of a fuming nitric acid by direct titration, and by this method, shows that, with these quantities, there is a constant error, probably manipulative, of about 0·7 per cent.; the addition of this loss would not be unjustifiable.

The Stability of Nitric and Nitrous Acids in Acetic Acid Solution.

For testing the stability of nitric and nitrous acids in acetic acid solution, we used the purest glacial acetic acid, which is not attacked by chlorine in the dark (Orton, Edwards and King, *J. Chem. Soc.*, 1911, **99**, 1178).

At first the solutions were carefully preserved in the dark, but, as we found later, exposure to diffused light has no perceptible influence. When nitrous acid is present, the original colour of the solution fades quickly to a scarcely perceptible tint. Concentrations of nitric acid, varying from 1 to 7 per cent., were used. As the nitrous acid disappears, the nitric acid increases somewhat in quantity. No reduction of the nitric acid was observed in any of the solutions which were prepared. The following numbers will illustrate the evidence we obtained:

1. *Glacial Acetic Acid Solutions.*—(*a*) The solution was made up to contain 7·03 grms. HNO_3 and 0·102 grm. HNO_2 per 100 c.c.:

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

ANALYSIS OF FOOD AND DRUGS.

Determination of Iron in (Pharmaceutical) Scale Preparations. W. R. Pratt. (*Pharm. J.*, 1912, 88, 641-642.)—For the analysis of *ferri citras cum quinina et strychnia* and other scale preparations of ferric salts, the author prefers the method of the U.S. Pharmacopœia to that of the British. If alkaloids be present they are separated, the residual liquids evaporated until free from ammonia and then diluted. The ferric solution is placed in a stoppered bottle together with hydrochloric acid and potassium iodide, heated in a water-bath, and the iodine liberated is titrated with thiosulphate. The author has investigated the limits of variation of the amount of acid, the time of reaction, and the temperature. He found that the quantity of hydrochloric acid must be at least twice the theoretical quantity, and may be increased to ten times the theoretical quantity without error. If a sufficient quantity of acid be used, the reaction is complete in ten minutes at 40° C., but no appreciable error is introduced by increasing the time to thirty minutes. The most suitable range of temperatures appears to be from 20° to 60° C., but at lower temperatures a longer time is required for the completion of the reaction. J. F. B.

Method of Preparing Lecithin Emulsions and the Subsequent Estimation of their Strength. J. C. Schippers. (*Biochem. Zeitsch.*, 1912, **40**, 189-192.)—The emulsion may be prepared by dissolving a weighed quantity of lecithin in the least possible amount of toluene, and then mixing the solution with a sufficient volume of 0·9 per cent. sodium chloride solution to give the required concentration. After the mixture has been shaken thoroughly, a current of hydrogen is passed through it until all the toluene has been removed, the emulsion being then submitted to centrifugal action, and filtered through cotton-wool. The following method may be employed for checking the strength of the emulsion thus prepared; the method is based on the estimation of the amount of oxygen required to oxidise the lecithin. Ten c.c. of the emulsion are heated to 90° C. for six hours in a stoppered flask with 10 c.c. of a solution consisting of potassium bichromate, 5 grms., 38 per cent. hydrochloric acid, 300 c.c., and water, 700 c.c. After cooling, 10 c.c. of a 5 per cent. potassium iodide solution are added, the mixture is allowed to stand for at least two hours, 30 c.c. of water are then added, and the solution is titrated with $\frac{N}{25}$ thiosulphate solution. A similar titration is made, using 10 c.c. of the sodium chloride employed in making the emulsion, and the difference in the quantity of thiosulphate used in the two titrations is a measure of the lecithin present. Experiments carried out by the author show that 1 c.c. of $\frac{N}{25}$ thiosulphate solution is equivalent to 1·12 mgrm. of lecithin. W. P. S.

Freezing-Point of Milk. J. B. Henderson. (*Aus. Assoc. Adv. Sci.*, 1912, 13.)—Since the reading of a paper before the Australian Association for the Advancement of Science at its meeting in Brisbane (1909), the determination of the freezing-point of all doubtful samples of milk has been continued in the Government Chemical Laboratory, Brisbane.

The added water indicated by the freezing-point is on the average well above that calculated from the 8·5 per cent. solids-not-fat standard, and still further emphasises the fact that the 8·5 per cent. solids-not-fat legal minimum standard is by no means too high.

During the year 1909 every milk sample containing less than 8·5 per cent. of solids-not-fat was found by the determination of the freezing-point to have been watered, and last year the same result was obtained, except in the two following cases:—

	(*a*) August 19, 1910 (4 cows).	(*b*) September 16, 1910 (? Cows).
Total solids	11·62 per cent.	11·6 per cent.
Fat	4·00 "	3·3 "
Solids-not-fat	7·62 "	8·3 "
Ash	0·64 "	0·68 "
Nitrogen	0·487 "	0·474 "
Freezing-point	—0·565°C.	—0·55°C.

But for the determination of the freezing-point there is little doubt that both of these samples would have been adjudged watered. As it was, the freezing-point showed them to be genuine, and the dairymen were warned to raise the quality of the milk to at least the legal minimum by better attention to their herds.

The determination of the freezing-point is useful in distinguishing between naturally poor milks and watered milks, and the author hopes that its use will soon lead to the prosecution of those who add water to a naturally rich milk, but do not add sufficient water to bring the milk below the legal minimum standards. The average composition of the milk of one herd in Brisbane, the result being the mean of 104 samples, is—Fat 4·5 per cent. and solids-not-fat 9·2 per cent. Such a milk could have 7·5 per cent. of water added, and yet pass the ordinary 3 per cent. fat and 8·5 per cent. solids-not-fat standard. The determination of the freezing-point would, of course, at once show the addition of water.

Estimation of Iron in Milk. F. E. Nottbohm and W. Weisswange. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 514-523.)—The small quantities of iron which occur in milk cannot be estimated satisfactorily by means of gravimetric or volumetric methods, and experiments carried out by the author show that the colorimetric method with thiocyanate yields incorrect results owing to the interfering influence of the phosphates and other constituents of the milk ash. It is therefore recommended that the iron be separated by means of "cupferron" (*cf.* ANALYST 1910, **35**, 327; 1911, **36**, 175), and then estimated colorimetrically with thiocyanate. One hundred c.c. of the milk are evaporated, ignited, and the white ash evaporated twice to dryness with hydrochloric acid free from iron. The residue is then dissolved in about 40 c.c. of $\frac{N}{5}$ hydrochloric acid, the solution is transferred to a flask, and oxidised with nitric acid. After cooling, the solution is rinsed into a separating funnel, 2 c.c. of a 5 per cent. "cupferron" solution are added, and, after the lapse of fifteen minutes the mixture is shaken with 25 c.c. of chloroform. The chloroform layer is now separated, evaporated to dryness, and the residue ignited; the iron oxide in this ash is dissolved in hydrochloric acid, the solution is oxidised with nitric acid, then evaporated twice with hydrochloric acid, and the iron estimated colorimetrically as thiocyanate. Experimental proof is given that the method is trustworthy.

W. P. S.

Estimation of Morphine in Opiates. E. Anneler. (*Arch. Pharm.*, 1912, **250**, 186-198.)—Details are given of a critical study of the different methods of estimating morphine in opiates, and especially in "Panopon Roche," a preparation containing hydrochlorides of all the opium alkaloids in a very pure form. It was found that the method of the b.-pt. and its modification in the French Codex was the most generally suitable, but that the results were invariably too low. The error was constant, however, and a correction could be made by adding 30 mgrms. per 50 c.c. of the mother liquor to the amount of morphine found. Of the shaking-out methods the following was the most satisfactory, the average error in the case of "panopon" being 1·5 per cent. too high: From 0·8 to 1·0 grm. of the sample is dissolved in 30 c.c. of water, and shaken with a concentrated solution of 1 grm. of sodium bicarbonate in a little water, which effects the separation of some of the morphine and the bulk of the other alkaloids. The latter are then removed by shaking the liquid with 10 c.c. of chloroform previously saturated with pure morphine (100 c.c. dissolve 0·051 grm. of morphine at 15° C.). After separation of the liquids, the chloroform is drawn off through a small filter, and the residual liquid extracted twice more with 10 c.c. of the saturated chloroform. The filter is then washed with 60 c.c. of a mixture in equal parts of isobutyl alcohol, and chloroform, and the washings transferred to the separating funnel, which is then shaken for about ten minutes and allowed to stand. The layer of isobutyl alcohol, and chloroform (which need not be absolutely clear) is withdrawn, and the extraction of the residue repeated first with 20 c.c. and then with 10 c.c. of the mixed solvents. The extracts are filtered into another separating funnel, where they are shaken with 20 c.c. of $\frac{N}{10}$ hydrochloric acid, and subsequently washed with three successive portions of 10 c.c. of water, after which the filtered acid extract and washings are covered with 30 to 40 c.c. of ether, and the excess of hydrochloric acid titrated, with iodeosin as indicator.

C. A. M.

Estimation of Essential Oil in Mustard. D. Raquet. (*Ann. Chim. anal.*, 1912, **17**, 174-178.)—The usual practice of mixing the mustard with water and allowing it to stand for some time before the essential oil is separated by distillation does not always yield concordant results; in some cases the preliminary digestion requires to be prolonged for an hour or more in order that the whole of the essential oil may be liberated, whilst in others the time required is much shorter. Further, the essential oil is decomposed by micro-organisms, and if the digestion be carried on for too long a time the results obtained will be too low. If, however, dilute alcohol be used in place of water, the digestion may be allowed to proceed for even twenty-four hours without loss of essential oil. Having regard to these conditions, the following method is recommended for the estimation of the oil: Five grms. of the mustard flour are mixed in a 250 c.c. flask with 100 c.c. of water and 20 c.c. of 90 per cent. alcohol; the flask is now closed and set aside for six hours, or heated to a temperature of 35° C. for one hour. The contents are then distilled, and 50 c.c. of the distillate are collected in a 100 c.c. flask in which 10 c.c. of ammonia have been placed previously; 20 c.c. of $\frac{N}{10}$ silver nitrate solution are now added, the distillation is continued until the 100 c.c. flask is filled nearly to mark, and after the flask has been closed with a stopper carrying a long glass tube, the contents are heated to 85° C. for one hour. When cold, the mixture is diluted to 100 c.c., filtered, and the excess of silver is titrated in 50 c.c. of the filtrate by means of $\frac{N}{10}$ thiocyanate solution after the addition of nitric acid. The number of c.c. of $\frac{N}{10}$ silver nitrate used is multiplied by 0·198 to obtain the weight of allyl thiocarbimide in 100 grms. of the mustard. The following percentage quantities of mustard oil (as allyl thiocarbimide) were found in samples of black mustard of different origin: English, 1·39; Greek, 1·20; French, 1·08; Sicilian, 0·99; Italian, 0·99; Bombay, 0·81.

W. P. S.

Detection of Adulterants in Saffron. E. Nockmann. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 453-456.)—The presence of added mineral matter in saffron can usually be detected by estimating the amount of ash in the sample, the presence of borax, potassium nitrate, etc., being also ascertained by means of the usual characteristic reactions for these substances. Ammonium salts can also be detected without difficulty in the saffron itself, but the detection of added sugars and glycerol is not such a simple matter, and the author records the results of his experiments with regard to this problem. The following results of analyses of seven samples of saffron of authenticated purity are given:

	In the Original Substance.		In the Dry Substance.			
				Reducing Substances, calculated as Invert Sugar.		
	Water.	Ash.	Aqueous Extract.	Before Inversion.	After Inversion by Official Method.	After Four Hours' Inversion.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Saffron, select ...	8·42	5·01	73·97	23·54	24·05	39·17

„ Sierra ...	9·23	5·84	70·87	23·45	24·35	38·40
„ Manzanares	8·68	6·83	70·13	22·57	23·35	38·11
„ commercial	13·54	6·05	76·01	23·56	24·44	39·75
„ „	13·49	5·81	74·72	24·35	24·92	39·65
„ „	11·51	6·11	70·83	22·56	24·03	38·84

The inversion process consisted in adding 4 c.c. of hydrochloric acid of sp. gr. 1·19 to 50 c.c. of the aqueous extract, and heating the mixture in a boiling water-bath for four hours, the maximum reduction being obtained after this length of time. The results obtained by the official method of inversion are also given. It will be seen that the presence of added sugar would be indicated plainly by the values for the invert sugar before and after inversion. Glycerol cannot be detected by oxidising the aqueous extract with permanganate and identifying the oxalic acid formed, as genuine saffron yields considerable quantities of oxalic acid when treated in this manner. Attempts to separate added glycerol from saffron by means of the method used in the estimation of glycerol in wine (evaporation with calcium hydroxide and extraction with a mixture of alcohol and ether) did not yield satisfactory results, as saffron itself gave 3 to 4 per cent. of extract which would be counted as glycerol. If, however, the glycerol residue be transferred to a flask, mixed with solid boric acid, distilled until carbonisation is attained, the distillate being collected in water, this distillate may be tested in the following manner: To 5 c.c. of the distillate are added 1 c.c. of albumin solution (1 c.c. of egg-albumin diluted with 7 c.c. of water and filtered through linen), and 18 c.c. of hydrochloric acid containing nitrous acid (0·1 c.c. of 3·6 per cent. potassium nitrite solution to 200 c.c. of hydrochloric acid of sp. gr. 1·18), and the mixture heated in a water-bath to 50° C. The distillate from a sample containing added glycerol yields a green coloration, whilst that from genuine saffron gives a faint red-blue tint. The spectrum of the distillate is also characteristic. When added glycerol is present in the sample, a dark absorption band is seen in the red portion of the spectrum, whilst the distillate from genuine saffron does not exhibit any absorption spectrum.

W. P. S.

Estimation of Nicotine in Tobacco. E. F. Harrison and P. A. W. Self. (*Pharm. J.*, 1912, 88, 718-719.)—In the method recommended, the tobacco is treated with slaked lime and distilled in a current of steam until all the nicotine has passed over into the distillate, as shown by a few drops giving no cloudiness when treated with acid and an excess of iodine. The distillate is received in a measured quantity of standard acid, and at the end of the distillation the distillate is titrated with standard alkali, using litmus as indicator. A further quantity of 10 c.c. of $\frac{N}{1}$ acid is then added to the neutral solution, the latter is evaporated to a volume of 50 c.c., the nicotine is next precipitated by the addition of an excess of iodine, and the ammonia is estimated by distillation. The whole of the volatile alkali is calculated as nicotine in the first instance, and ten times as much iodine as would be required to combine with that amount is dissolved in potassium iodide solution and added to the 50 c.c. of evaporated distillate; after diluting to 100 c.c. the mixture is filtered, 75 c.c. of the filtrate are treated with thiosulphate to destroy the excess of iodine, and then distilled in the presence of a large excess of sodium hydroxide. The quantity of nicotine present is then calculated. It is convenient to work on a weight of tobacco which will yield about 0·5 grm. of nicotine. The authors have proved that nicotine may be separated completely from ammonia by the above-mentioned method, and state that the process as a whole yields accurate results. W. P. S.

Detection of Other Hydrocarbons in Turpentine. Utz. (*Farbenzeit.*, 1912, 17, 1208-1209; through *Chem. Zentralbl.*, 1912, I., 1641.)—Mennechet (*Bull. Commer.*, 1911, No. 9) has proposed a test which consists in shaking 5 c.c. of the turpentine with a small quantity of magenta and 2 drops of nitric acid; at the end of five minutes the mixture remains bright red in the absence of added hydrocarbons, but should 5 per cent. of the latter be present the colour of the mixture is reddish-brown, and light brown or colourless with upwards of 25 per cent. of hydrocarbon. The author has examined this test and finds that, whilst turpentine and its various substitutes and adulterants by themselves give quite characteristic colorations, it is not possible to detect less than 30 per cent. of the substitutes when added to turpentine. The reaction may be used as a rough test, but the colour changes in the case of mixtures are so indefinite that the test cannot be relied on to give useful information as to the presence of adulterants in turpentine. W. P. S.

Critical Remarks on the Direct Estimation of the Total Solids of Wine. C. von der Heide and E. Schwenk. (*Zeitsch. anal. Chem.*, 1912, 51, 429-466.)—For reasons which are given below, the authors consider that the direct method of estimating the total solids of wine (evaporation and drying in the water-oven) should be abandoned, and that the total solids should be calculated from the sp. gr. of the de-alcoholised wine. The accuracy of this sp. gr. may be checked by determining the sp. gr. of the wine and of the alcoholic distillate from the same, Tabarie's formula being used to calculate the sp. gr. of the alcohol-free liquid. The experiments carried out by the authors show that, during the evaporation of the wine and the subsequent drying of the residue, the following changes in the constituents may, and do, take place: (1) Acetic acid and its homologues are not present in the residue; (2) lactic acid is volatilised to a varying extent; (3) tartaric acid is converted partially into *m*. tartaric acid; (4) succinic acid remains unaltered; (5) malic acid is decomposed partially; (6) the non-volatile acids form esters with the glycerol; (7) there is only a slight loss of glycerol; (8) the sugars are decomposed to a very considerable extent. As a result of these changes, the sp. gr. of the aqueous solution of the total solids is less than that of the de-alcoholised wine. The alterations which occur in the proportions of the constituents as a wine ages influence the changes which take place when the wine is evaporated. For instance, the total solids (as estimated directly) of a new wine, which contains much malic acid, but no lactic acid, cannot be compared with the total solids of the same wine after this has been kept for a length of time sufficient for the malic acid to have been converted into lactic acid. W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Estimation of the Amino-Acids in Plants by Means of the Formaldehyde Method. O. Bailly. (*Bull. Sci. Pharmacol.*, 1912, 18, 702-711; through *Chem. Zentralbl.*, 1912, I, 1640.)—Amino-acids may be titrated in the aqueous extracts of plants by means of the formaldehyde titration method, after the extracts have been treated with barium chloride to remove phosphates, and decolorised by means of quinine silicotungstate. As ammonia is estimated at the same time, this must be estimated separately in another portion of the extract, and an allowance made for its quantity. The details of the process are: One hundred c.c. of the extract are treated with 10 c.c. of $\frac{N}{1}$ hydrochloric acid, 10 c.c. of a 10 per cent. silicotungstic acid solution, and 10 c.c. of a 3·1 per cent. quinine hydrochloride solution, shaken, submitted to centrifugal action, and filtered. The filtrate is shaken with animal charcoal, again filtered, and 78 c.c. of the filtrate are treated with 1 grm. of barium chloride, then rendered alkaline with potassium hydroxide solution, diluted to 100 c.c., and filtered. Twenty-five c.c. of this filtrate (equivalent to 15 c.c. of the original extract) are acidified with $\frac{N}{10}$ hydrochloric acid, 1 drop of a saturated *p*-nitrophenol solution is added, and the solution exactly neutralised with $\frac{N}{10}$ potassium hydroxide solution. Fifteen c.c. of neutral formaldehyde solution are now added, and the amino-acids are titrated with $\frac{N}{10}$ potassium hydroxide solution, using phenolphthaleïn as indicator. Let N denote the number of c.c. required for the titration; the ammonia is then estimated by distilling a further quantity of 50 c.c. of the extract in the presence of magnesia; the quantity of ammonia is expressed in c.c. of $\frac{N}{10}$ acid—let it be n—then the amount of amino-acid in 100 c.c. of the extract expressed in terms of nitrogen, is found by formula: $\frac{(2N-n)\times 0{\cdot}014}{3}$. The results obtained are correct within 3 per cent., except in the case of tyrosine and histidine, when the error may amount to 10 per cent. The following quantities of amino-acids (expressed as nitrogen per 100 grms. of the dry substance) were found in various plants: Turnip leaves, 0·507; tobacco flowers, 0·272; cabbage leaves, 0·886; lucerne, 0·350; carrot tops, 0·280; birch leaves, 0·144; tobacco leaves, 0·420. W. P. S.

Detection and Estimation of Small Quantities of Copper in Plants. E. Guerithault. (*Bull. Sci. Pharmacol.*, 1912, **18**, 633-639; through *Chem. Zentralbl.*, 1912, I., 1639.)—The method employed by the author consisted in dissolving the ash of the plants in hydrochloric acid, separating the silica, precipitating the copper as sulphide, and converting the latter into oxide by ignition; the oxide is then dissolved in nitric acid, and estimated electrolytically and colorimetrically. Peas, beans, maize, rye, wheat, oats, barley, linseed, radish seeds, cress seeds, gentian root, juniper twigs, and verbena wood, were examined, and found to contain from 0·0046 to 0·0171 part of copper per 1,000 parts of dry substance. W. P. S.

Photographic Estimation of the Intensity Distribution in Blood Spectra. W. Heubner and H. Rosenberg. (*Biochem. Zeitsch.*, 1912, **38**, 345-384.)—A photographic method is described for estimating the relative intensity of the absorption of light in the absorption bands of blood spectra, the method depending on the microphotometric measurement of the light which is transmitted by the negative on which the absorption spectrum has been photographed. Under definite conditions, the extinction of light by the precipitated silver is a measure of the light absorbed by the blood colouring matters. Blood from rabbits, sheep, and pigs, was examined, and showed no difference in the intensity distribution. W. P. S.

Rate of Evolution of Hydrocyanic Acid from Linseed under Digestive Conditions. S. H. Collins. (*Univ. Durham Phil. Soc. Proc.*, 1912, **4**, 99-106.)—The author has digested linseed at temperatures approaching those of animal life, and has removed hydrocyanic acid by a stream of inert gas (hydrogen, air, etc.). The inert gas, passing at a regular rate obtained by means of a gas-governor (ANALYST, p. 330), bubbles through a vessel immersed in a thermostat (*loc. cit.*), the vessel containing the linseed to be tested and 50 c.c. of water. The vapours are caught in an absorbing vessel containing 5 c.c. of $\frac{N}{30}$ sodium hydroxide. A clock and meter are attached to the apparatus immediately before the issuing of the gas, and thus the rate of flow, the time, and the temperature are controlled. Generally, 10 litres of gas per hour at 45° C. were the conditions employed. From time to time the sodium hydroxide in the absorbing vessel is removed by a tap, and fresh quantities of alkali are added through an attached tap-funnel, so that several fractions of 5 c.c. of the hydrocyanic acid-containing solution are obtained. To each of these is added 1 drop of a solution of ferrous sulphate (12 per cent.), the liquids shaken up and allowed to stand for an hour, when 1 drop of diluted sulphuric acid (1 : 2) is added, and, after shaking, the liquids allowed to stand at least thirty-six hours. The colours are matched after three, four, and five days with standards, made from potassium cyanide solution of known strength, prepared with iron and acid similarly. Standards of prussian blue keep well (twelve months), 0·01 mgrm. to 0·30 mgrm. HCN being useful quantities to prepare. The mean reading of the separate days is taken as correct.

The amount of hydrocyanic acid yielded by linseed, and the rate of its yield, depend upon the amount of cyanogenetic glucoside and enzyme, on the temperature, degree of acidity of the liquid present, and on the presence or absence of a number of other substances. In normal health the acidity of the stomach is too high to allow of evolution of hydrocyanic acid, but under abnormal conditions—for example, in the case of a linseed rich in cyanogenetic glucosides fed to a beast suffering from indigestion such that the food was not rendered acid—hydrocyanic acid poisoning may set in. Acids of $\frac{N}{100}$ strength prevent the action of the enzyme, and hydrochloric acid of $\frac{N}{1000}$ retards the evolution of hydrocyanic acid. Probably all acids prevent this action.

The following are some of the results obtained by the above method:

Linseed (Calcutta).			Linseed Cake.

A. R. T.

Quantitative Estimation of *l*-β-Hydroxybutyric Acid in Urine and Blood.

B. O. Pribram. (*Zeits. exper. Path. u. Ther.*, 1912, **10**, 279-283; *Chem. Zentralbl.*, 1912, I., 1509.)—The method is based on the fact that the crotonic acid produced by the distillation of β-hydroxybutyric acid in sulphuric acid solution combines quantitatively with two atoms of bromine. The conversion of the β-hydroxybutyric acid into the volatile crotonic acid is best effected by means of sulphuric acid of 58 to 60 per cent. by weight. An excess of standardised bromine water is added to the distillate and titrated back with thiosulphate. In the estimation of β-hydroxybutyric acid in diabetic urine, the method is complicated owing to the presence of phenols and sugar. The difficulty is surmounted by saturating the urine with ammonium sulphate, acidifying with sulphuric acid, and extracting with ether. The estimation is made on the ethereal extract. Blood is defibrinated before the estimation by a preliminary treatment with six times its quantity of alcohol. J. F. B.

Use of Mice and Birds for Detecting Carbon Monoxide after Mine Fires and Explosions. G. A. Burrell. (Technical Paper II., Bureau of Mines, Washington, 1912.)—The formation of a cap on the safety-lamp flame is not satisfactory as a means of detecting carbon monoxide. Blood solution and cuprous chloride solution show its presence with considerable sensitiveness, but the best method is the use of mice or birds. When exposed to an atmosphere of carbon monoxide, canaries show signs of poisoning sooner than mice, and the symptoms are more easily observed. The author remained for twenty minutes in an atmosphere containing 0·25 per cent. of carbon monoxide, without experiencing more than a slight headache, though later he became ill for several hours; canaries in the same atmosphere showed distress in one minute and fell from their perches in five. A party exploring a mine in which an explosion had taken place, carried with them a canary, which collapsed on reaching a spot at which there was 0·2 to 0·3 per cent. of carbon monoxide; the party retreated without distress. O. E. M.

Modification of Wohlgemuth's Method for the Quantitative Investigation of the Pancreas Function. P. B. Hawk. (*Arch. Internal Med.*, 1911, **8**, 552-556, through *Chem. Zentralbl.*, 1912, I., 1477.)—Wohlgemuth (*Berl. Klin. Wochensch.*, 1910, **47**, 92) described a method for the quantitative estimation of fæcal-amylase. According to this method, a weighed quantity of fæces is extracted with a 1 per cent. sodium chloride solution, the extract is centrifuged, and the amylolytic power of regularly decreasing quantities of this extract is determined at 38° C. by the hydrolysis of 5 c.c. of a 1 per cent. solution of soluble starch. After twenty-four hours' action, iodine solution is added, and the degree of digestion is estimated colorimetrically. The author's experiments have shown that this method gives satisfactory results in the case of fæces having a reaction within the normal limits, but in the case of strongly acid fæces false results may be obtained, owing to the extreme sensitiveness of the amylase towards acids. In order to avoid this source of error, the author recommends, for the extraction of the fæces, a solution of 0·1 mol. of sodium dihydrogen phosphate and 0·2 mol. of disodium hydrogen phosphate in 1 litre of 1 per cent. sodium chloride solution. J. F. B.

Separation of Peroxydase from Catalase. A. Kasanki. (*Biochem. Zeitsch.*, 1912, **39**, 64-72.)—The method described is based upon the fact that catalase is precipitated when treated with pyrogallol, whilst peroxydase remains in solution.

On adding pyrogallol to the clear filtered juice obtained from hemp seedlings in quantity sufficient to make the concentration of the precipitant between 4 and 5 per cent., a precipitate is formed which is free from peroxydase; the latter, however, passes into the filtrate when the mixture is filtered. If the pyrogallol be added in sufficient quantity, the catalase is rendered inactive, and cannot be detected in either the precipitate or the filtrate. The method may be employed for preparing catalase-free peroxydase from different sources. W. P. S.

Experiments with the Castor-Bean Lipase. K. G. Falk and J. M. Nelson. (*J. Amer. Chem. Soc.*, 1912, **34**, 735-745.)—A comparative study was made of the hydrolysis of methyl acetate, ethyl butyrate, and olive oil, caused by the castor-bean lipase. No appreciable influence on the subsequent hydrolysis was found when small amounts of alkali were added at the beginning of the action on methyl acetate, but with ethyl butyrate the action was different, depending on the amounts of alkali added. Corrections were introduced in every case for the acid formed from ester solvent and lipase solvent. When the solvents used were ether saturated with water, and acetone containing a small amount of water, methyl acetate was hydrolysed to a considerable extent with lipase, both at the ordinary and at more elevated temperatures. Small amounts of an active constituent were extracted from the lipase preparation by water and by ethyl acetate. By the electrolysis in water of the lipase preparation a substance was produced in the anode solution, probably by oxidation, showing marked hydrolytic action. In all cases the amount of ester hydrolysed was measured by titrating with a $\frac{N}{10}$ aqueous solution of sodium hydroxide, using phenolphthaleïn as indicator. A large number of experiments are described with details as to temperature, time of action, solvent used, and titration figures. The lipase preparation used was prepared by grinding the castor-beans roughly, extracting a number of times with carbon tetrachloride or chloroform, and then grinding to a fine powder and passing through a hundred-mesh sieve and thus separating the majority of the shells. The fine powder was then exhaustively extracted with ether, leaving a light grey preparation containing 9 per cent. of ash, which, when mixed with water, had always a slightly acid reaction, increasing slowly on standing.

H. F. E. H.

Biochemical Method for the Estimation of Small Quantities of Salicylic Acid in Presence of Excess of p-Hydroxybenzoic Acid. J. Böeseken and H. Waterman. *K. Akad. van Wetensch., Amsterdam*, 1912, **20**, 548-552; through *Chem., Zentralbl.*, 1912, I., 1503-1504.)—*p*-Hydroxybenzoic acid is capable of being utilised by *Penicillium glaucum* as a source of carbon nutrition, whereas salicylic acid exerts a retarding influence on the growth of this organism. For the estimation of small quantities of salicylic acid in the presence of *p*-hydroxybenzoic acid, the following process may be adopted: 3 grms. of *p*-hydroxybenzoic acid, 0·5 grm. of dipotassium hydrogen phosphate, 0·5 grm. of ammonium chloride, and 0·2 grm. of magnesium sulphate, are dissolved in 1 litre of water, and several Erlenmeyer flasks are charged with equal quantities of the solution; increasing quantities of salicylic acid are added to the series of flasks, the contents are sterilised, and each flask is infected with a culture of *Penicillium.* A 0·3 per cent. solution of the acid mixture to be analysed is treated in the same manner, and the development of mould-fungus growth which takes place in the latter is compared with that in the flasks containing the standard mixtures. J. F. B.

Refractometer Value of the Serum of Cow's and Goat's Milk. K. Alpers. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 497-513.)—The author considers that the refractometer value of the calcium chloride serum of milk, as determined by the process described by Ackermann (Analyst, 1907, **32**, 117) is of value as a criterion in the detection of added water in milk. For the milk of separate healthy cows the value lies between 35·8 and 41·3 at 17·5° C., the average value for 126 samples of milk examined being 39·11. The daily variation observed did not exceed 1·4. Goat's milk showed values of from 34·7 to 40·3, with an average of 38·0, a value slightly lower than that given by cow's milk. W. P. S.

Value of Direct Enumeration of Bacteria in Water by Means of the Ultra-Microscope. Aumann. (*Zentralbl. Bakt.-u.-Parasitenk.*, 1912, II., 624-635; through *Chem. Zentralbl.*, 1912, I., 1594.)—The ordinary method of counting bacteria in the glass apparatus of Thomas and Zeiss is regarded as unsuitable, owing to the difficulty of completely sterilising the glass, though this objection does not apply to apparatus of quartz. The use of the latter is as a rule only practicable with water containing many bacteria, as, for example, in detecting large leakages in filtration. For the general examination of water the counting method with the ultra-microscope does not afford any certain conclusion as to the number of micro-organisms present, much less as to the suitability of the water for drinking purposes. C. A. M.

ORGANIC ANALYSIS.

Methods of Analysing Coal and Coke. F. M. Stanton and A. C. Fieldner. (U. S. Dept. of Interior, Bureau of Mines, Technical Paper, 8, pp. 19.)—This publication describes in detail the methods of analysis in use in the laboratories of the Bureau of Mines, and is published in consequence of the numerous requests addressed to the Bureau for information as to its methods. The methods are substantially those recommended by the American Chemical Society, but a few modifications have been introduced, and somewhat elaborate apparatus is figured. The practice in the Bureau laboratories is to dry the whole 3-pound samples received by them to constant weight at 30°-35° C., and an oven specially designed for this service is figured. After quartering down to about 400 grms., the sample is then reduced to 60 mesh in a ball mill. Moisture is determined in the usual way by drying for one hour at 105° C., and a glycerol oven of quite novel form, which is said to insure great uniformity of temperature, is illustrated. The greatest deviation from the methods of the American Chemical Society is in the use of a sheet-iron chimney to protect the crucible from draughts during the determination of volatile matter. The publication also includes descriptions of apparatus for the ultimate analysis of coal, and directions for the use of the bomb calorimeter and for the determination of true as well as apparent specific gravity. G. C. J.

Volatile Acidity of Gum Tragacanth compared with that of Indian Gum. W. O. Emery. (*J. Ind. and Eng. Chem.*, 1912, 4, 374-376.)—The author has investigated the question of the detection of Indian gum in admixture with tragacanth by a method based on the estimation of the volatile acid produced on hydrolysis with acids. Indian gum is derived from the *Sterculia urens* or the *Cochlospermum gossypium*, the specimens examined belonging to the former species. The quantitative estimation of the volatile acidity is carried out in the following manner: One grm. of the whole or powdered gum is treated in a 700 c.c. round-bottomed flask, provided with a long neck, for several hours in the cold with 100 c.c. of water and 5 c.c. of syrupy phosphoric acid until the gum is completely swollen. The mixture is then boiled gently for two hours under a reflex condenser, whereby a clear colourless solution is obtained, a very small amount of cellulosic residue remaining. The hydrolysed product is next distilled slowly in a vigorous current of steam until the distillate amounts to 600 c.c. and the acid residue to about 20 c.c., care being taken not to scorch the organic matter in the flask. The spraying of phosphoric acid may be prevented by fitting a spray-trap to the still-head. The distillate is titrated with $\frac{N}{10}$ potassium hydroxide in presence of 10 drops of phenolphthaleïn solution, finally boiling the liquid under titration until a faint pink colour persists. The result is controlled by a blank distillation with the omission of the gum. The volatile acidity is expressed in terms of c.c. of $\frac{N}{10}$ alkali per 1 grm. of gum. A number of authentic samples of gum tragacanth showed, for lumps, 3·2 to 4·2 c.c., mean 3·6 c.c.; for powder, 3·5 to 4·1 c.c., mean 3·7 c.c., equivalent to 2·2 per cent. of acetic acid from the original gum. As regards Indian gum, it has previously been shown by Robinson that the gum of *Cochlospermum gossypium* yields on hydrolysis 14·4 per cent. of acetic acid. The author has treated several samples of the gum of *Sterculia urens*, and found—for lumps, 25·9 to 28·3 c.c., mean 26·7 c.c., equivalent to 15·9 per cent. of acetic acid; for powder, 25·4 to 27·7 c.c., mean 26·5 c.c., equivalent to 15·89 per cent. of acetic acid. It is noted that, whereas gum tragacanth yields practically a colourless solution after hydrolysis, the gum of *Sterculia urens* yields a rose-pink solution on boiling with phosphoric acid. It is concluded that the volatile acidity values are sufficiently constant to afford a good means of detecting and estimating admixtures.

J. F. B.

Investigations on Mercury Fulminate. R. Philip. (*Zeitsch. ges. Schiess. u. Sprengstoffwesen*, 1912, 7, 109, 156, 180, 198, 221.)—The Brownsdon method for the estimation of fulminate (*J. Soc. Chem. Ind.*, 1884, 3, 17; 1905, 24, 382) consists in determining, without delay, the alkalinity produced by excess of sodium thiosulphate on the fulminate, using methyl orange. This was modified to eliminate the error due to the reduction of the alkalinity on standing, by using a large excess of thiosulphate, and working always under standard conditions. A method in which the excess of thiosulphate is titrated back with iodine was also evolved, and finally, a combination was found to give good results. Three grms. of pure potassium iodide (the use of which reduces the loss of alkalinity) are dissolved in 50 c.c. $\frac{N}{10}$ thiosulphate solution, 0·3 grm. of fulminate is washed in and dissolved by agitation with a rotary motion, and the solution titrated first with methyl orange and $\frac{N}{10}$ acid, then with starch and $\frac{N}{10}$ iodine (1 c.c. $\frac{N}{10}$ acid = 0·0071 grm. mercury fulminate; 1 c.c. $\frac{N}{10}$ iodine = 0·0142 grm. mercury fulminate). In most cases the results were consistent, and the two titrations agreed satisfactorily, the iodimetric ones being somewhat the higher; but with certain fulminates purified by crystallisation from potassium cyanide, the alkalimetric titration apparently showed 1·2 per cent. more mercury fulminate than the iodimetric. This is attributed to the possible presence of a product of the partial decomposition of the fulminate by the solvent. It was found that brown fulminate is not necessarily less pure than white. O. E. M.

Analysis of Indigos containing Starch. G. H. Frank and A. G. Perkin. (*J. Soc. Chem. Ind.*, 1912, **31**, 372-373.)—It has been shown by Thomson (ANALYST, 1911, **36**, 290) that the sulphonation methods of Rawson or Bloxam do not give accurate results in the analysis of indigo containing starch. The author's experiments upon mixtures of pure indigotin and starch confirm Thomson's conclusions, and show that the low figures obtained are probably due to the destruction of indigotin through a reducing action of the products of hydrolysis of the starch during the sulphonation. This process is counterbalanced more or less by an oxidising process, when fuming sulphuric acid is used for the sulphonation, as in Bloxam's process; and this would explain the concordance of the results obtained by Bergtheil and Briggs (*J. Soc. Chem. Ind.*, 1906, **25**, 733) with mixtures of indigotin and starch. Further experiments have shown that pure indigotin is not altered when digested with dilute hydrochloric acid in the presence of starch, and that there is no reason against the method of extracting the starch from a mixture by treatment with boiling dilute hydrochloric acid, and estimating the indigotin in the residue by the tetrasulphonate process. Only by boiling the mixture for a long time with the potassium acetate were the results too low with Bloxam's process; but this is unnecessary, and a temperature of about 90° C. is quite sufficient for obtaining a clear solution. C. A. M.

Occurrence of Methylcyclopentenolon in Pyroligneous Acid. J. Meyerfeld. (*Chem. Zeit.*, 1912, **36**, 549-552.)—A hitherto unknown unsaturated ketonic alcohol of the pentamethylene series, methylcyclopentenolon, $C_6H_8O_2$, has been isolated by the author from pyroligneous acid. In the pure condition it melted at 106° C., and sublimed with slight decomposition at 210° C. It had a characteristic odour and a sweet pungent taste. It could readily be obtained in crystalline needles from hot water, alcohol, acetone carbon tetrachloride, etc. In aqueous solution it gave a deep violet stable coloration with ferric chloride. It reduced ammoniacal silver nitrate on gently heating, and Fehling's solution on boiling, and with phenylhydrazine yielded an osazone, $C_{18}H_{18}N_4$, which crystallised from alcohol in yellow needles, melting at about 140° C. It yielded salts with metals, and from these the ketonic alcohol could be regenerated by treatment with a mineral acid.

C. A. M.

New Reaction for Organic Bases. Charitschkoff. (*Chem. Zeit.*, 1912, **36**, 581.)—A solution of the so-called inactive naphthenic acid in hydrocarbons or in ether does not react with copper sulphate by itself; but as soon as a trace of aniline, pyridine, quinoline, piperidine, coniine, codeine, nicotine, quinine, or other base that is soluble in ether is added, the reaction takes place with the formation of copper naphthenate. On this reaction is based a sensitive test for the detection of the above-named basic compounds, a solution of the inactive naphthenic acid in ether or petroleum spirit, with the addition of 3 per cent. of copper sulphate solution being used as the reagent. On shaking the mixture the liquid remains colourless until a trace of a base is added. It is suggested that the test may be of value for the detection of alkaloids and ptomaines in physiological investigations. Caffeine and diphenylamine do not give the reaction. Oleic acid may take the place of inactive naphthenic acid in the test. In the case of crystalline bases and alkaloids which are only sparingly soluble in ether or petroleum-spirit, free acid or amyl alcohol may be used for the extraction. C. A. M.

Use of Phenolphthaleïn as an Indicator. J. W. McBain. (*J. Chem. Soc.*, 1912, **101**, 814-820.)—Stress is laid upon the great influence of extraneous carbon dioxide upon the results of a titration, and it is shown that in the presence of that gas in solution about ten minutes are required for the final end-point of the reaction to be reached. In the absence of carbonate, however, or if much carbonate is present, as in the case of a normal bicarbonate solution, the end-point occurs practically instantaneously and is permanent. The effect of carbon dioxide (carbonates) upon the sensitiveness of the end-point was estimated by titrating solutions of potassium hydroxide freed from carbon dioxide and carbonate, with and without the addition of known quantities of carbonate. It was found that with the greatest care the amount of alkali needed to change the colour was about fifty times greater than the 0·0043 c.c. of $\frac{N}{10}$ alkali anticipated. The changes of colour in these experiments were compared with those of a colour scale ranging from No. 1 to 200, the first solution matching in colour that of a solution of 0·50 grm. of cobalt nitrate and 0·62 grm. of copper sulphate per litre, and the others containing two, three, four, etc., times these amounts. For comparing the colours above No. 10, a Donnan's colorimeter was used, and the colour of a solution nearly saturated with sodium phosphates and coloured with phenolphthaleïn was standardised against the cobalt and copper solutions. The difference between each member of the standard series was intended to correspond to the change in colour produced by the addition of one drop of $\frac{N}{250}$ acid or alkali. McCoy (*Amer. Chem. J.*, 1903, **29**, 437) gives the alkalinity of $\frac{N}{10}$ sodium hydrogen carbonate as $2{\cdot}9 \times 10^{-6}N - OH'$, which would correspond to about No. 70 in the phenolphthaleïn standard. Hence, the amount of alkali required to produce the colour change in a titration, considered in conjunction with McCoy's value, affords a sensitive means of estimating the amount of carbonate in a given solution. Estimations made with the different strengths of phenolphthaleïn solution showed that a pale colour, corresponding to about No. 3 in the standard scale, was the most sensitive for the end-point, and was also closer to the point of theoretical neutrality. It is advisable always to use about 20 drops of a 1 per cent. alcoholic solution of the phenolphthaleïn per 100 c.c.; since when carbonate is present the depth of colour is approximately proportional to the amount of phenolphthaleïn added up to the saturation point (50 to 60 drops). The error caused by adding only 1 drop instead of 20 drops of the indicator to 100 c.c. of distilled water corresponded to 0·08 c.c. of $\frac{N}{10}$ potassium hydroxide solution. The phenolphthaleïn solution had been freed from carbon dioxide, neutralised with alkali, and was protected by a guard-tube of potassium hydroxide. With regard to the degree of accuracy possible in ordinary titrations, 0·01 per cent. was found to be the limit of agreement in duplicate estimations when large quantities of acid and alkali were used, and all precautions were taken in the ordinary atmosphere. As a precaution it is suggested that the water in the titration flask should be coloured to a pale tint similar to that to be attained at the end-point, before adding the acid, and that care should be taken not to breathe in the direction of the flask. Under these conditions the results of two estimations should agree within 0·1 per cent. C. A. M.

Simultaneous Effect of Alcohol and a Neutral Salt on the Sensitiveness of Phenolphthaleïn. E. Lenk and G. Mondschein. (*Chem. Zeit.*, 1912, **36**, 534.)—The effect of varying amounts of water on the system-ammonium chloride, water, phenolphthaleïn—and of water and alcohol on the system—ammonium chloride-water-alcohol-phenolphthaleïn was investigated. Alcohol displaces the end-point very much more than does water. For example, 10 c.c. of 2 N ammonium chloride solution, neutral to litmus, required 2·4 c.c. $\frac{N}{10}$ potassium hydroxide solution to give a coloration with phenolphthaleïn; the addition of 20 c.c. of neutral water increased this to 3·8 c.c., while 20 c.c. of alcohol raised it to 38·0 c.c. This is not an ionisation phenomenon, but is due to constitutional alterations in the indicator.

O. E. M.

INORGANIC ANALYSIS.

Use of Arsenious Acid in Volumetric Analysis. II. Estimation of Mercury. F. Litterscheid. (*Chem. Zeit.*, 1912, **36**, 601.)—The solution of mercuric salt, which should not contain less than 0·1 grm. nor much more than 0·4 grm. of mercury, and which should have a volume of about 50 c.c., is mixed with 50 c.c. of $\frac{N}{10}$ arsenious acid solution and 5 grm. sodium bicarbonate in a 200 c.c. flask, and the mixture is heated on the water-bath until the precipitate acquires the dark grey tint of finely-divided metallic mercury. If the flask be shaken from time to time, the reaction is complete in half an hour. The contents of the flask are then diluted somewhat, cooled, and finally made up to 200 c.c. Since the mercury is very finely divided, the mixture is filtered through a double hard filter, or a teaspoonful of precipitated chalk is mixed with the contents of the flask before filtering through an ordinary paper. The first runnings are rejected, and the subsequent ones returned to the filter until 100 c.c. of clear filtrate has been collected. This is then diluted to about 500 c.c., and, after addition of a further 5 grms. of sodium bicarbonate, the excess of arsenious acid is determined by means of $\frac{N}{10}$ iodine solution. If the original solution contained ammonium salts, the filtrate from the reduced mercury is first acidified with sulphuric acid and then saturated with sodium bicarbonate (10 grms.). G. C. J.

System of Qualitative Analysis for the Common Elements. Part V. Acidic Constituents. A. A. Noyes. (*J. Amer. Chem. Soc.*, 1912, **34**, 609-643.)—This paper forms a continuation to those previously published by the author under the same main title (*J. Amer. Chem. Soc.*, 1927, **29**, 137; 1908, **30**, 481; 1909, **31**, 611). In the aggregate, these papers cover more than 200 pages, and constitute in effect a textbook of qualitative analysis, largely based on the author's original investigations, but necessarily embodying so much that is common knowledge that no ordinary abstract of them is possible. The scope of the present paper is indicated in its sub-title, and the system of analysis is based on the volatilisation of most acids by boiling with phosphoric acid, collecting the distillate in two portions, the first of which contains the readily volatile, slightly ionised acids, the second the less volatile, largely-ionised acids. In the search for individual acids, the attempt has been made to select or devise tests of known and roughly equal sensitiveness, and preference has been given to those methods which enable the experienced analyst to form an approximate estimate of the quantities present. G. C. J.

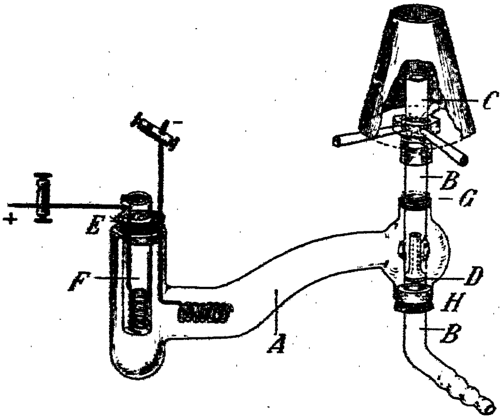
Study of Cobaltinitrites and their Application to Analytical Chemistry. L. L. Burgess and O. Kamm. (*J. Amer. Chem. Soc.*, 1912, **34**, 652-659.)—The sensitiveness of the cobaltinitrite test for potassium may be greatly increased by having silver nitrate present, the double cobaltinitrites of potassium and silver—$Ag_2KCo(NO_2)_6$ and $AgK_2Co(NO_2)_6$—being much less soluble than potassium cobaltinitrite or sodium di-potassium cobaltinitrite, one or other of which, according to the amount of reagent used, constitutes the precipitate of the ordinary test. For example, when 1 drop of a freshly prepared 25 per cent. solution of sodium cobaltinitrite is added to a solution containing less than 100 parts per million of potassium, no perceptible precipitate is formed. If the test is repeated in presence of $\frac{N}{100}$ silver nitrate, a copious yellow precipitate is formed immediately. In presence of $\frac{N}{100}$ silver nitrate, solutions containing only 2 parts of potassium per million give an almost immediate precipitate, which persists for half an hour, and a solution containing only 0·5 part per million gives a distinct precipitate within fifteen seconds, the precipitate persisting for about five minutes. In applying this test, it is essential that the solution be neutral, or only slightly acidified with acetic acid. Halogens are conveniently removed by addition of silver nitrate and filtering, such an excess of silver being used as will make the filtrate an approximately $\frac{N}{100}$ solution of silver nitrate. In the usual scheme of analysis, the test may be applied after removal of the heavy metals. The filtrate from the latter is acidified with an excess of nitric acid, evaporated to dryness and ammonium salts volatilised, since ammonium silver cobaltinitrite is so insoluble that the test here described would serve for the detection of ammonia in concentrations of 5 parts per million in absence of potassium. Rubidium, caesium, and thallium, form double cobaltinitrites with silver which are even less soluble than the corresponding potassium salt. No other metal is likely to interfere, for, though barium forms sparingly soluble cobaltinitrites, it will not interfere, unless the concentration of barium exceeds $\frac{N}{10}$ strength. G. C. J.

Separation of Iron from Titanium. F. Bourion. (*Comptes rend.*, 1912, **154**, 1229-1232.)—The substitution of sulphur monochloride for chlorine in the process where iron is separated from titanium by volatilisation in a current of chlorine and hydrogen chloride simplifies the apparatus necessary for this separation, and permits of its being accomplished at a lower temperature. To prevent volatilisation of titanium, it is necessary to keep the concentration of sulphur monochloride low, but this is readily accomplished as follows: The sulphur monochloride (2 c.c.) is contained in a flask of 160 to 170 c.c. content, surrounded by melting ice, and the stream of dry hydrogen chloride is introduced into the flask by a tube which comes within 4 to 10 mm. of the surface of the liquid, the mixed gases then passing to the combustion tube in which the mixed oxides of titanium and iron are contained in a porcelain boat. At its forward end the combustion tube is connected to a Will and Varentrapp apparatus, charged with water. The reaction commences at 200° C., and until a temperature of 400° C. is reached the gas stream may be as rapid as seventy-five bubbles per minute, but should then be reduced to half this rate, whilst the temperature is raised to 700° to 750° C., at which the reaction is complete in from two and a half to four hours with 0·3 to 0·5 grm. substance. After allowing the tube to cool, the hydrogen chloride in it is expelled by means of a current of dry air. Under the conditions described, no trace of iron will be left in the boat, nor can titanium be detected, even by the peroxide test, either in the contents of the receiver or in the washings of the combustion tube. In these washings and the contents of the receiver the iron is precipitated by means of ammonia after oxidation of any ferrous iron by means of nitric acid. Occasionally magnetic oxide of iron may be formed in the forward part of the tube, as the result of the action of the steam of reaction on ferrous chloride, and the analyst must bear this in mind and take appropriate steps for bringing this iron into solution. G. C. J.

Estimation of Radium in Minerals and Rocks. E. Ebler. (*Chem. Zeit.*, 1912, **36**, 604.)—The method depends on the determination of the quantity of emanation given off in some definite interval of time by a known weight of the mineral. The weighed substance is placed in a platinum boat, either alone or mixed with some suitable flux, such as potassium carbonate, borax, or alkali phosphates (*Cf.* Joly, *Phil. Mag.*, 1911 [vi], **22**, 134; Eve and McIntosh, *Trans. Roy. Soc. Canada*, 1910 [iii], **4**, III., 67), and is heated to free it completely from emanation. The boat is then placed in a quartz combustion tube, which lies in an electric furnace, and which is connected by ground connections and taps to a mercury pump. After an interval of time, which may vary from two days to a month, according to the amount of radium present, the gaseous contents of the tube are transferred by means of the pump to a small gasholder, the contents of the boat being strongly heated towards the close of the operation. The air and emanation are then transferred to an evacuated ionisation chamber, and the radium emanation measured in the usual manner by determination of the saturation current. The absolute weight of radium is arrived at by means of a control experiment on a weighed quantity of some substance of known radium content. For use as a standard, radium barium oxalate of approximately 10 per cent. radium content serves well, and its real radium content may be estimated with an accuracy of 0·5 per cent. by determining its mean molecular weight, for which purpose a small quantity is weighed on a micro-balance, converted into oxide, and reweighed. The use as standards of mixtures of radium and barium salts of organic acids of higher molecular weight than oxalic acid would increase the accuracy of the method, and experiments with this object in view are in progress. The method, as described, permits of the estimation of radium in minerals with an accuracy of about 0·5 per cent.

G. C. J.

Spectroscopic Process for the Estimation of Small Quantities of Rubidium in Presence of much Potassium. E. Wilke-Dörfurt. (*Zeitsch. anorg. Chem.*, 1912, 75, 132-140.)—The process consists in dissolving the substance (potassium salts) in water, feeding atomised spray from this solution to a special burner, photographing a portion of the spectrum and comparing the photograph so obtained with a series of standards prepared under nearly identical conditions. The illustration shows the atomiser and burner. The glass burner tube *B* is of 9 mm. internal diameter and extends for 7 cm. above the point *D*, where a capillary, 3 cm. long and 0·8 mm. in internal diameter, is fused into it. Opposite the capillary jet are two openings for the supply of air to the burner through the atomising device *A*. To the top of the glass burner tube, a porcelain tube of the same internal diameter and 5 cm. long is attached by means of rubber tubing. Rubber tube is also used for making the joints at *G* and *H*, where the burner tube enters and leaves the bulb-shaped extension of the vessel *A*. The vessel *A* is constructed from tubing of 2·8 cm. internal diameter, the height of the anode chamber being 8 cm., and the length of the knee-shaped portion, the lower part of which accommodates the cathode, 12 cm. The bulb through which the burner tube passes is of 3·5 cm. diameter, and the distance between *G* and *H* 5·5 cm. *E* is a cork sufficiently nicked to allow a free supply of air to the burner. The cathode wire passes between the cork and the glass wall of the tube, but the anode is suspended within a short length of glass tubing, which serves to allow the escape of electrolytic oxygen and traces of

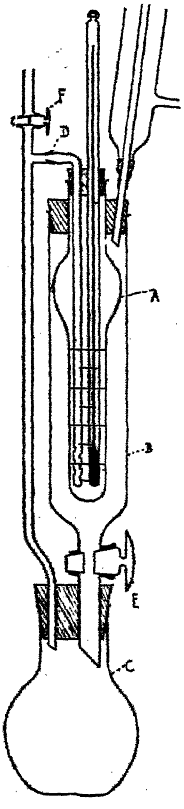


chlorine. The colouring of the flame is effected, on the Beckmann-Riesenfeld principle, by electrolytic atomising of the solution, of which 40 c.c. is placed in the vessel *A*. The solution should be a 10 per cent. solution of the mixed salt, as a high concentration of potassium insures the current being conducted by the potassium chloride, and avoids any possibility of rubidium becoming transformed into hydroxide or perchlorate. The electrodes are of 0·8 mm. platinum wire and a current of 2·5 ampères at 4·5 volts gives a suitable evolution of gas. For photographic work, the most suitable portion of the spectrum to select is that between 396 $\mu\mu$ and 435 $\mu\mu$, that is to say the blue, not the red, which serves best for work with the naked eye. The spectroscope used by the author has a prism, the dispersion of which between *c* and *h* amounts to 4·25°; the opening of the collimator and of the camera is 19 mm. As the inner cone of the Bunsen flame gives lines in the blue, the inner cone of the flame is kept as small and sharply defined as possible. Obviously, in attempting to make a process such as this quantitative, every precaution must be taken to work under constant conditions. Among important conditions, easily controlled, are gas pressure, region of flame observed, time of exposure, and manner of development of the plates. Uniformity in manufacture and age of the plates is insured by buying direct from the makers. The author uses Agfa "extra rapid" plates, and gives a half-hour exposure. This length of exposure tends to eliminate errors due to small periodical changes in some of the conditions which are difficult to suppress, but which neutralise each other during a prolonged exposure. Too long an exposure, however, leads to the appearance of a continuous spectrum, due to dust particles, which reach the flame, in spite of all precautions. The author describes the development of his plates, but any process, provided it be a rigidly uniform one, may be used. For concentrations of rubidium relative to potassium of from 0·05 to 10 per cent., the method is accurate to within about 10 per cent. It was designed to estimate only the order of magnitude of the rubidium percentage in new potash workings, but has proved more accurate than this, as stated. G. C. J.

Estimation of Sulphides in Lime Liquors. J. R. Blockley and P. V. Mehd. (*J. Soc. Chem. Ind.*, 1912, **31**, 369-372.)—Estimation of the sulphides in lime liquors for leather by titration with zinc sulphate gives abnormal results owing to the precipitation of zinc as hydroxide, and this is also the case when the zinc sulphate solution is prepared as suggested by Procter ("Leather Industries Laboratory Book," pp. 55, 87), by adding ammonia to the solution until the precipitate just redissolves. If, however, an excess of ammonium chloride is added to the zinc sulphate solution (50 grms. per litre of $\frac{N}{10}$ solution), or if the ammonium chloride is added to the liquor to be titrated with Procter's solution, the precipitation of zinc hydroxide is prevented, whilst only zinc sulphide is precipated, and a sharp end-point of the reaction is indicated with lead acetate or sodium nitroprusside (preferably the latter) as an outside indicator. It is usual to take the alkalinity of a lime liquor as an index of its freshness, and to discard the liquor when the increase in alkalinity due to amino-compounds from the hides has reached a certain limit. In the presence of sodium sulphide, however, this direct measurement of alkalinity is not applicable; nor does the alkalinity of a sulphide lime liquor correspond to the separate alkalinities due to the sulphide and to the lime, a liquor containing sulphide showing less lime than pure lime liquor, owing to the sulphide precipitating calcium hydroxide.

C. A. M.

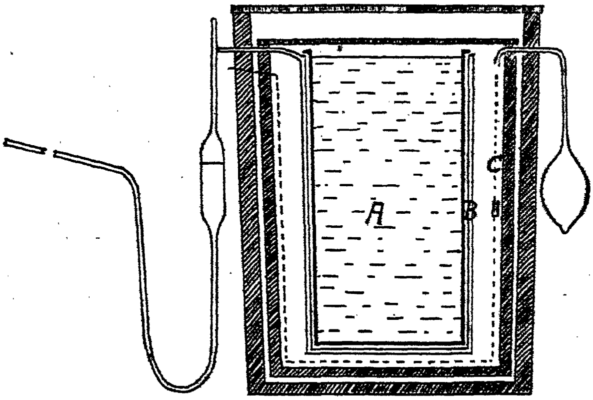
APPARATUS, ETC.



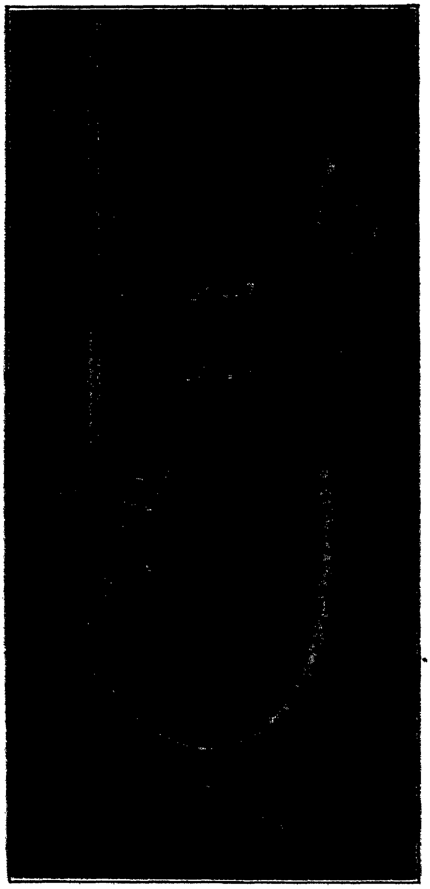
Modification of the Landsberger Boiling-Point Apparatus. J. H. Paterson. (*Proc. Phil. Soc. Univ. Durham*, 1912, **4**, 142-144.)—The author has simplified the apparatus of Landsberger (*Ber.*, 1898, **31**, 458). The boiling-flask *C* is partly filled with the pure solvent, and a few pieces of unglazed porcelain added to prevent bumping. The solvent is boiled with the tap *E* (of large bore) open, until the whole of the inner tube *A* is raised to the temperature of the boiling solvent, as shown by the condensation of the vapour from the condenser. The tap *E* is closed, when the vapour ascends by the side tube, and the measuring vessel *A* begins to fill with the liquid. When the thermometer registers a constant boiling-point, the burner below is removed and the tap *E* opened. The liquid collected above this tap flows back into the flask, causes a temporary cooling of its contents, and sucks the solvent in *A* back into the flask. A weighed quantity of the substance to be examined is next introduced into *A*, and the tap closed to such an extent that some vapour passes up through it and warms the outer jacket, while the rest passes by the side tube. When sufficient liquid has collected in *A*, and a definite temperature is noted, the tap *E* is opened, and simultaneously the tap *F* is opened to prevent the liquid being sucked back. The volume of liquid and the temperature are then noted, the tap again partly closed, and the experiment repeated at various dilutions. The apparatus gives good results. The thermometer has a range of 50° C., and is graduated in twentieths of a degree. The glass tap is greased with glycerol or vaseline according as benzene or alcohol is used as the solvent.

A. R. T.

Adiabatic Device for Bomb Calorimeter. J. A. Fries. (*J. Amer. Chem. Soc.*, 1912, **34**, 643-652.)—Adiabatic calorimeters have been described before (ANALYST, 1910, **35**, 283), but the present device is applicable to existing calorimeters of the more usual patterns. The calorimeter, *A*, is enclosed within and separated all round by a 4 to 5 mm. air space from a double-walled cylindrical copper jacket *B*, which has an air space of 4 mm. between its walls and bottoms, and is constructed of polished sheet copper of 0·25 mm. gauge. This copper jacket is in effect the bulb of an air-thermometer and is connected by a small brass tube, as shown, to a water-gauge which is shown—broken off—making an angle of 14° with the horizon, a capacious bulb being interposed between the gauge and the copper vessel to prevent water being sucked over into the latter should the temperature be unduly depressed. The fact that the air thermometer is sensitive to changes of barometric pressure is but rarely important, having regard to the short time required for a determination. The jacket is heated by means of an electric current passing through a German silver wire about 3·5 metres long and 0·8 mm. in diameter, with a total resistance of about 6 ohms. This wire is strung through brass eyelets screwed directly into the inner insulating fibre jacket of the Atwater-Berthelot calorimeter used by the author. The eyelets are so arranged that there is one coil of wire near the bottom a little distance from the sides, the rest of the wire going up and down along the sides, making eight loops spaced evenly, and coming to within 30 mm. of the top of the inner fibre jacket. The two ends are fastened to insulated copper wire and brought through the side of the fibre jackets. The manner of wiring described was adopted to avoid induction. The distance between heating wire and fibre vessel is about 6 mm., leaving 15 to 20 mm. between wire and calorimeter. On a 110 volt circuit, the current obtained through five 130 Watt lamps in parallel serves well. Since the air thermometer is affected by changes of pressure as well as changes of temperature its scale must be a movable one. This scale is graduated by placing a good mercury thermometer in the copper jacket, allowing the conditions to become constant, taking readings, then switching on the current for a short period and again taking readings when the conditions are constant, and so on, correcting for barometric changes if necessary. The scale of the air thermometer should be in 0·1°. With the author's instrument, adiabatic conditions are sufficiently realised if the heating device be put in operation when the charge is ignited and the current switched off after forty seconds, supposing, that is, that the charge is likely to generate some 4,500 calories. Whether another instrument would need a longer or shorter heating or one or two additional short contacts after the first can soon be determined. The author also finds that he gets the most exact results when his jacket temperature is maintained about 0·1 to 0·16° C. higher than that of the calorimeter, the explanation of this being probably the constant radiation from the water surface and top of the calorimeter. The advantages of the apparatus are these common to adiabatic



calorimeters generally—namely, obviation of tedious computation with some increase of accuracy. The following test numbers are given with some details of the experiments: Heat of combustion of benzoic acid, 6323, 6315, 6316, 6323, the best attested value known to the author being 6320. G. C. J.



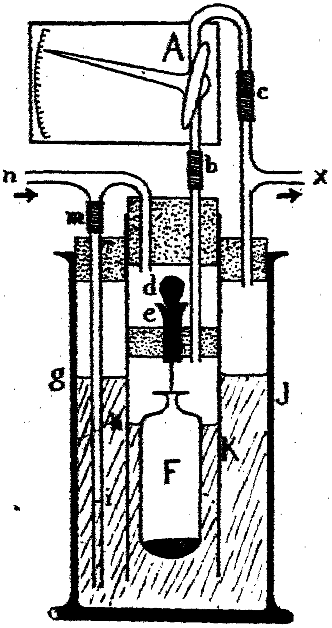
New Densivolumeter for Determination of Density of Solids. J. Escard. (*Comptes rend.*, 1912, 154, 1242-1244.)—The illustration is nearly self-explanatory. Before use the graduated tube (on the left) is raised and the other tube lowered, and the apparatus charged with water though *B*. By moving one of the tubes slightly up or down, the water level in *t* is made to coincide with the zero of the scale which is in $\frac{1}{20}$ c.c. A friction runner on *m* is then moved until it marks the level of the meniscus in the right-hand tube, which is then lowered until the bulb *A* is partly empty. The stopper *a* is removed, the weighed substance introduced, and the stopper reinserted. The levels of the tubes are readjusted until the meniscus in the right-hand tube again coincides with the position of the friction runner, and the volume of the solid introduced is read off direct on the graduated tube.

G. C. J.

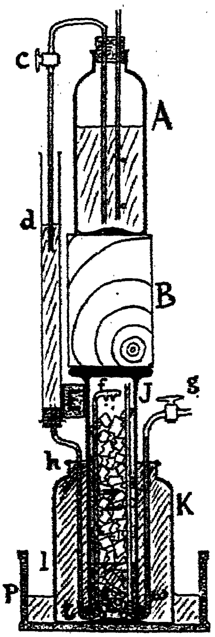
Apparatus for Determination of Vapour Pressure Isothermals of Silicic Acid Gels. R. Zsigmondy, W. Bachmann, and E. F. Stevenson. (*Zeitsch. anorg. Chem.*, 1912, 75, 189-197.)—The apparatus illustrated in the paper consists of (1) a small glass vessel for holding the gel, provided with a glass stopper, which is removed for the introduction of the gel, and which by a half-turn serves to make or break connection with the rest of the apparatus, from which it is detachable by a ground-glass joint; (2) a more capacious vessel for holding any liquid with the vapour pressure of which it is desired to bring the gel into equilibrium, this vessel being connected to a manometer, and also provided with a tap to disconnect its contents from the rest of the system; and (3) a T-tube connecting (1) and (2), the third limb of the T connecting through a tap to a mercury pump. For use with hydrogels, the taps and ground joints are greased for the upper part of their ground surface with "Ramsay grease"; but for use with alcohol or benzene grease is not permissible for the ground joint of the weighed vessel containing the gel, and mercury-cupping must be resorted to. As an example of the manner in which the apparatus is used, the following particulars relating to a series of experiments with a hydrogel of silicic acid are given. This gel was cut into pieces not larger than 4 mm. cube, and dried over concentrated sulphuric acid in an ordinary desiccator. The glass vessel for the reception of the gel was then weighed full of air, after removing every particle of grease from the stopper; the stopper was then greased, and the apparatus again weighed, exhausted, and weighed a third time. About 0·7 grm. of the gel was next transferred to the vessel, and the latter connected by its ground joint to the rest of the apparatus, the larger vessel, with manometer attachment, being charged with concentrated sulphuric acid. With the weighed vessel cut off by its tap from the rest of the apparatus, the rest of the apparatus was exhausted, connected momentarily with the weighed vessel, and the cycle repeated until, on opening the tap of the weighed vessel, the manometer remained stationary. The vessel containing the gel was then weighed daily, always closing its tap before disconnecting from the rest of the apparatus, and removing grease from its ground connection before weighing, until the difference between two successive weighings was less than 0·5 mgrm. Dry air was then admitted to the vessel and another weighing made. The concentrated acid in the vessel with manometer attachment was then replaced by acid of weaker strength, the system freed from air by the pump, and daily weighings again made, this series of operations being repeated with weaker and weaker acid, and finally with water. A reverse series, with increasing concentration of acid, was also made, and the results plotted on a system of rectangular co-ordinates, in which the ordinates are proportional to the vapour pressures, and the abscissæ to the water content of the gels in molecules of water per molecule of silica. The method, though tedious, is much less so than that of Van Bemmelen (*Zeitsch. anorg. Chem.*, 1897, 13, 239), and, unlike his method, can be applied to alcohol and benzene gels as well as to hydrogels. For use with benzene, sulphuric acid is replaced by mixtures of benzene with paraffin oil, whilst a mixture of glycerol and alcohol is used in experiments with alcohol gels. G. C. J.

Colorimeter for Rapid Work with Widely Varying Standards. C. H. White. (*J. Amer. Chem. Soc.*, 1912, 34, 659-662.)—The colorimeter is of the type in which the thickness of the sections observed is the variable. It consists essentially of two wedge-shaped hollow glass prisms of exactly equal dimensions, and open at the large end for the introduction of the solutions to be tested. The wedges are held in a vertical position side by side in a camera, and may be raised or lowered by rack and pinion, actuated by thumbscrews. The pinions are screened from view on the side towards the operator, except for a narrow horizontal slit across the middle of the camera, through which the solutions are observed when a test is being made. The carriers are graduated to correspond to the length of the wedges, the zero of the scale being opposite the index when the sharp edge of the wedge is opposite the narrow opening in the screen through which the colour is observed. The screens are adjustable, so that the opening may be varied to suit the operator. The ground glass shutter at the forward end of the camera, for diffusing the light, is hinged in the manner of a door to facilitate the transfer of the wedges to and from the camera. To carry out a determination with this instrument, equal quantities of the standard and of the material to be tested are diluted to equal volumes, and convenient amounts of the solutions are transferred to the wedges. The wedge containing the solution of unknown strength is set at the graduation representing the percentage—or some multiple of it—of the colouring matter in the standard. The wedge containing the standard is then adjusted, until the two fields seen through the camera appear identical. The percentage of colouring matter in the unknown is then indicated by the reading of the scale on the carrier containing the standard. If the depths of colour first compared are too great or too small for the most accurate comparison, the result may be checked, without changing the solutions, by setting the wedge containing the unknown at some new point on the scale, and again adjusting the other wedge until equality is reached. In the author's hands, the maximum error of a single observation is 0·6 per cent. The apparatus, which is illustrated in the paper, is made by Eimer and Amend, of New York. G. C. J.

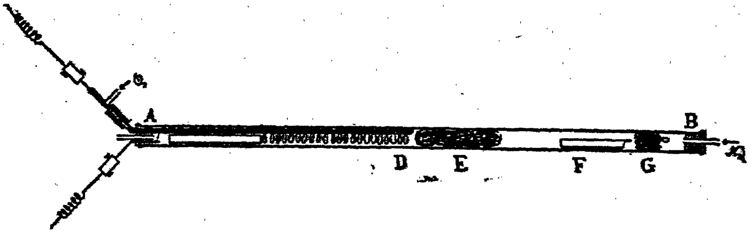
Combined Governor and Gauge for Regulating Flow of Gas. S. H. Collins. (*Proc. Phil. Soc. Univ. Durham*, 1912, 4, 110-113.)—The figure shows the governor and gauge for maintaining a flow of gas: *A* is a glass tap with pointer and scale; *b*, *c*, and *m* are rubber connections; *d* is a piece of glass rod drawn out to a long, fine point; *e* is a piece of glass Sprengel tube blown with a bulb and then ground down; *F* is a float containing mercury, and having a flat glass platform cemented on; *K* is a piece of wide glass tube, and *J* is a glass cylinder. The gas enters at *n* and leaves at *x*. When working the gas depresses the water to *i*, but instead of entering here, it passes by *d* into the chamber containing the valve. The rate at which the gas passes through this valve depends upon the position of *F*, which is kept hovering about a position determined by the level *h*, according to the size of the instrument. The level of water *g* is dependent on the amount of water placed in the jar, and may be adjusted at the commencement. The height *gh* is thus fixed; the height *gi* shows the pressures of the incoming gas, *hi* the surplus pressure being got rid of by the valve. As the difference of pressure on the two sides of the tap is kept constant, and the tap is fixed by experiment, both pressure and resistance are constant, and the current also in the absence of variation of specific gravity of the gas. The instrument in trial has shown an average flow of 10·05 ± 0·22 litres of gas per hour when 10 litres were required. A. R. T.



Constant-Pressure Hydrogen Generator. S. H. Collins. (*Proc. Phil. Soc. Univ. Durham*, 1912, 4, 107-109.)—The author claims that the apparatus delivers pure hydrogen at a steady rate. The figure shows a Winchester quart bottle, *A*, containing diluted sulphuric acid (1 : 8 by volume), and supplied with a stopcock, *C*. The wooden block *B* and the air-tube in *A* provide coarse and fine adjustment respectively for pressure of gas. The wide tube *d* is roughly graduated in c.c., the level of the sprinkler *f* being zero. The large bottle *K* serves to hold the waste acid, and in conjunction with the inverted cylindrical jar *J* acts as a gas-holder. The trough *P* receives the waste acid and is emptied occasionally. The jar *J* contains about 7 kgrms. of zinc in lumps (not granulated) resting on a ball of copper wire. Between the mouth of *J* and the bottom of *K* are two pieces of wide rubber tube to prevent breakage. The acid tube has a rubber connection at *t*, and the gas delivery tube similarly one at *w*, and these should be narrower than the tubes used as a cushion for *J*, to prevent their being closed by the weight of zinc. *hl* is only about three-quarters of *df*. Three corks are placed in the mouth of *K* to fix *J* firmly. The hydrogen is freed from sulphuretted hydrogen and other impurities by passing it through a tube containing "mercury lime," prepared by mixing 3 parts of mercuric chloride and 1 part of lime, making into a paste with water, drying the mixture, and breaking it into convenient sized lumps ready for use. This purifier gradually becomes yellow and then black by absorption of the impurities. A. R. T.



Analysis of Organic Substances by an Electrical Method. E. E. Reid. (*Amer. Chem. J.*, 1912, 47, 416-419.)—The following method is recommended for the simultaneous estimation of carbon, hydrogen, and sulphur. A combustion-tube of transparent quartz 600 mm. long by 17 or 18 mm. internal diameter is used, though one of hard glass may serve. In the end *A* is inserted a two-holed rubber-stopper, through one hole of which passes a small quartz tube, 300 mm. long by 4 mm. external diameter (*A* to *D*). At 25 mm. from the end this tube is bent to an angle of 45°, the bent end projecting from the stopper. To the outer end of this is fastened a T-tube, into the other side of which is fused a platinum wire. This wire must be



large enough to carry a current of 3 ampères without heating. The wire passes through the T-tube and small quartz tube, and connects at the end of the latter with one end of two metres of fine platinum wire ("No. 30") used as the heating coil; this is wound into a spiral about 12 mm. in diameter, and is supported on the small quartz tube. When hot, this has a resistance of 24 ohms, and is used on a 110-volt circuit, in series with an external resistance of 18 ohms, taking 2·6 ampères of current. This wire is coiled tightly round the small quartz tube for a distance of about 125 mm. from the stopper, and its end is joined to a rather stout platinum wire passing through the stopper. These close coils are so placed as to keep the lead peroxide in the boat just below them nearly, but not quite, up to its decomposition point.

A piece of platinum foil 100 by 25 mm. has welded across it, 1 mm. from the end, a piece of platinum wire. The other end is notched and turned up, and the foil bent to form a semicircular trough to fit inside the combustion tube. At *E*, just beyond the end of the small quartz tube, is placed a plug of quartz wool, 75 mm. long (asbestos will not answer, as it absorbs oxides of sulphur). Over this portion of the combustion tube is suspended a shield of thick asbestos board, and under it is placed a strong burner with a "wing" top. The plug of quartz wool at *G* contains a loop of platinum wire, to withdraw it when the boat is to be inserted. The portion of the tube containing the heating coil is provided with a close-fitting cover of asbestos board having a narrow slit through which the coil may be observed.

Lead peroxide is used as the oxidising material. A blank experiment, to determine its loss in weight when reduced to the monoxide, is made by heating a weighed quantity of the peroxide in the platinum boat in the combustion tube, using two burners under the tube and one from above. The peroxide is heated till it is at a red heat (3 mins.), when the source of heat is removed, and the boat cooled quickly. The resulting pure yellow monoxide is weighed, and the loss of weight calculated per grm. of peroxide. For an estimation, 1 to 2 grms. of the peroxide in the boat, spread out evenly, are placed in the combustion-tube, the quartz plug at *E* heated very hot, and the platinum coil brought to a bright red heat before inserting the boat containing the substance to be burned. Next the burner under the plug *G* is lighted, and a slow current of oxygen is admitted through the small quartz tube, care being taken that an excess of oxygen is present in the gases issuing at *A*. A third burner heats the boat at *F* to cause slow volatilisation of the substance, and the vapours are passed through the quartz plug at *E* by means of a slow current of air or nitrogen admitted at *B*. The most refractory substances are completely burned at the high temperatures possible in the quartz tube, admitting oxygen at *B* if necessary. 0·2 grms. of substance is burnt in about one hour, and even if complete combustion of the carbon is not assured, the sulphur is usually satisfactorily burned and absorbed. When the combustion is complete, the platinum boat containing the peroxide is heated to reduce it, as already described. Using the results of the blank, the loss in weight on reduction is calculated. The weight of the boat and its contents is diminished by this amount, and the remainder, subtracted from the final weight, gives the weight of sulphur trioxide absorbed during the combustion. A. R. T.

New Method for Quantitative Analysis of Solutions by Precise Thermometry. T. W. Richards and J. W. Shipley. (*J. Amer. Chem. Soc.*, 1912, 34, 599-603.)—The method depends upon noting the precise temperature at which the solution attains exactly the same density as a given, previously calibrated float, and its application is of course limited to cases where not more than one substance, in addition to the solvent, is present. When, as is usual, the solution is denser than the solvent, the more concentrated the solution, the higher is the temperature necessary to reach floating equilibrium; hence, each concentration corresponds to a definite temperature, and after a few points on the almost linear curve connecting the two variables have been determined by means of known solutions, all the intervening ones are determinable by simply reading the thermometer at the points where floating equilibrium is attained. When the solution is less dense than the solvent, it must be cooled instead of warmed to attain floating equilibrium, as the concentration increases. The exact density of none of the solutions need be known, since the method depends only on differences of density.

A mercury thermometer used for this purpose is best calibrated with great care; but if the bore is very uniform and the graduation is perfectly spaced, the degrees need not correspond to any recognised scale. Good results may be got with any good Beckmann thermometer. Platinum resistance thermometers may be used by those familiar with very exact electrical measurements, and in this case ohms or multi-volts may be plotted directly against concentrations without translation into Centigrade degrees. A thermostat capable of being adjusted to any needed temperature and of being kept there within 0·005° C. is required in order that the greatest accuracy may be attained. The solution to be investigated is placed in a litre Erlenmeyer flask, immersed in the thermostat and the float within the flask is viewed by reflection in a small inclined mirror kept beneath the water of the bath. The glass float should be small (5 c.c.) and cigar-shaped and, if permanency in calibration is desired, should have been made several months before use. A recently-made float may be used, but will require calibration every few days. For wide ranges of concentration, several floats will be necessary. Because the co-efficient of expansion of the float enters into the effect, the results obtained with floats made of different materials are not directly comparable. Probably Jena thermometer glass (59^{III}) is the best material available. The exact density of the float is of no consequence: all that is necessary is that it shall float at room temperature in the lightest solution for which it is to be used, and sink when the temperature is raised a few degrees. A float of slightly too low density is easily adjusted by attaching to it a few points of glass. The sensitiveness of such floats is very great and the temperature at which they sink or rise can be determined within 0·001° C. As an example of the order of magnitude of the temperature differences corresponding to differences of concentration which the method is designed to measure, the following may be given: A particular float just sank in alcohol of 98·99 per cent. strength at 15·391° C. On adding water so that the percentage of water in the alcohol was increased from 1·01 per cent. to 3·44 per cent., the temperature of floating equilibrium was 24·093, and intermediate experiments showed that the increase of temperature of floating equilibrium was very nearly a linear function of the concentration of water. It is obvious that this float affords a means of determining the percentage strength of strong alcohol with a degree of accuracy which is limited rather by errors inherent in the methods available for determining the strength of the 98·99 per cent. spirit used as the basis of calibration than by the experimental errors of the method now described.

REPORT.

The Softening, Purification, and Sterilisation of Water Supplies. A. C. Houston. (Metropolitan Water Board. Eighth Report on Research Work.) —The report deals with a novel method of using lime primarily as a bactericidal agent, and only secondarily and incidentally for softening purposes. This would make possible the safe and speedy utilisation of flood-water, and the absolute elimination, so far as the portion of water treated with an excess of lime is concerned, of any danger from such epidemic water-borne diseases as typhoid fever and cholera. As an illustration of the method, it is assumed that it is required to deal with 10,000 gallons of the Thames supply, to remove at least 15 parts of total hardness, and to render the water innocuous. Fifteen pounds of quicklime, costing 1½d., would be added to 7,500 gallons of raw, unstored Thames water. This would kill within twenty-four hours the *B. coli*, and inferentially, but certainly, the microbes also of epidemic water-borne disease—*e.g.*, the typhoid bacillus. The water would also be improved considerably as judged by physical and chemical standards. The excess of lime (about 0·007 per cent.) would then have to be neutralised with 2,500 gallons of *adequately* stored water, which, according to all the author's experiments, would not contain any of the microbes of epidemic water-borne disease. Thus 75 per cent. of the water would be sterilised chemically, and the remaining 25 per cent. by storage. The mixture would have lost about 15 parts of its total hardness, and would contain no undesirable excess of free lime, besides being perfectly innocuous. Rapid filtration alone would then be required to remove the precipitate of inert carbonate of lime, and to bring the water up to a reasonable standard of chemical purity. As an alternative, the case of a well water is considered, having over 15 parts of temporary hardness, which is considered to be dangerous. Seventy-five per cent. of the whole would be lime-sterilised, and the remaining 25 per cent. sterilised by ozone or heat, or by active chlorine, and the two portions mixed together to produce a softened and bacteriologically safe drinking-water. As only 25 per cent. of the total would require the more expensive treatment, the cost is proportionately reduced, and the faint taste in the 25 per cent. portion would be diluted to such an extent as to be negligible. Experiments are cited showing that the bactericidal dose of lime with hard waters is about 1 to 5,000, falling in the case of very soft waters to about 1 to 50,000. The experiments were made with "uncultivated" *B. coli*—the state in which they would be ingested by the consumer. The *B. coli* in London crude sewage were killed by 1 part of quicklime (about 75 per cent. CaO) in 2,000 parts of sewage. The disadvantages and the advantages (of the excess lime method) are set out, and among the former, assuming the method to be grafted on to an existing water-purification plant, is the fact that the mere cost of lime to reduce the hardness, even by 10 parts, would be about double the cost of the existing process of sand-filtration. The capital expenditure on the machinery and softening tanks would be very large, and the periodical removal and disposal of sludge would entail great expense, and might even be impracticable. Softening proposals (apart from the novel application of utilising the lime as a germicidal agent) would seem to run counter to the authoritative "findings" of the "Richmond," "Balfour," and "Llandaff" Commissions, and of the Arbitration Court. As against all these, the method can be applied to 75 per cent. or any smaller proportion of the total supply, and is specially suitable for flood-waters, because the water is then usually less hard, and the treatment has a clarifying and purifying action, apart from its bactericidal effect. The cost of lime treatment is not wholly unremunerative, and it is even claimed by some that a substantial gain on balance is obtained, due to saving in soap and fuel consumption. Of first-rate importance is the capacity of the method quickly (five to twenty-four hours) to render an initially foul water absolutely safe bacteriologically; it also virtually increases the yield of the sources of supply by rendering them always fit for abstraction. The method is perfectly innocuous, since no substance is left in the water which was not there initially in greater amount. The construction of new storage reservoirs could be postponed, as the lime-treated water is brought into a parallel bacteriological condition with the *adequately* stored water. This would mean, in effect (on the 75 per cent. basis), prolonging the period of storage from 30 to about 120 days, since 25 per cent. of the water from the storage reservoirs could be mixed with 75 per cent. of raw water after lime-sterilisation.

REVIEWS.

METHODS OF AIR ANALYSIS. By J. S. HALDANE, M.D., F.R.S. Pp. x + 130. London: Charles Griffin and Co. 1912. Price 5s. net.

Most of those who are actively engaged in air analysis are more or less familiar with the work of Dr. Haldane in this direction, and to these it is enough to say that this little book contains illustrations and detailed instructions for the use of all those pieces of apparatus which we owe to the author—illustrations and instructions which until now were hard to come by, as they were scattered among a number of journals not usually to be found on the analyst's shelves and among Bluebooks. To those whose general knowledge of the subject was acquired a few years ago, and who have not given close attention to more recent periodical literature, it may be said, without exaggeration, that the work of Haldane has revolutionised methods of air analysis—at any rate of methods designed to estimate three or a less number of constituents in a gas mixture. Haldane's original apparatus was described as long ago as 1898, but since that date various modifications of it have been devised for special purposes, and perhaps the best known is his apparatus for the gasometric estimation of carbon dioxide in the air of ordinary rooms, and this apparatus serves as well as any to illustrate the principles common to all.

For the gasometric estimation of the small proportion of carbon dioxide usually found in ordinary rooms and factories, a portion at least of the measuring burette must be of very narrow diameter, and a feature of all apparatus of the Haldane type is a burette with a bulb of relatively large dimensions, and a narrow, graduated stem. The relation between the volume of the graduated stem and the bulb differs according to the purposes the apparatus is intended to fulfil; but for the determination of carbon dioxide in air the stem makes up only one-hundredth of the volume of the whole burette, and is divided into 100 divisions. Since the scale is sufficiently open to allow fractions of a scale division to be estimated with an error not exceeding 0·1, very close reading is possible; but it is obvious that such close reading would be futile unless there existed means for correcting for variations—even very small variations—of temperature and pressure between two readings. An essential feature of the Haldane apparatus is that it provides such a means of compensating for variations of pressure or temperature. The means adopted is a control-tube, of the same size and shape as the burette, placed alongside the latter in a water jacket, the burette and control-tube being connected by independent connections to separate limbs of what is in effect a differential pressure gauge, charged with a solution of caustic potash. Dr. Haldane, in his book, acknowledges the use of a control-tube by Williamson and Russell, and the use of the same principle by Pettersson; but the application of the principle in a simple and practical form is due to Dr. Haldane alone, as is constantly recognised by designers of new forms of gas apparatus when, to shorten their descriptions, they say their apparatus embodies the Haldane principle.

Since the appearance of the publications in which Dr. Haldane's various pieces of apparatus were first described, many minor improvements have been introduced, and some of these were described in a paper by Butterfield (ANALYST, 1909, **34**, 257)—a paper which had a special value at the time because of the inaccessibility to many of Haldane's original papers. All these minor improvements are referred to in the present book, which will therefore be welcomed even by those familiar with the original papers.

In addition to gasometric methods, the book includes a description of the Haldane and Pembrey method for the gravimetric determination of moisture and carbon dioxide—a method which, by simple means, enormously increased the speed and accuracy of such determinations—and modern methods for the recognition and determination of small proportions of carbon monoxide in air are also dealt with at length. In this connection, again, the work of Haldane (and Douglas) has at once simplified and increased the accuracy of the blood test, the use of the spectroscope being dispensed with and the delicacy of the test increased about fivefold.

This book, which, in addition to its other merits, is well illustrated and exceptionally free from misprints, must find a place in the library of every chemist who is at all interested in the subject with which it deals, and those chemists who are not interested in the analysis of simple gas mixtures must be few.

G. CECIL JONES.

An Introduction to Quantitative Analysis. By S. J. M. Auld, D.Sc. (Lond.), Ph.D., F.I.C. London: Methuen and Co., Ltd. 1912. Pp. x + 215. Price 5s. net.

This is one of Methuen's Textbooks of Science series, and aims at providing "an introductory course in quantitative analysis, suitable for college and university students, without entering too deeply into the details of special technical analysis," and in this object it succeeds. That it does so to an appreciably greater extent than many of the existing similar handbooks is open to doubt. Little can be said in favour of the practice of multiplying elementary textbooks, which do not efficiently replace good laboratory teaching, which do not particularly encourage independent ingenuity on the part of the student, or which fail to emphasise the scientific foundations of analytical chemistry.

The author has traversed practically the whole range of ordinary analysis, and has been in this respect too ambitious; for instance, the accounts of water and gas analysis are inevitably scrappy. No doubt the actual manipulative detail of water analysis may be properly described in seventeen pages, and it may be argued that the really important thing, which is the interpretation of the results, can be taught by experience alone. This branch of analysis is surely better left to the special technical treatise.

As to the methods and exercises properly included in a college course, the selection in the present volume is satisfactory. It is to be regretted that the use of standard thiocyanate is omitted, and that no reference is made to the volumetric estimation of mixed alkali, hydroxide, and carbonate, but, on the other hand, one is pleased to see borax brought into line with other weak alkalis.

The book is reasonably free of errors and misprints, but grave exception will be taken to the explanation of bichromate oxidation by the scheme—

$$Cr_2O_6 \longrightarrow Cr_2O_3 + 3O, \text{ on p. 58.}$$

In the estimation of sulphur by means of sodium peroxide, the possible injury to a platinum vessel should be indicated, and in the determination of the equivalent of magnesium by heating in air, mention ought to have been made of the formation of magnesium nitride, a point that often puzzles a thoughtful student. The weighing of a precipitate on a "tarred" filter-paper (p. 125) points to a somewhat hasty revision. Apart from these criticisms, which after all might be directed against most elementary books, this volume has the merit of brevity, and will no doubt be of use to the students for whom it is intended. G. Druce Lander.

Sulphuric Acid and Alkali. By G. Lunge. Vol. iii.: Ammonia Soda, Various Processes of Alkali Making and the Chlorine Industry. London: Gurney and Jackson. 1911. Price 30s. net.

The analyst who may have to refer to the third volume of Dr. Lunge's great work on alkali industries in search of detailed information respecting special analytical methods will be disappointed. For these another volume by the same author must be consulted; but the present volume contains a number of tables of specific gravities and strength of solutions, as well as sufficient analytical information for carrying out the various operations in a factory. Many tables of statistics are given which might have been useful had they been brought up to date. The production of ammonia soda, for instance, is only given to 1895, and can only possess historical interest sixteen years later. There are numerous indications throughout the book that it has neither been carefully revised nor brought up to date since the issue of the second edition in 1896. As the author remarks, even the description of many antiquated or impracticable processes may be of occasional use to the professional reader; but still those who refer to a work by a technical expert expect up-to-date information as to the actual working of factories and a little more guidance than a mere enumeration of processes because they have been patented. The reader who is not already an expert will have difficulty in ascertaining what the best practice is at the present time in factories producing the materials referred to in the work. For instance, Schlœsing's ammonia soda process of 1889 is called new, and the same term is applied to a patent taken out in 1893 and long since expired.

The bulk of the volume might, with advantage to the reader, be reduced by at least one-third, and it is to be hoped that in any future edition the editing will be more carefully done and the matter brought up-to-date. Errors are very numerous, and in some cases misleading. We are told, for instance, that the American short ton is 1,000 pounds, and in a description of apparatus on p. 121, a drum is substituted for a chain. Even the reprint of a German title contains two errors in one line.

The 184 illustrations are clear and well executed, but many of them are mainly of antiquarian interest to the chemical technologist of to-day. WALTER F. REID.

NITROCELLULOSE INDUSTRY. By E. C. WORDEN. 2 vols. London: Constable and Co., Ltd. 1911. London. Price 42s. net.

The compilation of this book has been a work of very great magnitude. It is impossible, in the course of a short review, to do anything approaching justice to the results of the author's industry. The text runs to over 1,000 pages, the references total nearly 18,000, some 500 different journals have been consulted, and the patent specification references are international, and are inclusive of Japan and Mexico. The reviewer has been particularly struck with the reliable and up-to-date nature of the information in those sections of the book which deal with gun-cotton and propellants. The analyst will find many subjects very fully dealt with. Fusel oil and amyl acetate are treated at considerable length from the manufacturing point of view, and the analysis of amyl acetate, crude fusel oil, and purified amyl alcohol are dealt with very adequately. The section on camphor, artificial camphor and camphor substitutes, is a very important one. Very full details are given of the methods adopted for the analysis of lacquers, celluloid, photographic films, and pharmaceutical collodion. The article on artificial filaments is especially worthy of note, as it deals with the subject in a most interesting manner. Thirty pages are devoted to the United States regulations for denatured alcohol. The book, as a whole, claims the highest commendations, and it can certainly be consulted with very great profit by everyone who has to deal with nitrocellulose, either in its wide ramifications in the arts, or in its use in explosives. GEORGE W. MACDONALD.

AUGUST, 1912. Vol. XXXVII., No. 437.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

ON THE APPLICATION OF ADSORPTION TO THE DETECTION AND SEPARATION OF CERTAIN DYES.

BY A. CHASTON CHAPMAN AND ALFRED SIEBOLD.

(*Read at the Meeting, June* 5, 1912.)

DURING recent years a very considerable amount of attention has been devoted to the study of certain phenomena to which the general term "adsorption" has been applied. Whatever may be the precise explanation of these phenomena, the facts are comparatively simple, and many instances—*e.g.*, the decolorisation of solutions by means of animal charcoal—have been known and utilised for a very long time. Among adsorbent substances, kaolin occupies an important position, and a number of references to its power of removing dyestuffs from solution are to be found in chemical literature. These, as a rule, occur in communications dealing with the theory or practice of dyeing, and, with the exception of the valuable work of Goppelsroeder on the separation and identification of certain colouring matters by capillary methods, no systematic study of this property, from the analytical standpoint, has, so far as we are aware, been made. It is true that H. Wislicenus (*Zeitsch. Chem. Ind. Kolloide.*, 1908, 2, Supt., II., 11-20) has suggested the application of the so-called "fibre-alumina" to the examination of various kinds of extracts, including dyes, and that LaWall has employed kaolin as one of the reagents in a scheme for the detection of certain natural colouring matters ("Select Methods of Food Analysis," Leffmann and Beam, 2nd Edition, pp. 74-75), but no very definite results appear to have been obtained, and no mention is made of the separation and identification of artificial dyes. Among the more important papers dealing with the question of adsorption of coal-tar dyestuffs, attention may be specially directed to a paper by Suida (*Monatsh. Chem.*, 1904, 25, 1107), in which the adsorbing properties of kaolin and other silicates and silicious materials have been studied.

Few problems are more difficult than the identification of the dyes used in the colouring of foodstuffs, particularly when two or more are present together, and no apology is needed for bringing to the notice of analysts any method which is capable of facilitating such investigation, even if only to a small extent. The experiments described below had their origin in some observations made in the laboratory of one of us, that certain artificial dyestuffs could be readily separated by the use of kaolin, and that this property could in some cases be usefully applied to the examination of artificially coloured food-products.

The method of experimenting was very simple, and consisted in stirring in a small glass mortar the solution of the dye with a weighed quantity of kaolin, previously ground with a little water. Alternatively the dry kaolin was added to the dye solution, and the mixture thoroughly stirred, or in some cases the solution of the dye was merely filtered through a layer of kaolin. The dye solutions contained in all cases 1 grm. of the dyestuff per litre. For the purposes of the experiments, 10 c.c. of the dye solution were stirred for several minutes with 5 grms. of kaolin, previously mixed with 10 c.c. of water, and the mixture filtered through a Buchner funnel with the aid of a pump. The above amount of kaolin was always employed, but in the case of those colours which are very rapidly adsorbed, it was found that the kaolin was capable of taking up in some cases more than 1 per cent. of its weight of the dye. When tested in this manner, it was found that the various dyes experimented with could be divided into three classes: (*a*) those which are entirely adsorbed under the above-mentioned conditions; (*b*) those which are partially adsorbed, giving coloured kaolin from which the bulk of the dye can be extracted by washing with water; and (*c*) those which are not appreciably adsorbed.

The following table contains a list of the dyes experimented with, and shows their behaviour when treated in the manner above described:

TABLE I.

Adsorbed.	Partially Adsorbed, but Adsorbed Colour partly extracted by Washing with Water.	Not Adsorbed.
Congo red.	Acid green.	Acid magenta.
Safranine.	Patent blue.	Eosin.
Magenta.	Soluble blue.	Erythrosin.
Neutral red.	—	Fluorescein.
Malachite green.	—	Methyl orange.
Brilliant green.	Acid green. (Practically all extracted by boiling water.)	Tropæolin.
Methylene blue.	—	Orange IV.
Bismarck brown.	—	Ponceau 4R.
	—	Bordeaux R.
Crystal violet.	—	Sudan red.
Methyl violet B extra.	—	Tartrazin.
Auramine.	—	Naphthol yellow.
		Picric acid.
		Naphthol green.
		Indigo carmine.
		Cochineal (1 per cent. solution).

Although three entirely different lots of kaolin which were experimented with behaved very similarly so far as their powers of adsorption were concerned, yet slight differences were observed, particularly in the case of certain of the partially adsorbable dyes.

A convenient method of ascertaining whether any particular sample of kaolin is suitable for the examination of dyes by this method, is to mix 10 c.c. of a 0·1 per cent. aqueous solution of naphthol yellow, and 5 c.c. of a 0·1 per cent. aqueous solution of soluble blue. In the case of a really good kaolin, 5 grms. should be sufficient for the complete separation of these two colours—that is to say, the filtrate should be yellow and not tinged with blue. Satisfactory separations of the following dyes were effected :

Methyl violet B extra and naphthol yellow, crystal violet and naphthol yellow, crystal violet and eosin, auramine and naphthol green, auramine and indigo carmine, auramine and acid magenta, magenta and tropæolin, methylene blue and cochineal (1 per cent.), malachite green and tropæolin, brilliant green and tropæolin, methylene blue and tartrazin, crystal violet and methyl orange, soluble blue (5 c.c. only) and naphthol yellow.

In some cases it happens that, although a dye is itself readily soluble in alcohol, it is yet incapable of being dissolved from the coloured kaolin by means of that solvent. It is clear, therefore, that this property might in some instances be made use of in order to effect the approximate separation of three dyes when present together. Thus, the 5 grms. of kaolin, having been shaken or stirred with the dye solution in the manner indicated above, and filtered, the coloured kaolin remaining on the filter might, after one or two washings with hot water, be treated with hot alcohol. The following are examples of separations effected in this manner :

TABLE II.

Ponceau 4 R:	Aqueous filtrate.	Red.
Crystal violet:	Alcoholic filtrate.	Purple.
Safranine:	Kaolin.	Pink.
Naphthol yellow:	Aqueous filtrate.	Yellow.
Magenta:	Alcoholic filtrate.	Red.
Methylene blue:	Kaolin.	Purplish-blue.
Fluorescein:	Aqueous filtrate.	Dirty pink and fluorescent.
Brilliant green:	Alcoholic filtrate.	Green.
Congo red:.	Kaolin.	Pink.

That the coloration of the kaolin in the above cases was, in fact, due to the safranine, methylene blue, and congo red respectively, was proved by the application of well-known tests.

Experiments were next made for the purpose of ascertaining to what extent the adsorption results given above apply to saccharine solutions. In the case of magenta, methyl violet, safranine, Bismarck brown, brilliant green, auramine, and soluble blue, the results were substantially the same as when sugar was absent. The above results apply entirely to the removal of dyes from *aqueous solutions* by means of the kaolin, but in many cases the removal of the dye from alcoholic solutions can be

TABLE III.

Kaolin Dyed by Adsorption of—	H_2SO_4.	H_2SO_4, 10 per cent. by weight.	HCl.	HNO_3.	NaOH, 10 per cent.	NH_4OH.	Alcohol.
Congo red.	Deep blue.	Slate blue.	Deep blue.	Bluish-slate.	No change.	No change.	Alcohol, tinted light pink.
Safranine.	Green, changing to dull violet on dilution.	Purple.	Greenish-blue.	Bluish-green.	„	„	Alcohol, coloured light pink.
Magenta.	Brownish-yellow.	Brownish.	Yellow.	Yellowish-brown.	„	Slowly becomes lighter.	Deep pink solution.
Neutral red.	Green.	Violet-blue.	Blue.	Bluish-slate.	Yellow-brown.	Yellow-brown.	Little change; reddish-yellow filtrate.
Methyl violet B extra.	Yellowish-brown.	Fawn.	Brownish-yellow.	Greenish.	Lighter and duller.	No change.	Violet solution.
Crystal violet.	Brownish-yellow.	Greenish.	Orange-yellow.	Dull orange.	No change.	„	„
Malachite green.	Yellow.	Fawn.	Bright yellow.	Yellow-red.	Nearly decolorised.	Decolorised.	Greenish solution; partly extracted.
Brilliant green.	Orange.	Yellowish-brown.	Yellow.	Yellowish-red.	„	„	Deep green solution; easily extracted.
Methylene blue.	Yellowish-green, becoming blue on dilution.	No change.	No change.	Bluish-green, becoming blue on dilution.	No change.	No change.	No action.
Bismarck brown, or Vesuvin.	Puce.	Darker.	Puce.	Puce.	Browner.	Yellower.	Yellow on boiling.
Auramine.	Fawn.	Much lighter.	Decolorised.	Decolorised.	Decolorised.	Lighter.	Yellow solution.

effected by the same method, although not in the same degree. Thus, working under the above conditions, safranine which is completely removed from water, was only partly adsorbed from a solution in 90 per cent. alcohol. The kaolin containing the adsorbed dyes can be tested by the application of reagents similar to those which have been employed for the detection of dyes on wool and other fibres. As we have verified these reactions in the case of the colours experimented with, it may be useful to give the table (p. 342), although the reactions are in many cases to be found in various textbooks dealing with the subject:

The coloured kaolins were, in all cases, dried before the application of the above-mentioned reagents. The dilute sulphuric acid referred to was prepared by mixing one part by weight of the acid with nine parts of water; the sulphuric acid, hydrochloric acid, and nitric acid were the ordinary pure laboratory reagents. The caustic soda solution was a 10 per cent. solution, and the ammonia was prepared by mixing one volume of the strong ammonia solution with two volumes of water. The alcohol referred to in the last column was 90 per cent. strength.

It will be seen that we have only dealt with a few of the more commonly occurring dyestuffs, but doubtless the method would prove applicable in the case of a great many other colouring matters with which we have not experimented. It may be said that no difference could be observed in the adsorbing properties of kaolin when this was extracted with dilute hydrochloric acid and thoroughly washed. On the other hand, the ignition of the kaolin seemed to weaken its adsorbing properties to some extent. Precipitated aluminium hydroxide ground up with water (the so-called alumina cream) was found to be very inferior to kaolin as an adsorbent.

DISCUSSION.

Mr. BEVAN asked whether the respective proportions in which the dyes were present would make any difference in the accuracy of the test, and also whether there appeared to be any connection between the chemical composition of the various dyes and their degree of adsorption.

Mr. RAYMOND ROSS asked whether kaolin had any action upon natural vegetable colouring matters, such as occurred in fruits and in jam.

Mr. J. CONNAH asked whether this method had been applied to the identification of vegetable colours (*e.g.*, fruit juices) as well as to the coal-tar colours, and remarked that the method would doubtless be useful for the detection of artificial colouring matters in wines.

Mr. E. R. BOLTON asked whether the method could be used to separate colours from oils, and also whether the authors had tried the use of Fuller's earth. He suggested that possibly the use of kaolin and Fuller's earth consecutively might be found advantageous. Fuller's earth, of course, varied a good deal in its action on oils, some samples being capable of bleaching oils that would not be affected by other samples.

Mr. H. E. BURGESS said that he had recently found that when a solution containing three or four of these dyes was applied to ordinary blotting-paper the colours were separated, and could be fairly accurately identified by cutting up the blotting-paper and dissolving out the separate colours. The colours in that case were dissolved in glycerol before being applied to the blotting-paper; when water was used, the same effect was not obtained.

Mr. **Evershed** said that those colours which were adsorbed by kaolin were all, or nearly all, basic colours, whereas those which were not adsorbed were "acid" dyes. The action of the kaolin was therefore analogous to that of animal fibres. A skein of wool would take up the basic colours from a neutral bath, while the acid colours would only dye wool in the presence of a little mineral acid. He should like to ask whether the authors had tried the effect of mineral acids upon the adsorption of any of these dyes by kaolin. Had any quantitative tests been made with mixtures of acid and basic colours to see whether the former passed through the kaolin completely? It was well known that if fairly strong solutions of acid and basic colours were mixed, a precipitate was generally formed. If this precipitation occurred with weak solutions in passing through the kaolin, the separation must be incomplete. Had the kaolin method any superiority over the well-known methods of testing by means of wool and cotton?

Mr. L. M. **Nash** asked whether this method applied to spirit-soluble colours.

Mr. **Richmond** said that a good many years ago a method was published for detecting artificial colours in butter and margarine by shaking up with "Spanish earth," which, while not affecting the natural colouring matters, removed a good many artificial colours.

The **President** remarked that the fact that it was possible, when two out of a mixture of three dyes had been adsorbed by kaolin, to remove one of these by treatment with alcohol, showed how great an influence was exercised by the liquid in which the colours were dissolved. No doubt, if alcohol had been used in the first instance, different effects as regards adsorption would have been produced, and it might perhaps be possible, by varying the solvent, to extend the application of the method.

Mr. **Chapman**, in reply, said that the classification of the various dyes into those which were adsorbable by kaolin and those which were non-adsorbable was not, of course, an absolutely sharp one, but the method was at least capable of permitting of the separation of a number of dyes from one another, and of rendering their identification possible. It was true that, generally speaking, the dyes which were adsorbable by the kaolin were those which had a basic character, whilst those of an acid character remained, as a rule, unadsorbed. This had been pointed out some years ago by Suida and others. It was, of course, also true that some of the dye stuffs, to which he had referred, interacted and produced some precipitation. One advantage of the kaolin method over the ordinary one of dyeing wool, and also over such capillary methods as those mentioned by Mr. Burgess, was that larger quantities of the dyes could be separated, and that the dyed kaolin could be tested by means of various reagents, which could not well be applied to wool or paper. He and Mr. Siebold had not devoted much attention to natural colouring matters, but a good deal of work had already been done on that part of the subject, and had been referred to at the beginning of the paper. They had had no experience of the application of this method to the testing of wine, but it seemed quite possible that it would enable certain artificial dyes to be separated from the natural colouring matters of the wine. In the case of alcoholic solutions, separation could in many cases be quite readily effected, although they were of a different character from those which had been described in the case of aqueous solutions. They had not made any experiments with oils, and could not say what results would be obtained.

A NEW METHOD FOR THE DETECTION AND ESTIMATION OF SMALL QUANTITIES OF NITROUS ACID.

By E. HOLL MILLER.

(*Read at the Meeting, June* 5, 1912.)

THIS method is a colorimetric one, and depends on the formation of paranitrosodimethylaniline, when a solution of dimethylaniline hydrochloride is added to an acidulated solution containing nitrous acid. A yellow colour is developed immediately, unless the nitrous acid solution is very weak, in which case the colour develops on standing.

The following process is recommended for carrying out the estimation: A solution of dimethylaniline hydrochloride is required, containing 8 grms. of dimethylaniline and 4 grms. of hydrochloric acid per 100 c.c., and a standard solution of sodium nitrite containing 1 part of nitrous acid per 100,000. The estimation is performed in Nessler cylinders, or a colorimeter. Fifty c.c. of the solution under examination are introduced into a cylinder, and acidulated with 1 drop of concentrated hydrochloric acid, and 3 drops of the dimethylaniline solution added, and allowed to stand fifteen minutes. If the solution is very weak, it may be necessary to allow it to stand for thirty minutes, or longer, for the complete development of the colour. The colour is then matched in the usual manner against the standard solution, which is acidulated with 1 drop of concentrated hydrochloric acid, and 3 drops of the dimethylaniline solution added. The method is very sensitive, and will detect with ease 1 part of nitrous acid per 1,000,000. The presence of nitrates does not interfere with the estimation. The great advantages of the method are its sensitiveness and simplicity.

NOTE ON THE DETECTION OF BENZOIC ACID IN MILK.

By CECIL REVIS.

THE use of benzoates for the preservation of milk has shown a considerable and wide-spread increase this year, though they seem to be seldom detected. This is undoubtedly due to the fact that benzoic acid is not usually looked for in a routine manner, and also, that the quantity of milk taken for official purposes is, as a rule, too small to allow of the examination when other tests have been made. As a further difficulty arises from the unreliability of some of the methods employed, it may be of interest to note that the following method gives certain results. While not entirely original, it embodies the most necessary procedure in the detection of benzoic acid, viz., that the removal of fat, protein, etc., shall be done in an alkaline medium, otherwise there is much liability of the benzoic acid being removed with the precipitate or coagulum. The method is as follows:

One hundred c.c. (not less) of milk are diluted with an equal volume of water, and, after the addition of 5 c.c. of 10 per cent. sodium carbonate solution, heated in boiling-water for two to three minutes; 10 c.c. of 20 per cent. calcium chloride solution are then added, and the heating continued, until coagulation of the casein, etc., is complete. The liquid is then cooled and filtered, and the filtrate, neutralised with hydrochloric acid to litmus-paper. Ten c.c. of Fehling copper sulphate solution (not mixed with the tartrate solution), followed by 10 c.c. of a solution of potassium hydrate (containing 31·18 grms. per litre) are now added, and the liquid again filtered. The filtrate is poured into a separating-funnel, acidified with hydrochloric acid, and extracted with about 50 c.c. of ether. The ether is then washed three times with a little distilled water. About 10 c.c. of water are now added to the ether in the funnel, together with 1 drop of phenolphthaleïn solution, and then a saturated solution of barium hydrate added gradually, until, on violent shaking, the aqueous layer remains pink. This is then filtered off into a porcelain basin and evaporated to about 5 c.c. The contents of the basin are filtered into a test-tube and dilute (1 in 100) acetic acid dropped in until the pink colour is discharged, after which two more drops are added. The liquid is then tested with 1 drop of 10 per cent. neutral, freshly-prepared solution of ferric chloride, when, in the presence of benzoic acid, the usual characteristic precipitate is obtained. This method will detect 0·02 per cent. of benzoic acid.

The test with ferric chloride is the most reliable and characteristic, but it is necessary that everything else shall, as far as possible, have been removed, which the above method ensures.

When examining cream, 50 c.c. should be diluted to 200 c.c. with water and the same treatment applied.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

ANALYSIS OF FOOD AND DRUGS.

Examination of Copaiba Oil. E. Deussen and B. Eger. (*Chem. Zeit.*, 1912, **36**, 561-562.)—On treating β-caryophyllene with nitrogen peroxide, a compound, $C_{12}H_{19}N_3O_6$, which may be termed β-nitro-caryophyllene (m.-pt. 159·5° to 160° C.), is obtained. This reaction may be used in the examination of copaiba oil in the following manner: Three grms. of the sample are dissolved in 27 c.c. of anhydrous ether, and the solution treated with nitrogen peroxide until the precipitated β-nitro-caryophyllene begins to agglomerate. The precipitate is then separated, washed with ether, dried on porous porcelain, and weighed (*cf. Annalen*, 1912, **388**, 138). The following yields of β-nitro-caryophyllene were thus obtained: Caryophyllene (from clove oils) 50 to 52; Para copaiba oil (*a*), 9·5 to 10; (*b*, *c*, *d*,) 15 to 16; Maracaibo copaiba oils, 3 to 6; Maranham copaiba oil, 8 to 9; Para copaiba oil (*d*) adulterated with 10 per cent. of gurjun oil, 13·3 to 14·3; with 20 per cent. of gurjun oil, 11·7 to 12·7; with 30 per cent., 10·7 to 11·7; and with 50 per cent., 7·7 to 8·3 per cent. For the detection of 10 per cent. of African copaiba oil in Para oil, the optical rotation may be determined. The melting-point of the dihydrochloride also rises with the increase in the proportion of African copaiba oil. Thus, on passing hydrochloric acid gas into pure Para oil, a mixture of β-caryophyllene dihydrochloride (m.-pt. 69° to 70° C.) and of *l*-cadinene hydrochloride (m.-pt. 117° to 118° C.) is obtained, melting at about 75° C., whilst in the presence of African copaiba oil, which is rich in cadinene, the m.-pt. of the mixed hydrochlorides is raised to about 85° C. by 5 per cent.; about 111° C. by 10 per cent.; and about 114° to 115° C. by 20 per cent. In testing Para copaiba oil for gurjun oil by Turner's reaction 3 drops of the sample are dissolved in 3 c.c. of glacial acetic acid, and the solution treated with 2 drops of freshly prepared 10 per cent. sodium nitrite solution, and then cautiously with concentrated sulphuric acid. In the presence of gurjun oil the acetic acid solution becomes dark violet within thirty minutes. Since certain pure copaiba balsams give a faint positive reaction in this test, the author modifies the method by using 1 drop of the sample and 1 per cent. sodium nitrite solution, and only taking note of colorations produced within five minutes. When a positive result is obtained by this method, 170 grms. of the sample are separated by distillation into three fractions of 50 grms. each up to 145° C. Each of these fractions is dissolved in 300 grms. of acetone (containing water), and the solution oxidised by adding, with constant shaking, 160 grms. of powdered potassium permanganate in portions of about 3 grms. every fifteen minutes. After oxidation is complete, the acetone solution is decanted, and the manganese residue shaken, first with 200 grms. of acetone, and then with 200 grms. of ether. The solvent is evaporated, and the residual oil dried and fractionated under a pressure of 2 to 3 mm., so as to obtain three fractions, boiling respectively below 130° C., 140° C., and 165° C. The second and, especially, the third fractions are then subjected to the semi-carbazone test as follows:

Two grms. of the fraction are added, drop by drop, to a concentrated aqueous solution of 1·1 grm. of semi-carbazide hydrochloride, to which has been added 1 grm. of potassium acetate dissolved in 3 grms. of alcohol and 1 drop of acetic acid, and the final mixture is cleared by the addition of sufficient alcohol. The semi-carbazone is collected after two days, washed with water, dried on porcelain, and weighed. Its m.-pt. ranges from 215° to 228° C., rising to 234° C. after recrystallisation from boiling alcohol. The high specific rotation (+317°) in concentrated aqueous chloral hydrate solution is characteristic of the semi-carbazone from gurjun oil.

C. A. M.

Estimation of Hydrocarbons in Beeswax and Carnauba Wax. A. Leys. (*J. Pharm. Chim.*, 1912, **5**, 577-591.)—A method of estimating hydrocarbons in waxes is based upon the fact that the higher alcohols in beeswax, etc., are soluble in a mixture in equal parts of amyl alcohol and concentrated hydrochloric acid, whilst hydrocarbons may be separated as a solid cake from the solvent. Ten grms. of the wax are saponified with 25 c.c. of alcoholic potassium hydroxide (45 grms. per litre of absolute alcohol) and 50 c.c. of crystallisable benzene in a flask, with a tubulus and tap at the side, so that it may also serve as a separating funnel. After heating the mixture for twenty minutes, 50 c.c. of hot water are added, the boiling continued under a reflux condenser for another ten minutes, and the flame then withdrawn. The liquid soon separates into two layers, and the lower soap solution is then drawn off without cooling. The residual benzene is heated again for ten minutes with 50 c.c. of water, which is subsequently drawn off as before, and the benzene is then evaporated, leaving a residue of alcohols and hydrocarbons. This is treated little by little with 100 c.c. of hot amyl alcohol, and the whole afterwards mixed with 100 c.c. of concentrated hydrochloric acid, and gently heated, with continual stirring, until the mixture has become completely fluid. The flask is now slowly cooled, and the cake of hydrocarbons at the top is separated from the semi-crystalline mass below, redissolved in the 50 c.c. of the mixture of amyl alcohol and hydrochloric acid, separated as before, pressed between filter-paper, heated on the water-bath in a tared basin, and weighed. The wax alcohols in the solvent are separated by heating the liquid with an excess of water, cooling the mixture, drawing off the lower layer of diluted hydrochloric acid, evaporating the amyl alcohol, taking up the residue with benzene, and evaporating the solution in a tared basin. As a further test the liquid fatty acids of the wax may be estimated by treating the lead salts with benzene. Two samples of pure beeswax thus examined gave the following results: Alcohols, 39·21 and 39·60 (melting at 77° C.); hydrocarbons, 10·44 and 13·03; and liquid fatty acids, 8·40 and 8·52 per cent. respectively. In the presence of ceresin or other foreign hydrocarbons, the amount of beeswax is calculated from the ester value, and the corresponding quantity of hydrocarbons deducted from the total hydrocarbons separated. Carnauba wax thus examined yielded 49·22 per cent. of alcohols (m.-pt. 81° C.), but no hydrocarbons.

C. A. M.

Refractive Index of Beeswax. L. Feldstein. (*Chem. Engineer*, 1912, **15**, 211-212.)—To obtain data as to the refractive index of pure beeswax at temperatures above the m.-pt., twenty-seven samples of known purity were examined. These gave results falling within the limits of 1·4398 and 1·4451 at 75° C., whilst samples known to contain small quantities of foreign substances gave values outside these limits. Since all pure waxes give a sharp reading at 75° C., it is recommended that that temperature should be adopted for the estimation, and that the calculation of results to the corresponding values at 40° C. should be abandoned. C. A. M.

Detection of Benzoic Acid in Foods. O. Biernath. (*Veröffentl. a. d. Gebiete d. Militärsanitätswesens*, 1912, Heft 25; through *Chem. Zentralbl.*, 1912, I., 1929.)—The reaction of A. Jonescu (*J. Pharm. Chim.*, 1909, **29**, 523) with 1 drop of 1 per cent. ferric chloride solution and 3 or more drops of 1 per cent. hydrogen peroxide solution is very sensitive; it renders possible the detection of 0·001 grm. benzoic acid in foods, by distillation, in fifteen minutes. Mineral acids, volatile fatty acids, and other volatile acids hinder the reaction. If the first distillate from material containing benzoic acid does not yield a reaction within fifteen minutes, four subsequent distillates from the residue will each give the reaction within fifteen minutes. Salicylic acid, accompanying the benzoic acid, may be destroyed by means of alkaline permanganate in the liquid obtained by distilling the sample with 20 c.c. of water and 0·5 c.c. of sulphuric acid. The benzoic acid is then distilled off, and its presence determined as before. O. E. M.

Analytical Constants of Some Vegetable Fats. H. Sprinkmeyer and A. Diedrichs. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 581-596.)—The following results were obtained with samples of different vegetable fats which are now being used for edible and other purposes:

	$[N]_{D\,40^\circ}$ C.	Iodine Value.	Saponification Value.	Acid Value.	Melting-Point ° C.	Solidifying Point ° C.	Reichert-Meissl Value.	Polenske Value.	Unsaponifiable Matter.

Mowrah butter is obtained from the seeds of *Bassia longifolia*, adjab fat from the seeds of *Mimusops djave*, shea butter from the seed kernels of *Bassia Parkii*, tulucuna fat from the seeds of *Carapa procera*, dika fat from the seeds of *Irvingia gabonensis*, and malukang butter from the seeds of *Polygala butyracea*. With the exception of tulucuna fat, and possibly stillingia tallow, all the above-mentioned fats are suitable for edible purposes. Tulucuna fat possesses a bitter taste. W. P. S.

Behaviour of Milk when treated with Ammonium Sulphate, and a New Method for the Estimation of Lactose. E. Salkowski. (*Zeitsch. physiol. Chem.*, 1912, **87**, 89-95.)—When milk is saturated, or nearly so, with ammonium sulphate, the proteins are precipitated completely together with the fat, and a clear solution is obtained in which the lactose may be estimated polarimetrically. Fifty c.c. of the milk are shaken with 17·5 grms. of ammonium sulphate, and, when the salt has dissolved, the mixture is diluted to 100 c.c. with saturated ammonium sulphate solution. The whole is shaken and passed through a dry filter, the filtrate being examined polarimetrically. W. P. S.

Detection of Saponin in Beverages and Foods by Hæmolysis. C. Sormani. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 561-566.)—A résumé is given of the papers published by A. Rusconi (*Boll. Soc. Med. Chir.*, Pavia, 1910, 1911, 1912) on the detection of saponin by hæmolysis—that is, the property possessed by certain substances of dissolving the red colouring matter from blood-corpuscles when the latter are suspended in a suitable medium. The blood-corpuscles are obtained by submitting defibrinated blood to centrifugal action with 1 per cent. sodium chloride solution, separating the corpuscles, and suspending them in physiological salt solution. The liquid or substance to be tested must not contain alcohol or carbon dioxide, and must be neutral in reaction; before being added to the corpuscle liquid it is rendered isotonic or slightly hypertonic by the addition of 2 per cent. of sodium citrate. The test may be used for the detection of *Agrostemma githago* in flour, the injurious properties of these seeds being due to the presence of saponin. In this case the flour is made into a dough with 2 per cent. citrate solution, and the dough is then kneaded with a further quantity of the citrate solution, the extract obtained being filtered, and a portion of the filtrate used for the test. The mixture of corpuscle liquid and the solution to be tested is placed in a thermostat for three hours, at the end of which time the red colouring matter will have been dissolved, and the supernatant liquid will appear coloured, should hæmolysis due to the presence of saponin have taken place. Red wine contains a substance which inhibits hæmolysis by saponin, but which may be removed by precipitation with albumin. The test will detect the presence of 1 part of saponin in 10,000 parts of beer, or in 40,000 parts of aerated water. W. P. S.

Detection of Saponin. J. Rühle. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912 **23**, 566-577.)—The author has investigated various tests for the detection of saponin, and finds that Vamvakas' reaction, and colour reactions with sulphuric acid, with Frohde's reagent, and with naphthol, thymol, and ox-gall, are all unreliable, chiefly owing to the presence of interfering substances in the articles under examination (*cf.* ANALYST, 1912, 22). Saponin may, however, be readily detected, even in the presence of glycyrrhizin, by means of its hæmolytic properties. The action of the saponin is dependent on the amount of cholesterol contained in the corpuscles, those containing the largest quantity being most resistant to the hæmolytic action of the saponin. If cholesterol be added to the corpuscle liquid, a point is reached finally at which saponin has no action, and in this way saponin may be differentiated from other hæmolytic substances. In carrying out the test, 1 c.c. of a corpuscle liquid (obtained by mixing 1 c.c. of defibrinated blood with 99 c.c. of a 0·9 per cent. sodium chloride solution, submitting the mixture to centrifugal action, pouring off the supernatant liquid, and diluting the residue to 100 c.c. with the sodium chloride solution) is mixed in a test-tube with from 1 to 3 c.c. of the solution to be tested. If, after the lapse of some length of time, the corpuscles have dissolved, a further quantity of the liquid under examination is mixed with cholesterol and the test repeated; the absence of hæmolytic action in this test indicates definitely that saponin is present. About 4 parts of cholesterol will inhibit the action of 20 parts of saponin. The cholesterol is most conveniently added to the saponin solution in the form of an ethereal solution, the mixture being then heated to 36° C. for some hours in order to expel the ether. When only very small quantities of saponin are being dealt with, the test may be carried out on a microscope slide, the hæmolytic action of the saponin being observed under the microscope. W. P. S.

Polarimetric Estimation of Starch. C. J. Lintner. (*Zeitsch. angew. Chem.*, 1912, **25**, 1177.)—Wenglein's method of hydrolysing the starch with sulphuric acid of sp. gr. 1·7 is liable to give irregular results in hot weather owing to the hydrolysis proceeding too far. The substitution of hydrochloric acid for sulphuric acid is not practicable, since, even without heating, the stage of gelatinisation followed by colloidal solution may be rapidly passed. Under the conditions found most suitable for obtaining constant results, barley starch gave $[\alpha]_D = 198^\circ$ either with sulphuric acid of sp. gr. 1·7 kept cool, or with acid of sp. gr. 1·4 at 22° C., the latter being found the more reliable. The method finally based on these experiments was as follows: 2½ grms. of the finely-ground barley are thoroughly mixed with 5 c.c. of 96 per cent. (by vol.) alcohol in a 100 c.c.-flask with a wide neck, and 50 c.c. of sulphuric acid of sp. gr. 1·4 (=50 per cent. of sulphuric acid) introduced with continual shaking. The flask is then left for an hour, with frequent shaking, at 22° C., after which 10 c.c. of a 2 per cent. phosphotungstic acid solution are added, and the contents made up to 100 c.c. with sulphuric acid of sp. gr. 1·3 (=40 per cent. acid). After thorough shaking, the mixture is filtered, and examined polarimetrically, using sodium light. The rotation multiplied by 10·1 gives the amount of starch in the air-dried barley. C. A. M.

New Method for the Estimation of Glycerol in Wines. C. Beis. (*Bull. Soc. Chim.*, 1912, **11**, [iv.], 618.)—Existing methods for the estimation of glycerol in wines usually involve removal of the sugar by means of barium or calcium hydroxide, variations in the quantities of which lead to inconsistent results; too little allows sugar to pass into the glycerol, while too much causes the retention of glycerol. To meet this difficulty the following method was devised: 100 c.c. of ordinary wine, 50 c.c. of sweet wine, or 25 c.c. of wine over 1·035 sp. gr., are neutralised in a porcelain basin with barium hydroxide and concentrated at 70° C. to a syrup, mixed with sand, and extracted by warming with acetone below its boiling-point. The first portion of acetone is sufficient in quantity to prevent its dilution by the water in the residue below 95 per cent. of acetone; succeeding portions are smaller. (40 to 50 c.c.) Each portion is cooled and filtered; the process is carried on until the volume of the filtrate reaches 200 c.c. Two aliquot parts of the filtrate are evaporated without ebullition. The sugar is estimated by Fehling's solution in one of them. To the other is added five times its volume of water, and powdered barium hydroxide; a few milligrams in excess of the weight of sugar, if this is not more than 0·050 grm.: a weight equal to that of the sugar if this is between 0·050 and 0·300 grm.; and four-fifths of the weight of the sugar if between 0·300 and 0·500 grm. Sand is added, and the mixture extracted with 40 c.c. of acetone, followed by several portions of 25 c.c. Each extract is filtered, and the united filtrate evaporated in a suitable vessel and the residual glycerol weighed. O. E. M.

Analyses of Wines from Eastern France. G. Filaudeau. (*Ann. Falsific.*, 1912, **5**, 296-303.)—The wines examined comprised samples from the departments of Meurthe-et-Moselle (10 samples), Meuse (9), Vosges (8), Haute-Saône and Doubs (10), and Jura (10). The results obtained were normal as compared with those found in other years for these wines. W. P. S.

Analyses of Wines from the Department of Gironde. E. Dubourg. (*Ann. Falsific.*, 1912, **5**, 281-296.)—Results of analyses of 206 samples of red wines and 71 samples of white wines from different districts in the department of Gironde (France) are recorded, the wines all being of the 1911 vintage. The average percentage results for all the red wines were: Alcohol, 9·8; total solids, 23·58; ash, 2·42; reducing sugars, 3·75; volatile acid, 0·85; non-volatile acid, 2·70; potassium hydrogen tartrate (from the total potassium), 4·60; (from the tartaric acid), 1·95. In the case of the white wines (excluding the sauternes) the average results were: alcohol, 10·1; total solids, 28·47; ash, 1·74; reducing sugars, 7·74; volatile acid, 0·55; non-volatile acid, 3·19; potassium hydrogen tartrate (from the total potassium), 2·69; (from the tartaric acid), 2·20. As compared with other years, the red wines contained less non-volatile acid and a correspondingly larger amount of potassium. These irregularities were less accentuated in the case of the white wines. W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Estimation of Small Quantities of Bilirubin. E. Herzfeld. (*Zeitsch. physiol. Chem.*, 1912, **77**, 280-284.) — When an alcoholic solution of bilirubin is treated with a few drops of a solution of *p*-dimethylaminobenzaldehyde (prepared by dissolving 20 grms. of this substance in 500 c.c. of hydrochloric acid and adding 500 c.c. of water) a green coloration is produced, the intensity of which is proportional to the amount of bilirubin present, and this amount may be estimated by examining the mixture with the spectrophotometer. For the estimation of bilirubin in blood, 20 c.c. of the latter are mixed in a mortar with absolute alcohol, then transferred to a 100 c.c. flask, diluted to about 75 c.c. with alcohol, and 2 c.c. of the reagent are added. The mixture is heated on a water-bath until the green coloration has developed, then cooled, and diluted with alcohol to the mark. The solution is now examined with the spectrophotometer. The quantity of bilirubin, x, is calculated from the extinction coefficient, e, observed, according to the formulæ:

$$x = \frac{0\cdot00132 . e}{e}.$$

W. P. S.

Mechanism of Coagulation. J. Duclaux. (*Comptes rend.*, 1912, **154**, 1426-1429.)—A theory of coagulation by osmotic action is based upon the following hypotheses: (1) The osmotic pressure of a solution of several substances is the sum of the partial osmotic pressures; and (2) in a state of equilibrium the relative proportions of different substances that a membrane will allow to pass will be the same on each side of the membrane, the only differences being in the proportions of substances that cannot pass through the membrane. If, for example, to alcohol containing one substance in solution a second soluble substance be added, the alteration in the osmotic pressure will depend upon the size of the molecule of the added substance. If the molecules are very small, the increase of volume caused by their addition will be negligible; whereas, if they are large, there will be considerable increase in volume and a corresponding decrease in the pressure. If, further, two vessels, A and B, are charged with the same alcoholic solution, and separated by a membrane porous to water and alcohol, and a substance capable of reducing the osmotic pressure in B and of not traversing the membrane, be added, water will pass from B into A. But since, according to the second hypothesis, the relative proportions of water and alcohol must always be the same in A and B to obtain equilibrium, alcohol must also pass from B into A in such quantity that the composition of the liquid in A remains constant in so far as concerns the relative proportions of water and alcohol. But under such conditions the osmotic pressure in B must remain lower than in A, and consequently the osmosis will only cease when the whole of the original liquid in B has passed through the membrane into A. The added substance will separate spontaneously. If the original solution contained one grm.-molecule per litre, it is necessary that the grm.-molecule of the added substance should occupy in solution a volume greater than 1 litre before such conditions of osmosis are brought about; and this is usually the case with colloidal substances. In colloidal solutions the place of the porous membrane is assumed to be taken by the free space between the particles of the colloidal substance, and this space will be indefinitely enlarged by the force of osmotic action, until separation of the colloid occurs spontaneously.

Studies on Enzyme Action. II. Hydrolytic Action of Some Amino-Acids and Polypeptides on Certain Esters. K. G. Falk and J. M. Nelson. (*J. Amer. Chem. Soc.*, 1912, **34**, 828-845.)—The authors suggest as a tentative hypothesis that the hydrolytic action of lipase is due to an optically active substance of protein character, readily hydrolysed in aqueous solution to form lipolytically inactive substances. The characteristic groups of protein substances are the amino and carboxyl groups, free or combined. The possible hydrolytic actions of some simple amino-acids and polypeptides were therefore studied by observing the quantity of acid produced at 38° C., when methyl acetate, ethyl butyrate, and olive oil were dissolved or suspended in aqueous solutions containing glycin, alanin, phenylalanin, leucin, glycylglycin, leucylglycin, glycylleucin, diglycylglycin, aspartic acid, and glutamic acid. Three sets of measurements were necessary for each experiment: with solutions containing amino-acid or polypeptide alone, ester alone, and with a mixture containing both. Sörensen's formol method (ANALYST, 1908, **33**, 19) was used for the estimation of amino-acids and polypeptides, except that $\frac{N}{10}$ soda was used for the titrations in place of $\frac{N}{5}$; phenolphthaleïn was used as indicator throughout, most of the end-points being a distinct pink colour, and not the definite red recommended by Sörensen. Many hundreds of determinations are tabulated, and there was found to be a satisfactory agreement between the results obtained and those already published by Sörensen, in so far as the work covered the same ground. Glycin and alanin showed the greatest amount of action with ethyl butyrate, and least with methyl acetate. Phenylalanin showed a markedly greater action with methyl acetate, less with ethyl butyrate, and least with olive oil. Leucin gave practically no action with the three esters. Glycylglycin gave the same slight action with methyl acetate and ethyl butyrate, but none with olive oil. With leucylglycin, glycylleucin, and diglycylglycin, maximum, though small, actions were obtained with ethyl butyrate, very slight but distinct with olive oil, while with glycylleucin and diglycylglycin and methyl acetate, negative values were obtained. With aspartic and glutamic acids the order of magnitude of action was methyl acetate, methyl butyrate, olive oil, considerably greater action being caused by the former, as was to be expected from the greater ionisation constant of the former. The selective action with different esters is strongly suggestive of the selective action of lipases from different sources with different esters. It seems probable that many of these selective actions of the lipases may be reproduced with amino-acids and polypeptides of varying structure or in the presence of other substances. There is no evidence, however, that the hydrolytic action of lipase is to be attributed to amino-acids or polypeptides. The specific groupings present in the amino-acids or polypeptides which show this activity may be present in more complex substances, such as the proteins, and from this point of view the study of the hydrolytic actions of the decomposition products, such as the amino-acids from preparations possessing lipolytic activity, and of the more complex polypeptides or other substances synthesised from them, may throw light upon the substances capable of causing such lipolytic action. H. F. E. H.

Kumagawa-Suto Method of Estimating Fat in Animal Substances.

R. Watanabe. (*Biochem. Zeitsch.*, 1912, **41**, 71-77.)—As the result of a critical examination of this method (ANALYST, 1908, **33**, 362), the author finds that it is quite reliable for the direct estimation of fat in the following animal substances without drying the latter before saponification: Flesh, heart, liver, pancreas, kidneys, intestines, bones, skin, ascitic and pleural fluids, and frogs. In the case of blood, defibrinated blood, blood-plasma, blood-serum, and brains, better results are obtained when the substances are extracted with alcohol, and the extract used for the estimation of the fat (*cf.* ANALYST, 1910, **35**, 527). Suprarenal glands yielded, after saponification, 27 per cent. of matter soluble in petroleum spirit, but more than one-half of this consisted of unsaponifiable substances.

W. P. S.

Loss of Fat during the Drying of Animal Tissues. M. Tamura. (*Biochem. Zeitsch.*, 1912, **41**, 78-101.)—Shimidzu has already drawn attention to the fact that an apparent loss of fat takes place when animal tissues are dried before the fat is estimated by the Kumagawa-Suto process (*cf.* ANALYST, 1910, **35**, 527), and this is confirmed by the result of an extended investigation carried out by the author. If, however, the substance be dried as quickly as possible in quantities of from 100 to 200 grms., with the addition of an equal quantity of alcohol, the loss of fat due to oxidation does not usually exceed 0·5 per cent. of the total quantity of fat present.

W. P. S.

Blue Colour-Reaction of Phosphotungstic Acid with Uric Acid and Other Substances. O. Folin and B. Macallum. (*J. Biol. Chem.* 1912, **11**, 265; through *Chem. Zentralb.*, 1912, I, 1928.)—Phosphotungstic acid in presence of saturated sodium carbonate solution gives a blue coloration not only with uric acid, but also with phenol, tyrosin, tannic acid, thymol, orcinol, resorcinol, vanillin, and phloroglucinol. The reaction appears to be characteristic of aromatic compounds containing a hydroxyl-group in the *p*-position. Moreover, it appears to be due to an impurity in the phosphotungstic acid, and not to the acid itself. O. E. M.

Refractive Indices of Solutions of Certain Proteins. VI. The Proteins of Ox Serum: a New Optical Method for the Estimation of the Various Proteins in Ox Serum. T. B. Robertson. (*J. Biol. Chem.* 1912, **11**, 179; through *Chem. Zentralbl.* 1912, I, 1929.)—The alteration *a* in the refractive index of a solvent produced by dissolving in it 1 grm. of protein was the same, whether the proteins were dissolved in the native serum, or whether they were precipitated with alcohol, washed with alcohol and ether, dried, and dissolved in $\frac{N}{100}$ potassium hydroxide solution. The value of *a* was also independent of the dilution, and was not altered when the serum was made acid. For the proteins of ox serum the value of *a* is 0·00195. The refractive power of the mixed proteins in ox serum represents the sum of the refractive powers of the individual proteins. For refractometric purposes the non-proteins of the serum may be regarded as a $\frac{1}{8}$-grm. molecular sodium chloride solution. The value of *a* for the albumins of ox serum dissolved in $\frac{3}{8}$ saturated or weaker ammonium sulphate solution is identical with the value for solutions in distilled water: it is 0·00177. The discovery of the additive character of the refractive indices rendered it possible to modify the method of Reiss so that the individual proteins hitherto identified in blood serum could be estimated separately. Ox serum was found to contain 2·34 per cent. soluble globulins, 0·76 insoluble globulins, and 5·4 per cent. total albumins. O. E. M.

Estimation of Sugar in Blood and Urine. E. Frank. (*Zeitsch. physiol. Chem.*, 1912, 78, 165-166.)—The author replies to criticisms of his method for the estimation of sugar in blood (ANALYST, 1910, **35**, 260). W. P. S.

Estimation of Benzoic Acid, Hippuric Acid, and Phenaceturic Acid in Urine. H. Steenbock. (*J. Biol. Chem.*, 1912, **11**, 201; through *Chem. Zentralbl.*, 1912, I, 1930.)—For the estimation of hippuric acid 100 c.c. of urine are boiled for two hours with 10 grms. sodium hydroxide and 25 c.c. of hydrogen peroxide; the hippuric acid is thus converted into benzoic acid, and the colouring matter of the urine is oxidised. The liquid is rendered acid with sulphuric acid, bromine water is added and the liquid made up to 200 c.c. and filtered; 50 c.c. of the filtrate are extracted with ether, the ether evaporated off, and the residue sublimed and weighed. To estimate the phenaceturic acid, the sublimate is titrated with $\frac{N}{20}$ sodium hydrioxide, and the proportion of the benzoic acid to the phenylacetic acid formed from the phenaceturic acid calculated from this titration and the weight of the dry sublimate. O. E. M.

New Method for the Estimation of Hippuric Acid in Urine. O. Folin and F. F. Flanders. (*J. Biol. Chem.*, 1912, **11**, 257; through *Chem. Zentralbl*, 1912, I, 1930.)—A mixture of 100 c.c. urine and 10 c.c. of 5 per cent. sodium hydroxide solution is evaporated to dryness on the water-bath; the hippuric acid in the urine is thus converted into benzoic acid. The residue is transferred by means of 25 c.c. of water and 25 c.c. of concentrated nitric acid to a flask fitted with a reflux condenser, and boiled for four and a half hours with 0·2 grm. copper nitrate to destroy colouring matter and similar substances in the urine. The contents of the flask are saturated with ammonium sulphate in a separating funnel, and extracted with chloroform, and the united chloroform extracts washed once by shaking with a solution of sodium chloride containing hydrochloric acid, and the benzoic acid in the chloroform extract titrated with $\frac{N}{10}$ sodium ethoxide and phenolphthaleïn. O. E. M.

Estimation of Phenol in Urine. M. Hensel. (*Zeitsch. physiol. Chem.*, 1912, **78**, 371-381.)—The method proposed depends on the fact that phenol is dissolved from its acid aqueous solution by ether, and that it can be extracted from the ethereal solution by means of sodium hydroxide, but not by sodium hydrogen carbonate. Five hundred c.c. of the urine are rendered alkaline and evaporated to 100 c.c., the solution being then acidified with phosphoric acid and distilled with frequent additions of water, until all the phenol has passed over, as is shown by the distillate ceasing to give a reaction with Millon's reagent. The distillate is then extracted four successive times with ether, the united ethereal extracts are shaken four times with a 4 per cent. sodium hydrogen carbonate solution, and afterwards the same number of times with $\frac{N}{1}$ sodium hydroxide solution. The sodium hydroxide extracts are united, acid added until the alkalinity of the solution is equivalent to

20 c.c. of $\frac{N}{10}$ solution, and the phenol in the alkaline solution is titrated by Penny and Kossler's method. The method yields trustworthy results in the case of urines containing large quantities of carbohydrates. A method described by Mooser (*Zeitsch. physiol. Chem.*, 1908, **63**, 155), in which the distillate from the urine, acidified with phosphoric acid, is redistilled from calcium carbonate in a current of carbon dioxide, and the phenol titrated in this distillate, was found to yield accurate results.

W. P. S.

Estimation of Urea in Urine by Riegler's Method. A Correction Factor. T. Ekecrantz and S. Erickson. (*Zeitsch. physiol. Chem.*, 1912, **79**, 171-176.)—In the estimation of urea in urine by Riegler's method (*c.f.* ANALYST, 1912, 100), substances other than urea, such as uric acid, purine bases, creatinine, neucleo-albumin, etc., are decomposed and yield carbon dioxide and nitrogen, and the results are, consequently, too high. Those substances which interfere may be removed by treating the urine with twice its volume of a solution containing 10 per cent. of phosphotungstic acid and 1 per cent. of hydrochloric acid of sp. gr. 1·12, and removing the precipitate by filtration after the lapse of four hours; the urea is then estimated in the filtrate. In most cases, however, sufficiently accurate results for all practical purposes may be obtained by treating the urine directly and multiplying the result obtained by 0·926 in order to correct for the amount of nitrogen liberated by the substances other than urea.

W. P. S.

Detection of Savin Oil in Toxicological Cases. J. Hamalainen. (*Biochem. Zeitsch.*, 1912, **41**, 241-246.)—Savin oil contains about 50 per cent. of sabinol acetate, which constitutes the toxic principle of the oil; this acetate on hydrolysis yields sabinol, which, in the body, combines in part with glycuronic acid, and is excreted in the urine as sabinol-glycuronic acid. When the latter is boiled with a mineral acid a cymene is formed, and the identification of the latter has been suggested as a means of detecting savin oil in urine. Other oils, however, such as turpentine, thuja oil, etc., when administered to animals, pass into the urine in the form of derivatives which yield cymene. Sabinol-glycuronic acid may be identified by means of the characteristic crystalline salts it yields with certain bases, particularly with strychnine, and the following method is described by the author for the detection of savin oil in cases of suspected poisoning by this substance: The urine is treated with neutral lead acetate in neutral or feebly acid solution, the precipitate formed is separated by filtration and washed, and, after the filtrate has been rendered ammoniacal, basic lead acetate is added as long as a precipitate is produced. The basic lead salt is collected on a filter, washed with water, decomposed with cold 5 per cent. sulphuric acid, the lead sulphate is separated, and the solution neutralised with barium carbonate. After filtration, the filtrate is concentrated, preferably under reduced pressure, and the barium is precipitated by treating the warm solution with hot strychnine sulphate solution. The mixture is filtered while hot, and the filtrate allowed to cool. Strychnine sabinol-glycuronate separates out in the form of brilliant needles which melt at 196° C. with decomposition. This salt has 2 molecules of water of crystallisation; it is fairly soluble in hot water and but slightly soluble in cold water, alcohol, ether, acetone, chloroform, benzene, petroleum spirit, or ethyl acetate. On concentrating the mother-liquor, a strychnine salt with 3 molecules of water crystallises out, melting at 193° C. It is more readily soluble than the first-mentioned salt, and on cooling its solution rapidly, the salt with 2 molecules of water is obtained. Urine from rabbits, which had received a dose each of 1·5 c.c. of savin oil, yielded crystals of strychnine sabinol-glycuronate when examined by the above method. W. P. S.

Microchemical Reaction of Spermatic Fluid. P. Aleixandre. (*Zeitsch. anal. Chem.*, 1912, **51**, 473-475.)—A reaction proposed by De Dominicis (*Resveglio Medico*, May 15, 1910) consists in treating a trace of the fluid with a drop of a saturated gold tribromide solution on a microscope slide, heating the mixture to boiling, and examining it under the microscope. At a magnification of 300 diameters rectangular or cross-shaped crystals, having a garnet colour, are observed. The crystals are soluble in alcohol and in alkali solutions, but not in acids. The author has examined this test, and finds that it is not very sensitive; the crystals are rarely obtained unless the spermatic fluid is of a concentration of more than 2 per cent. Quadratic crystals are also frequently obtained, and are due to the presence of cholin.

W. P. S.

Colorimetric Method for the Estimation of Uric Acid. E. Riegler. (*Zeitsch. anal. Chem.*, 1912, **51**, 466-470.)—The method depends on the blue coloration which is obtained when uric acid is treated with phosphomolybdic acid and disodium phosphate. The coloration is not given by albumin, peptones, albumoses, creatine, creatinine, or sugar, although these substances yield a similar colour when treated with phosphomolybdic acid and potassium or sodium hydroxides. For the estimation of uric acid in urine, 1 c.c. of the sample is placed in a test-tube, and in two similar tubes are placed, respectively, 1 c.c. of a 0·1 per cent. uric acid solution and 1·2 c.c. of the same urine from which the uric acid has been removed by means of ammonium chloride. (This is effected by heating 10 c.c. of the urine with 3 grms. of ammonium chloride to 40° C., and filtering the mixture after the lapse of thirty minutes; 1·2 c.c. of the filtrate is employed, in order to allow for the increase of volume due to the ammonium chloride.) To each of the tubes are then added 2 c.c. of a 10 per cent. phosphomolybdic acid solution, and a sufficient quantity of a 5 per cent. disodium phosphate solution to make the contents of each tube up to 10 c.c.; a mark may be provided on the tubes for this purpose. After the contents of the tubes have been mixed, they are heated over a flame until small bubbles of gas are evolved, then cooled, and the colorations compared in a colorimeter. The coloration yielded by the urine is first compared with that given by the known quantity of uric acid. The apparent quantity of uric acid in the 1·2 c.c. of urine from which the uric acid has been removed is also estimated by comparison with the standard, and its quantity deducted from the amount found in the urine itself. This correction has to be made, as urine contains substances other than uric acid, which give a coloration with the reagents. Should the urine contain albumin, this must be separated by boiling the urine and filtering it before the estimation is carried out. The standard solution of uric acid is prepared by boiling 0·1 grm. of uric acid and 0·1 grm. of sodium hydrogen carbonate with 50 c.c. of water, cooling the solution, and diluting it with water to a volume of 100 c.c. W. P. S.

ORGANIC ANALYSIS.

Angeli's Reaction for Aldehydes. O. Baudisch and J. H. Coert. (*Ber.*, 1912, **45**, 1775-1779.)—Angeli's test for aldehydes is based on the fact that an aqueous solution of the sodium salt of nitrohydroxylaminic acid forms with various aliphatic and aromatic aldehydes hydroxamic acids which are readily detected in minute quantities by their characteristic iron reaction. The sodium salt of nitrohydroxylaminic acid first splits up into nitrosyl-sodium and sodium nitrite:

$$NaO.N : NO.ONa = NONa + NaNO_2.$$

The nitrosyl-sodium, or perhaps free nitrosyl, combines with the aldehyde; the hydroxamic acid produced may be isolated in the form of its internal complex copper salt. Form-hydroxamic acid may also be produced by the action of light on an aqueous formaldehyde or methyl alcoholic solution of potassium nitrate or nitrite, owing to the formation of nitrosyl or nitrosyl-potassium. In this reaction it appears probable that the combination of nitrosyl with formaldehyde or methyl alcohol takes place through intermediate stages, forming first nitroso-methyl alcohol, which then changes to methylene-nitronic acid, and, finally, to form-hyrdoxamic acid. If this course be actually followed, the formation of the nitroso alcoholate should be accompanied by the temporary appearance of a blue-green coloration. In performing Angeli's test in the ordinary way no such coloration can be observed; the change is too rapid. But in presence of certain substances—*e.g.*, methyl acetate, acetone, ethyl acetate, or gelatin—Angeli's salt shows with aldehydes the blue-green colour of the intermediate nitroso compound. Angeli's salt is dissolved in a little water with a large excess of methyl acetate, and the mixture is shaken; aqueous formaldehyde is added, the liquid being rotated; the methyl acetate then acquires a blue-green colour, which lasts for several seconds. J. F. B.

Precipitant for Amino-Acids. C. Neuberg and J. Kerb. (*Biochem. Zeitsch.*, 1912, **40**, 498-512.)—When a dilute solution of an amino-acid (for instance, glycin) is rendered distinctly alkaline with sodium carbonate, and then treated with a 25 per cent. mercuric acetate solution, a white precipitate is obtained, and, on the addition of from 4 to 5 volumes of alcohol, the amino-acid is precipitated almost completely. The following results were obtained with various amino-acids, the figures representing the percentage of the total nitrogen precipitated: Glycin, 95·7; *d*, *l*-alanin, 95·8; *d*-alanin, 97·3: *d*, *l*-valin, 70·0; leucin, 96·6; *l*-asparagin, 98·6; *d*-glutaminic acid, 97·2; *d*, *l*-serin, 94·9; *l*-cystin, 98·1; *d*, *l*-phenylalanin, 97·9; *l*-tyrosin, 96·9; *d*, *l*-prolin, 75·4; *l*-histidin, 99·4; *l*-tryptophan, 97·7; *d*-glucosamine, 99·5; α-β-diaminopropionic acid, 99·4; *d*, *l*-isoserin, 97·8; δ-amino-valeric acid, 96·1. W. P. S.

Detection and Estimation of Arsenic in Organic Compounds. G. Bressanin. (*Gazz. Chim. Ital.*, 1912, **42**, 451-455.)—The method of estimating arsenic by means of the insolubility of its iodide in sulphuric acid may also be used with organic compounds. Treated with potassium iodide in sulphuric acid of sp. gr. 1·45, precipitates of different kinds were obtained with commercial organic compounds. Thus atoxyl gave a maroon precipitate; sodium cacodylate, a vinous red; and arrhenal, a yellow precipitate. The precipitations were not complete, and Ehrlich's "606" (di-hydroxy-diamino-arseno-benzene hydrochloride) gave no precipitate in acid of this concentration. For the estimation of arsenic in such compounds it is necessary to decompose them completely by heating 0·2 to 0·4 grm. with 10 c.c. of sulphuric acid over a very minute flame (to prevent liberation of cacodylic oxide), after which the arsenic may be quantitatively precipitated as described before (*loc. cit.*). Ehrlich's "606" is sold as a canary-yellow powder, decomposing at 175° C. without melting. It dissolves in sulphuric acid of sp. gr. 1·84 with decomposition, and the solution, when diluted to sp. gr. 1·45, now gives a precipitate with potassium iodide. Silver nitrate gives a yellow coloration, followed by a gelatinous precipitate; copper salts give a blue precipitate; picric acid a yellow precipitate; and potassium ferrocyanide a green precipitate, emitting hydrocyanic acid on heating. A positive reaction is obtained with Gutzeit's test, and Fehling's solution is reduced on heating. C. A. M.

Esterification of Monamino Acids by Means of Ethyl Iodide. Separation of Pyrrolidonecarboxylic Acid from Glutamic Acid. E. Abderhalden and K. Kautzsch. (*Zeitsch. physiol. Chem.*, 1912, **78**, 115-127.)—The silver salt of pyrrolidonecarboxylic acid is readily esterified when boiled for two hours under a reflux condenser with an excess of ethyl iodide. After the silver iodide has been removed by filtration, the ester may be obtained in the form of a white crystalline mass by evaporating the solution under reduced pressure over sulphuric acid; it melts at 60° to 61·5° C. Under similar conditions, glutamic acid, aspartic acid, asparagin, and prolin remain unaltered. When a mixture of the silver salts of pyrrolidonecarboxylic acid and glutamic acid is boiled with ethyl iodide, the former is esterified, and may be separated from the insoluble silver salt of glutamic acid by means of benzene. Attempts to isolate pyrrolidonecarboxylic acid in the digestion products of casein resulted in the formation of an ester which could not be identified; this ester yielded glutamic acid hydrochloride when hydrolysed with hydrochloric acid. W. P. S.

Influence of Metallic Carbonates on the Estimation of the Volatile Substances in Coal. E. Prost and M. Ubaghs. (*Bull. Soc. Chim. Belg.*, 1912, **26**, 216-222.)—Estimation of the volatile substances in coal may give an erroneous idea of the calorific value of the coal or its suitability for gas manufacture, unless account be taken of the amount of carbon dioxide in the volatile substances. In the case of two samples of coal more than 2·5 per cent. of carbon dioxide was present in the volatile substances, whilst other samples gave amounts ranging from 0·5 to 2 per cent. The gas was found to originate from carbonates of iron, calcium and magnesium in the coal. This was found to be the explanation why a coal yielding 15 to 16 per cent. of volatile substances was suitable for the manufacture of coke, whilst another coal from the same source, yielding more than 17 per cent. of volatile substances, was quite unsuitable for the purpose. C. A. M.

Combustion of Volatile Organic Liquids. L. Clarke. (*J. Amer. Chem. Soc.*, 1912, **34**, 746-747.)—A combustion tube is drawn out at one end, and a tube bearing a female ground glass joint is sealed on. That part of the tube which is within the heating zone of the furnace is filled with copper oxide, held in place by plugs as usual, and the end remote from the ground glass joint is provided with a perforated rubber stopper for attachment to the usual sulphuric acid tube and potash bulb. The end of the tube bearing the ground glass joint protrudes about 4 inches from the end of the furnace. The liquid to be analysed is weighed out in a small stoppered U-tube of the type in which the stoppers close the limbs, and, by turning, may be made to put the side tubes in or out of connection with the U. To one side tube is sealed a male ground glass joint, which has been ground to fit the ground seat on the combustion tube. The stoppers of the U-tube and the joint between U-tube and combustion-tube are very lightly greased with vaseline for the upper third or fourth of their ground surfaces. The unlubricated space below, wherever pervious, is filled with air, forming an effective cushion to prevent absorption by the vaseline of any vapour, should this be soluble in paraffin. After weighing, the U-tube is connected to the hot combustion-tube, the other arm being connected to the usual apparatus for drying the air on its way to the combustion-tube. The stopcocks are turned, and the stream of air allowed to pass over the surface of the liquid, carrying forward vapour to the combustion-tube. If the liquid has a boiling-point as low as that of ether, it is well to immerse the lower end of the U-tube in cold water to prevent too rapid volatilisation. For liquids boiling at 100° to 125° C., it is best to immerse the lower part of the U-tube in water at 50° to 60° C. With acetone and similar liquids, neither heating nor cooling is necessary. G. C. J.

Estimation of Caoutchouc as Tetrabromide. Utz. (*Gummi Zeit.*, 1912, **26**, 968-970; through *Chem. Zentralbl.*, 1912, I., 1797-1798.)—In order to avoid the loss of bromine which various authors have found to take place when caoutchouc tetrabromide, prepared by Budde's method, is heated with nitric acid in presence of silver nitrate, the author recommends the method of Baubigny and Chavanne for the estimation of the bromine. The caoutchouc tetrabromide is decomposed by means of chromic and sulphuric acid mixture; a slight modification in the apparatus, consisting in the introduction of a stoppered dropping funnel, is advised. The author, independently of Hübener, has devised a method of bromination in aqueous solution: 0·1 grm. of caoutchouc is treated in a Lintner's pressure-flask with 60 to 70 c.c. of water and 5 to 7 c.c. of bromine, and heated in the closed flask for some hours in the water-bath at 50° to 60° C. When the bromination is complete, the liquid is poured off through a filter, and the contents of the flask are extracted with boiling water. The residue of caoutchouc bromide is washed with alcohol and ether and digested with chloroform for six hours at the ordinary temperature. The bromide is reprecipitated by an excess of petroleum spirit, and, after settling, is collected on a filter, washed with alcohol and ether, dried *in vacuo* at the ordinary temperature, and the bromine estimated in Baubigny and Chavanne's apparatus. The bromine found ranged from 70·12 to 70·25 per cent. in six estimations; theoretical, 70·14 per cent. for $C_{10}H_{16}Br_4$. A sample of Para rubber showed 93·96 and 93·72 per cent. of caoutchouc by this method. The author is investigating the error due to the presence of nitrogenous impurities in the raw rubber. J. F. B.

Latent Heats of Vaporisation of Mixed Liquids. Part III.: Mixtures of Associated with Non-associated Liquids, and the Detection of Solvates in Mixtures of Liquids. D. Tyrer. (*J. Chem. Soc.*, 1912, **101**, 1104-1113.)—Results are given for the boiling-points, vapour compositions, latent heats at constant pressure, and latent heats at constant composition for the following mixtures: Benzene and ethyl alcohol, chloroform and methyl alcohol, chloroform and acetone, carbon tetrachloride and ethyl alcohol. It was found that the mixture of chloroform and acetone gives a maximum boiling-point; the three other mixtures give minimum boiling-points. From a study of the latent heats of such mixtures a method is established by which the existence of solvates in the mixtures can be detected. In all four cases studied solvates are formed. Molecular association in liquids is the result of the combination of hydroxyl groups, and when two hydroxyl substances are mixed solvates are always formed. When a hydroxyl substance is mixed with one containing no such group, the latent heat affords a reliable test for the formation of solvates. In normal mixtures each constituent retains its own latent heat unaffected by the presence of the other constituent; thus the latent heat of either constituent can be calculated from the latent heat of the mixture and the latent heat of the other constituent. Applying this rule to the case of an associated liquid in admixture with a non-associated liquid, the apparent latent heat of the associated constituent can be calculated at various concentrations. If no solvates are formed, the latent heat of the associated liquid in the mixture should gradually diminish as the concentration gradually diminishes, owing to the progressive dissociation of the associated molecules, until at infinite dilution it becomes constant, indicating complete dissociation. If this is not the case, then undoubtedly to some extent solvates are formed in the mixture. In the mixtures above mentioned the diminution was not steady, but the latent heat in all cases, over a portion of the range of concentrations, increased with increase of the dilution. This means that solvates are formed, but it is not possible to determine their amount or composition. The acetone apparently functions in the above case as an hydroxyl substance. J. F. B.

Estimation of Ferrocyanides. H. E. Williams. (*J. Soc. Chem. Ind.*, 1912, **31**, 468-471.)—The following process is stated to be free from most of the possible sources of error inherent in the Feld method: Half a gram of the ferrocyanide is dissolved in 100 c.c. of water, and the liquid distilled after adding 0·05 to 0·1 grm. of cuprous chloride (dissolved in a few drops of hydrochloric acid, or a little saturated sodium or potassium chloride solution) and 25 to 30 c.c. of 4N sulphuric acid. The distillate is passed from the condenser into absorption-flasks containing caustic alkali solution. The ferrocyanide is completely decomposed, and the hydrocyanic acid distilled, by about half an hour's gentle boiling. The cyanide in the alkaline hydroxide solution is then titrated in the usual way with standard silver nitrate solution, in the presence of a few drops of potassium iodide solution. Much larger quantities of ferrocyanide may be taken if desired, and in such cases it is only necessary to add an amount of cuprous chloride equal to 2 to 3 per cent. of the weight of ferrocyanide. Sufficient sulphuric acid must be present to give an excess of acid over that required to form ferrous sulphate and sodium bisulphate. The cuprous chloride used should first be freed from cupric salt by washing with a little dilute sulphuric acid. The addition of cuprous chloride decomposes the ferrocyanide, forming cuprous cyanide, which is decomposed by the acid present, yielding hydrocyanic acid and cuprous chloride again, which latter then attacks a further quantity of ferrocyanide. Both soluble and insoluble ferrocyanides may be determined by the method, but if the substance be dry it should be finely powdered. Ferric ferrocyanide requires more cuprous chloride than above stated for its complete decomposition.

For the estimation of the ferrocyanide content of cyanogen mud or spent oxide, a weighed quantity of the dried material, from which the sulphur has been removed by extraction with carbon disulphide, is boiled with sodium hydroxide, filtered, washed to a definite volume, and a portion of the liquid distilled with cuprous chloride and sulphuric acid as before. The results on spent oxides are higher, generally by about 0·2 to 0·4 per cent., than those given by the titration method, and are more accurate. Thiocyanates are stated to have no influence on the distillation; if present in spent oxide, a larger amount of cuprous chloride should be added to insure their precipitation before distilling (*cf.* Colman, ANALYST, 1910, **35**, 295). A. R. T.

Direct Estimation of Geraniol in Citronella Oil. J. Dupont and L. Labaune. (*Ann. Chim. anal.*, 1912, **17**, 210-213.)—The method depends upon the conversion of the citronellal into a nitrile, which is not affected by the potassium hydroxide in the estimation of the geraniol as geranyl acetate. Ten grms. of citronella oil (or of a mixture of geraniol and citronellal) are shaken for two hours at the ordinary temperature with an aqueous solution of hydroxylamine, prepared by dissolving 10 grms. of hydroxylamine hydrochloride in 25 c.c. of water, adding a solution of 12 grms. of potassium carbonate in 25 c.c. of water, and filtering the mixture. The oil rising to the surface is decanted, dried over anhydrous sodium sulphate, and boiled under a reflux condenser for one and a half hours with twice its volume of acetic anhydride. Under these conditions the citronellal oxime is converted into citronello nitrile. After washing, neutralisation, and drying, 2 grms. of the acetylated oil are saponified with $\frac{N}{2}$ alcoholic potassium hydroxide solution, and the amount of geraniol calculated from the result in the usual way. The difference between the total products of acetylation in a preliminary test and the amount of geraniol thus found, gives the quantity of citronellal. Thus, a Ceylon oil containing 60·2 per cent. of acetylisable products was found to contain 43 per cent. of geraniol, whilst a Java oil contained 43 per cent. of geraniol and 40 per cent. of citronellal. The results given by test mixtures were in close agreement with theory. C. A. M.

Oil of the Southern Cypress. A. F. Odell. (*J. Amer. Chem. Soc.*, 1912, **34**, 824-826.)—The cones of the Southern cypress (*Taxodium distichum*) contain considerable quantities of a volatile oil, consisting of *d*-pinene, 85 per cent.; *d*-limonene, 5 per cent.; a pseudo terpene alcohol (? sabinol), 2 per cent.; carvone, 3 per cent.; tricyclic sesquiterpene, 3 per cent.; the remainder being composed of substances boiling above 275° C. No aldehydes were found in the oil. H. F. E. H.

Estimation of Hydrazine. G. S. Jamieson. (*Chem. News*, 1912, **105**, 268.) —According to the author, Rimini's method requires much time, while the following procedure, based on the general method of Andrews (ANALYST, 1903, **28**, 306), is stated to be rapid and accurate: Hydrazine salts, or the double salts of hydrazine and the metals, are analysed by titration with a standard solution of potassium iodate (3·567 grms. KIO_3 per litre) in presence of hydrochloric acid and chloroform. Suitable proportions are 20 c.c. water, 30 c.c. hydrochloric acid, and 6 c.c. chloroform. The solution of potassium iodate is run in gradually, the reaction proceeding according to the equation:

$$N_2H_4 \cdot H_2SO_4 + KIO_3 + 2HCl = N_2 + ICl + 3H_2O + KCl + H_2SO_4.$$

The liquid is shaken between each addition of iodate, until the chloroform, which at first is coloured, becomes decolorised. Metallic double salts (such as zinc and hydrazine sulphate) may be examined by this method, and the published results are accurate. In the case of the nickel double salt, which is only sparingly soluble, the reaction proceeds very slowly. A. R. T.

Detection and Estimation of Methyl Alcohol. F. Wirthle. (*Chem. Zeit.*, 1912, **36**, 700.)—In testing spirits for methyl alcohol, the first 50 c.c. (at most) of the alcoholic distillate from 100 c.c. are distilled and twice fractionated, so as to obtain first 15 c.c. and finally 3 c.c. as the final fraction. One c.c. of this distillate is oxidised by the official potassium permanganate method, after the addition of 4 c.c. of dilute (1 : 2) sulphuric acid, the liquid filtered, and 1 c.c. of the colourless filtrate heated with 5 c.c. of concentrated sulphuric acid. On treating the cold mixture with 5 mgrms. of solid morphine hydrochloride, a reddish-violet coloration is produced in the presence of as little as 20 mgrms. of methyl alcohol (corresponding to about 5 per cent of the denatured alcohol in the spirit). At the same time a control test is made with a mixture of 20 mgrms. of methyl alcohol and 1 c.c. of 90 per cent. ethyl alcohol. If the preliminary test has given a strong violet coloration, and the spirit contains about 40 per cent. (by volume) of alcohol, 60 c.c. (from 100 c.c.) are taken, whilst with a higher alcoholic strength a proportionately smaller quantity of the distillate is used. The initial temperature of distillation in a fractional distillation-flask affords information as to the amount of methyl alcohol present. Thus a liquid containing 10 per cent. of methyl alcohol begins to distil at 75° C., and after five minutes the temperature will have risen to 76·8° C., whilst in the presence of 20 per cent. of methyl alcohol the initial temperature will be 71·5° C., rising, after five minutes, to 75·5° C. It is advisable to treat the residue from the first distillation with alcohol and to fractionally distil it again, the process being repeated so that from solutions containing about 10 per cent. of methyl alcohol about 80 c.c. in all are obtained, from 20 per cent. solutions about 100 c.c., and from 30 per cent. solutions about 125 c.c. The mixture of methyl and ethyl alcohols is now converted into iodides by heating it under a reflux condenser with iodine and amorphous phosphorus; these are separated by fractional distillation, and the methyl iodide identified by its saponification value (394·3). For the conversion of 10 c.c. of methyl alcohol into methyl iodide 31·7 grms. of iodine and 1·79 grm. of amorphous phosphorus are required, whilst ethyl alcohol requires only 22 grms. of iodine and 1·79 grm. of phosphorus for the formation of the corresponding compound. The necessary amounts may thus be approximately calculated from the temperatures observed in the fractional distillation, a slight excess of iodine being taken. The iodides from a quantity of distillate corresponding to 10 c.c. of alcohol are distilled into 10 c.c. of water, decolorised by shaking with 14 to 16 c.c. of 10 per cent. potassium hydroxide solution, separated from the supernatant liquid, washed twice with water, allowed to stand overnight, and then run into a tared flask, which is immediately closed and weighed. The small residue of iodides remaining in the burette is collected in a narrow calibrated tube, and its weight calculated from the specific gravity. Since 10 c.c. of methyl alcohol yield 31·35 grms. of methyl iodide, and 10 c.c. of ethyl alcohol yield 24·0 grms. of ethyl iodide, each 0·736 grm. of iodide in excess of 24 grms. corresponds to 1 c.c. of methyl alcohol. To obtain reliable quantitative results it is advisable to dilute the distillate from the spirit under examination with sufficient 96 per cent. ethyl alcohol to give a mixture containing approximately 10 per cent. of methyl alcohol, whilst at the same time a blank test is made with a mixture of methyl and ethyl alcohols containing 10 per cent. of the former. C. A. M.

Activity of Organic Nitrogen as measured by the Alkaline Permanganate Method. C. H. Jones. (*J. Ind. Eng. Chem.*, 1912, 4, 438-441.)—It is generally recognised that soluble organic nitrogen is readily available as plant-food, whereas nitrogen in insoluble combinations may or may not be so available. Thus, though dried blood and hoof meal contain most of their nitrogen in insoluble forms, they are known to possess high manurial value, whereas there is reason to believe that the nitrogen of peat, roasted leather, garbage tankage, and some other materials, is not immediately available as plant-food. For this reason certain States of the American Union forbid the use of these latter materials in compound fertilisers offered for sale. In other States, agricultural chemists are called upon to report on the manurial value of mixed fertilisers which may contain nitrates, ammonia, and soluble and insoluble organic nitrogenous substances. The valuation of the insoluble nitrogen has hitherto presented a difficulty for the reasons stated, and the author now proposes to differentiate between the insoluble nitrogen which is converted into ammonia by digestion under standard conditions with alkaline permanganate and that which is not so transformed. That which is converted into ammonia under the conditions described in the paper is designated active insoluble organic nitrogen, and it is suggested that this active nitrogen should be assigned a manurial value but little inferior to the soluble nitrogen, whereas the residue of insoluble nitrogen, designated inactive, is held to have a very low value indeed. These views find support in field experiments—referred to but not described in the paper—and in the fact that in dried blood, high grade tankage, fish, hoof meal, cotton-seed meal, and many other substances which give manurial results in close relation to their nitrogen contents, the proportion of inactive nitrogen, as determined by the author's method, is low, whereas the same method shows that the inactive insoluble organic form is the predominant form of nitrogen in peat, garbage tankage, charred leather, and other substances of notable nitrogen content but negligible manurial value.

Active insoluble organic nitrogen is determined as follows: Total insoluble nitrogen is first determined by extracting 2 grms. of the sample on a filter-paper, with water at room temperature, until the filtrate amounts to 250 c.c. The filter-paper and its contents are subjected to the Kjeldahl process. So much of the substance is now weighed out as contains 50 mgrms. of insoluble nitrogen, and, if a mixed fertiliser, is extracted with water, as in the determination of total insoluble nitrogen. Highly nitrogenous raw materials are mixed in a mortar with 2 grms. of powdered rock phosphate before extracting with water, and very oily materials should have a preliminary treatment with ether. The filter and insoluble matter are dried at a temperature not exceeding 80° C., and the insoluble matter is then transferred to a 500 to 600 c.c. round-bottomed flask, together with 20 c.c. of water, a few glass beads, and 100 c.c. of an alkaline permanganate solution containing 150 grms. of caustic soda and 25 grms. of potassium permanganate per litre. The flask is connected to a condenser as for an ammonia determination, the receiver being charged with a measured quantity of standard acid. The contents of the flask are digested short of boiling for at least thirty minutes, local overheating of the insoluble residue being avoided by the use of wire gauze and asbestos-paper between the flame and the flask. About 95 c.c. are now distilled, preferably at such a rate that the operation requires an hour. A tendency to froth may be overcome by prolonging the digestion until this no longer manifests itself, and then distilling at a somewhat brisker rate, so that the whole process occupies about ninety minutes as usual. The ammonia in the distillate is the measure of the active insoluble nitrogen.

The method has been adopted since March, 1911, by the experiment stations of New York, New Jersey, and the New England States, as the result of laboratory and field experiments in 1910. G. C. J.

Action of Permanganate on Organic Substances. J. Hetper. (*Zeitsch. anal. Chem.*, 1912, 51, 409-429.)—In earlier papers (ANALYST, 1911, 36, 232, 422) the author has shown that many organic substances are quantitatively oxidised to carbon dioxide and water by permanganate in acid solution, whilst the members of another large group of compounds may also be estimated by means of permanganate, the reaction being a quantitative one, with acetic acid for one of the end products. The influence of alkaline permanganate has now been studied. In the majority of cases it proves a less useful reagent than an acid solution. For example, ethyl alcohol, which can be quantitatively oxidised to acetic acid in acid solution, is oxidised partly to acetic acid and partly to carbon dioxide in alkaline solution, the former reaction predominating if the action begins in the cold, the latter if the mixture is hot from the start; but at no temperature between 0° and 100° C. can either reaction be suppressed entirely. Methyl alcohol is much more quickly oxidised in alkaline than in acid solution, the products being carbon dioxide and water in either case. Caffeine, theobromine, and antipyrin, which only consume from 40 to 80 per cent. of the theoretical amount of permanganate in acid solution, are almost quantitatively oxidised to carbon dioxide, water (and ammonia) in alkaline solution. Many substances which are oxidised quantitatively in acid solution behave similarly in alkaline solution, but in a much greater number of instances the results in alkaline solution correspond to no single reaction. However, the author thinks that the consumption of permanganate in alkaline solution under standard conditions may prove a useful constant, especially when compared with the corresponding number obtained in acid solution.

The experimental conditions followed in the author's laboratory are as follows: The permanganate solution is $\frac{N}{2}$, and contains 40 gr. of caustic soda per litre. Of this solution, 25 c.c. is placed in a 200 c.c. flask with 65 c.c. of water, and the substance dissolved in 10 c.c. of water. So much of the substance is taken as may be expected to reduce about 10 c.c. of the permanganate, and, if the substance is insoluble in water, it is mixed with 1 grm. of glass powder, not omitting in such a case to add 10 c.c. of water to the contents of the flask to insure uniformity of conditions in all experiments. The flask, with its contents, is heated on the water-bath for one and a half hours; 25 c.c. of $\frac{N}{2}$ oxalic acid (containing 75 c.c. concentrated sulphuric acid per litre) is then added, and the solution titrated with $\frac{N}{2}$ permanganate containing 40 grms. of glacial phosphoric acid per litre. The result is calculated to c.c. of $\frac{N}{1}$ permanganate per gram of substance. The amount of permanganate reduced by forty-two substances under these and some other conditions are given in the paper. G. C. J.

Influence of Peptones on the Estimation of Reducing Sugars by Fehling's Solution. A. Bernardi. (*Biochem. Zeitsch.* 1912, **41**, 160-164.)—Although peptones do not reduce Fehling's solution, their presence in sugar solutions causes more cuprous oxide to be precipitated than is due to the reducing action of the sugar alone. In cases, therefore, where sugar has to be estimated in solutions containing peptones, the latter should be removed by means of phosphotungstic acid previous to the estimation of the sugar. W. P. S.

Physico-Chemical Basis of the Seliwanoff Lævulose Reaction. A. Jolles. (*Biochem. Zeitsch.*, 1912, **41**, 331-332.)—When dextrose is placed in contact with concentrated hydrochloric acid for some months, the solution yields a reaction for lævulose with the Seliwanoff test. The author finds, however, that the polarisation of the sugar is not changed, a fact which shows that either the quantity of lævulose formed is so small that it cannot be estimated, or, which is more probable, that the substance giving the Seliwanoff reaction is not lævulose. The action of dilute alkali solutions on dextrose is much more pronounced, and the change is accompanied by the formation of appreciable quantities of an acid. For instance, 200 c.c. of a 0·5 per cent. dextrose solution were mixed with about 40 c.c. of $\frac{N}{10}$ sodium hydroxide solution; 50 c.c. of this mixture required 9·1 c.c. of $\frac{N}{10}$ acid for neutralisation when titrated at once, but after the lapse of ninety-four hours the same quantity of the mixture used only 7·7 c.c. of the acid, phenolphthaleïn being used as the indicator in both cases. The author also found that the Seliwanoff test would detect the presence of as little as 0·1 per cent. of lævulose in urine containing dextrose.

W. P. S.

Method for Determining the Value of Commercial Starches for Use in Cotton Mills. G. M. MacNider. (*J. Ind. Eng. Chem.*, 1912, **4**, 417-422.)—The value of starch for cotton-mill purposes depends on its property of swelling and forming a viscous solution when treated with hot water, the principal starches used being maize, potato, cassava, and, to a small extent, wheat, sago, and rice. As each of these starches has a different viscosity, to obtain the best results they must each be used in a different manner. No definite relation exists between their behaviour and the size or shape of the grains. The author determines the viscosity of each starch at a high temperature under conditions similar to those in which it is used in the mills, employing for the purpose a Scott viscosimeter in the following manner: 12 grms. of the starch are weighed into a 600 c.c. beaker, 300 c.c. distilled water added (thus making a 4 per cent. solution), and heated over a Bunsen burner, with constant stirring, to the boiling-point and boiled for ten minutes; 200 c.c. of this solution are then poured into a viscosimeter cup, which is jacketed with boiling water, the temperature allowed to become constant, which it does with most starches, at 94° C., and 50 c.c. run out into a graduated vessel, the time being measured with a stop-watch. The number of seconds so required divided by the number of seconds required to deliver 50 c.c. of boiling water (nine seconds) gives the viscosity value.

The recorded results show that not only is there a difference between different starches, but also a considerable variation in the viscosity of different samples of the same starch, only a small part of this latter difference being due to variation in moisture content.

The viscosity of maize starch increases uniformly with the length of time of boiling, and corresponds to the increase in concentration brought about by continued boiling. This is a valuable property of maize starch as compared with others.

Potato starch reaches its maximum viscosity after being boiled five minutes; it then decreases rapidly, the increasing concentration having no effect and after thirty minutes' boiling it has fallen below that of maize starch, which has been boiled for the same length of time.

Cassava starch attains its maximum viscosity at the boiling-point, after which it decreases uniformly with the length of time of boiling, and thus resembles potato starch, though to a less extent; the former starch, therefore, has a much wider application in sizing and finishing.

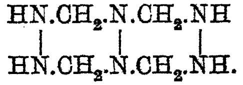
Wheat starch has a much lower viscosity than any of the others examined, and shows a gradual but small increase with the time of boiling. Wheat starch foams more in boiling than any other.

Rice starch, even at the end of thirty minutes' boiling, still shows a value only very slightly greater than unity. The degree to which starches go into solution on continued boiling was examined, and it was noticed that those from roots and tubers developed under ground (potato and cassava) showed a high rate of solution, while those from the grains developed above ground were very insoluble. An examination was made of some "thin boiling starches," which usually consist of maize starch treated in some way to reduce the viscosity. Experiments are described showing the effect of boiling maize starch with borax, alkali, and boric acid, as regards viscosity changes. A small amount of all these reagents reduces, while a slightly larger amount increases, viscosity. H. F. E. H.

Estimation of Thymol, Salicylates, and Allied Compounds. A. Seidell. (*Amer. Chem. J.*, 1912, **47**, 508-526.)—The method given in the author's previous paper on this subject (Analyst, 1909, **34**, 536) is admittedly tedious, and was only suggested as a possible improvement over the ordinary bromate titration in which tribromo-phenol bromide is formed. The control of the too vigorous action of bromine on the compounds under examination has now, in the author's opinion, been accomplished more satisfactorily. The method is as follows: A quantity of 0·1 to 0·5 grm. of thymol or other substance to be estimated is placed in a glass-stoppered bottle, with 1 to 2 c.c. of carbon tetrachloride and 100 c.c. of water. Bromine vapour is poured in till the mixture, after thorough shaking, shows a considerable excess. After half an hour, 5 c.c. of carbon disulphide, immediately followed by 5 c.c. of aqueous potassium iodide (20 per cent.), are added, and the liberated iodine titrated with $\frac{N}{10}$ thiosulphate. An additional amount of potassium iodide is added, and if there is no further liberation of iodine, the burette reading is taken, 5 c.c. or an excess of aqueous potassium iodate solution (2 per cent.) added, and the titration, after thorough shaking, continued till the iodine colour is discharged. The second titration corresponds to the hydrobromic acid formed by the action of bromine on the compound used. Two molecules of hydrobromic acid are equivalent to 1 molecule of thymol; 1 c.c. $\frac{N}{10}$ thiosulphate, therefore, is equal to 0·0075 grm. thymol. The results quoted vary from 99·0 to 100·8 per cent. of the theoretical. Carbon disulphide and tetrachloride serve to remove the compound from the aqueous layer, and the reaction in the organic solvent is more under control, only dibromothymol being produced. Carbon tetrachloride, unlike carbon disulphide, is little acted on by bromine on standing, and is therefore added first; but a satisfactory end-point in the titrations is not obtainable without the addition of the disulphide as described. Salicylic acid may be determined when in admixture with benzoic acid, the latter being unacted on. Other substances tried gave variable results.

A. R. T.

Tetraformal-trisazine from Formaldehyde and Hydrazine Hydrate, a New Reducing Agent for Analytical Use. K. A. Hofmann and D. Storm. (*Ber.*, 1912, **45**, 1725-1730.)—Hydrazine hydrate is employed in analytical chemistry for the precipitation of silver, gold, mercury, platinum, selenium, and tellurium, but its reducing power is too great to permit of fine differentiations among the noble metals, and it also reduces solutions of copper and bismuth. The precipitates are not easily filtered, and firm mirrors are not obtainable on glass. Hydrazine hydrate also attacks glass, and is not free from alkalis. The authors, therefore, recommend as a reducing agent far more under control and free from alkalis and acid, the compound tetraformal-trisazine, $C_4H_{12}N_6$, formed by the combination of formaldehyde with hydrazine hydrate. This substance has the structural formula—



$$\begin{array}{ccccc} HN & .CH_2. & N & .CH_2. & NH \\ | & & | & & | \\ HN & .CH_2. & N & .CH_2. & NH. \end{array}$$

For its preparation, 50 c.c. of 35 per cent. formalin are poured slowly into 50 c.c. of hydrazine hydrate cooled with ice, and after one hour a further 30 c.c. of formalin are similarly added. The mixture is placed in a basin, covered with paper, and left for one or two days, when the yield of crystallised compound should amount to 27 grms. The crystals are filtered off, washed with spirit, redissolved in water, and precipitated with alcohol and ether; they may also be recrystallised as flat, silky needles from slightly alkaline hot water. At 28° C., 100 grms. of water dissolve 14 grms. of the azine. Silver nitrate yields first a white precipitate, changing immediately on warming to a fine adherent metallic mirror; palladium chloride also yields a mirror. Gold chloride yields first a blue colloid, and later a dark precipitate. Copper sulphate gives a reddish-brown solution. The azine is not decomposed by alkalis, from which it crystallises unchanged. In alkaline solution, copper salts are reduced to cuprous oxide, mercury, gold, and silver salts to the metals, whilst platinum and palladium chlorides give stable, reddish-brown solutions. In presence of excess of potassium hydroxide, chromates, molybdates, vanadates, selenites, and tellurites remain unchanged, even at the temperature of the water-bath; but on the addition of ammonium chloride, indigo blue molybdenum oxide, red selenium, or black tellurium are precipitated. Tungstates are not reduced even in ammoniacal solution. Thus tetraformal-trisazine may be recommended as a selective reducing agent which is readily prepared in a perfectly pure form. The substance, though stable towards alkalis, is very sensitive to the action of acids, even carbonic and acetic acids, forming polymerised formalazine, $(CH_2N_2CH_2)_n$, as an insoluble white powder. Ammonia is one of the principal products of the action of hot dilute sulphuric acid. J. F. B.

Examination and Valuation of Turpentine. H. Wolff. (*Farbenzeitung*, 1912, **17**, 1492; through *Chem. Zentralbl.*, 1912, I., 1930.)—The colour is more conveniently determined by a comparison with solutions of iodine, potassium dichromate, etc., than by means of the Lovibond colorimeter. The polymerisation with sulphuric acid, which involves oxidation, should not be omitted (*cf.* Marcusson, *Chem. Zeit.*, 1910, **34**, 285); otherwise, adulteration with residues from the manufacture of turpentine may be overlooked. The distillate obtained before and after the chief fraction in the distillation of turpentine are to be found on the market and are difficult to detect when added to turpentine. The greater part of the residual oil distils earlier when mixed with turpentine than it does alone. On the other hand, with concentrated or fuming sulphuric acid, more separates from the mixture than would be anticipated from the amount of residual oil. It is evident that sulphuric acid has less action in the presence of high-boiling constituents. A separation of more than the normal 2 to 4 per cent. is sometimes shown, when the resinification is well started, even by pure turpentines, in which there is a slight natural increase of these constituents, and, consequently (petroleum being excluded), is not a proof of adulteration with these residues. A small increase in the residue on evaporation, with a large increase in the amount separated by fuming sulphuric acid, points to an adulteration with these waste products, whereas an increase in the resinification is of no value as an indication. A residue of 1 per cent. on evaporation has a noticeably bad effect on the drying-period, whilst 2 or 3 per cent. renders a turpentine useless for many purposes in the varnish and colour industry. O. E. M.

Estimation of Petroleum in Turpentine. H. Wolff. (*Farbenzeitung*, 1912, **17**, 1553; through *Chem. Zentralbl.* 1912, I, 1931.)—The constituents dissolved by nitric acid are, contrary to the statement of Herzfeld (*Chem. Zeit.*, 1910, **34**, 885), cyclic hydrocarbons, since they can be reduced by the slow action of nascent hydrogen, the solution being kept warm. It was found that xylene can be dissolved in concentrated sulphuric acid alone, but that long shaking is necessary; this explains the conflicting results obtained by Marcusson and Herzfeld with turpentines containing xylene. Consequently Herzfeld's method of determining benzene has only a qualitative value, and only then if it is positive and agrees with the other constants (boiling-point, bromine number, etc.). The separation of petroleum or paraffin hydrocarbons by concentrated fuming sulphuric acid is more valuable, especially if, by the method of Utz, the refraction of the separated residue is determined. The Marcusson method is preferable for the exact determination of petroleum and benzene hydrocarbons. In the case of a strongly resinified oil, if there is a considerable separation with concentrated sulphuric acid, even when the Marcusson test gives a negative result, it is better to examine once more the substance separated with sulphuric acid by the Marcusson method. O. E. M

Tests for Determining the Purity of Oil of Turpentine. R. Marcille. (*Ann. Falsific.*, 1912, **5**, 241-251.)—Determinations of the solubility of oil of turpentine in acetic acid, the rise in temperature when mixed with sulphuric acid, and the solubility in sulphuric acid, are stated to yield results which will afford evidence as to the genuineness of a sample of turpentine.

Solubility in Acetic Acid.—The acetic acid employed should contain 98 per cent. of the acid and 2 per cent. of water; it should be capable of dissolving an equal volume of anhydrous carbon disulphide at a temperature of 39 to 40° C., at which point a mixture of equal volumes of the two liquids should just become turbid; if the temperature at which the turbidity is observed is lower or higher than this, the strength of the acid must be adjusted accordingly. Five c.c. of the oil of turpentine are placed in a stoppered graduated tube, and shaken with successive additions of acetic acid until a clear mixture is obtained at a temperature of 15° C. The quantity of the acid required to dissolve 1 part of the oil of turpentine is then calculated. For genuine samples this quantity is usually less than 4. The oil of turpentine may also be distilled, the distillate being collected in five separate portions, which are then submitted to the test. The first fractions dissolve in about 3·5 parts of acetic acid, whilst the fifth fraction may require up to 4·5 parts of acid. The presence of petroleum diminishes the solubility of the oil, the fifth fraction of a sample containing 5 per cent. of petroleum requiring from 6 to 7 volumes of acetic acid. Oil of turpentine adulterated with "benzine" has a greater solubility than pure oil of turpentine.

Thermal Test with Sulphuric Acid.—The method of carrying out this test in the case of fatty oils has been described by Tortelli (ANALYST, 1909, 34, 168). The same procedure is adopted with oil of turpentine, but, as the latter evolves very considerable heat when mixed with sulphuric acid, it is better to perform the test on a mixture of 5 c.c. of the sample and 15 c.c. of "vaseline oil." Genuine oil of turpentine gives a value of from 68 to 72, and the presence of 10 per cent. of mineral oil will diminish this value by about 7.

Solubility in Sulphuric Acid.—One hundred c.c. of petroleum, 20 c.c. of oil of turpentine, and 50 c.c. of sulphuric acid are mixed in a Röse tube, and the increase in the volume of the sulphuric acid is ascertained after the lapse of one hour. In the case of genuine oil of turpentine, the increase will be about 19·2 c.c. (that is, 96 per cent. of the oil is soluble in the acid), whilst with an oil containing 10 per cent. of mineral oil the increase in the volume of the acid will be only 17·1 c.c. The test is useless should "benzine" be present. Care should be taken to examine the petroleum used in the test, as some specimens yield notable quantities of matter soluble in sulphuric acid. W. P. S.

INORGANIC ANALYSIS.

Detection of Small Quantities of Alkali Bicarbonate in Presence of much Normal Carbonate. R. T. Haslam. (*J. Amer. Chem. Soc.*, 1912, 34, 822-823.)—The carbonate suspected to contain bicarbonate is dissolved in recently boiled water, and excess of calcium chloride is added. If alkali bicarbonate was originally present, some calcium bicarbonate will remain in solution with the calcium chloride. After standing five minutes, a portion of the solution is filtered free from calcium carbonate, and a few drops of ammonia are added to the filtrate. An immediate precipitate of calcium carbonate indicates a large amount of bicarbonate in the original sample. With only small amounts of bicarbonate present, the precipitate may not appear for ten minutes. The test will detect 0·1 per cent. of bicarbonate in normal sodium carbonate. The presence of ammonium salts vitiates the results because of the solubility of calcium carbonate in such solutions. G. C. J.

Neutral Ammonium Citrate Solution. A. J. Patten and C. S. Robinson. (*J. Ind. Eng. Chem.*, 1912, 4, 443-446.)—According to the official methods of analysis drawn up for the guidance of American agricultural chemists, the ammonium citrate solution for use in determining available phosphoric acid is to be prepared by dissolving citric acid in water, adding ammonia until the solution is neutral to corallin, and then diluting it with water until the sp. gr. is 1·09. The authors point out that the determination of the end-point with corallin is very difficult, and that purified litmus, though better, is also unsatisfactory as an indicator. Solutions "neutralised" by four experienced analysts were used to extract a phosphatic manure, with the result that the manure was found to contain 2·83, 3·69, 4·17, and 4·82 per cent. of insoluble phosphoric acid. The authors think that the amount of ammonia necessary for neutralisation should be determined by the conductivity method as suggested by

Hall and Bell (*J. Amer. Chem. Soc.*, 1911, 33, 711; *J. Ind. Eng. Chem.*, 1911, 3, 559). The solution is nearly neutralised, and then equal measured portions are transferred to measuring-flasks, and a measured and different amount of dilute ammonia is added to the contents of each flask, so that two flasks at least contain an excess of ammonia and two an excess of acid. The contents of the flasks are then diluted to the mark, and their relative conductivities determined. It is unnecessary to determine the absolute conductivities. Provided the same apparatus is used for all the determinations, the Wheatstone bridge readings may be plotted against the volumes of dilute ammonia, and the break in the curve will indicate the volume of ammonia necessary to neutralise so much of the solution as was taken for the test. The error of this method, even in the hands of persons with no previous experience of conductivity measurements, is only one-tenth the error of the most careful titration with corallin or litmus.

G. C. J.

Separation of Beryllium from Aluminium. M. Wunder and P. Wenger. (*Zeitsch. anal. Chem.*, 1912, 51, 470-473.)—From a mixture of beryllia and alumina, the former may be separated as follows: The mixture is fused with 5 grms. of sodium carbonate in a crucible, which is covered at first, but subsequently uncovered, whilst the mixture is maintained in a state of fusion for two to three hours. The melt is boiled out with water, about a gram of sodium carbonate is added, and boiling continued for a few minutes. Beryllia remains undissolved. It is filtered off, washed, dried, ignited, and weighed, and re-fused with sodium carbonate, and the whole process repeated to insure the solution of the last traces of alumina. In the mixed filtrates, alumina is precipitated by boiling with excess of ammonium nitrate, and is filtered, washed, dried, ignited, and weighed in the usual manner. The worst recorded results are 0·1466 grm. beryllia and 0·1385 grm. alumina found with 0·1472 and 0·1379 grm. respectively present. The results are not stated in such a way as to show what additional error, if any, might be expected to result from the omission of the second fusion.

In practice, more or less iron will, as a rule, be present in the material presented for analysis, and the whole of this iron will remain as insoluble hydroxide with the beryllia, any chromium also present passing as chromate into the solution of sodium carbonate and aluminate. Precipitates of beryllia contaminated by ferric hydroxide are ignited, fused with bisulphate, and the aqueous solution of the melt is poured into a solution of 10 grms. of caustic soda in 150 c.c. of water, and the whole boiled. The precipitate consists of ferric hydroxide free from beryllia, and is washed, re-dissolved in acid, re-precipitated by ammonia, and weighed as ferric oxide as usual. The alkaline solution of beryllia is acidified, and the beryllia precipitated by means of ammonia.

When chromium is present in the original material, it will exist as chromate in the filtrate from the alumina, and may be recovered by reduction with alcohol and precipitation with ammonia.

G. C. J.

Volumetric Estimation of Chloric Acid and Chlorates. A. Kolb. (*Chem. Zeit.*, 1912, 36, 635.)—The high results obtained by the action of hydrochloric acid on chlorate in presence of potassium iodide at the ordinary temperature are due to the presence of atmospheric oxygen, and may be avoided by removing the air from the hydrochloric acid solution by means of a current of carbon dioxide, dissolving the chlorate in water which has been boiled and carrying out the reaction in a vessel filled with carbon dioxide. To 10 c.c. of air-free potassium chlorate solution (about $\frac{N}{10}$) are added 1 grm. of solid potassium iodide and 50 c.c. air-free hydrochloric acid of sp. gr. 1·125 in the order given, and the mixture allowed to stand five to ten minutes in a stoppered vessel in the dark. After addition of 200 to 300 c.c. water, the separated iodine is titrated. If the quantity of chlorate solution is more than 10 c.c., the hydrochloric acid must be increased proportionately, otherwise the reaction is slower. An increased quantity of chlorate in the 10 c.c. is without effect on the reaction-velocity, but more potassium iodide is required to keep the iodine in solution.

O. E. M.

Quantitative Determination of Perchlorates. A. B. Lamb and J. W. Marden. (*J. Amer. Chem. Soc.*, 1912, **34**, 812-817.)—The minus errors which attend estimations of perchlorate by fusion with sodium carbonate or other substances, and determination of the resultant chloride as silver chloride, are shown to be due to loss of chloride by volatilisation. This may be wholly avoided as follows: The substance (0·5 grm.) is weighed into a Jena glass test-tube of about 25 to 30 c.c. capacity. An asbestos plug is pushed down into the tube within 2 inches of the bottom, and a second plug 2 inches nearer the top. The tube is clamped in a nearly horizontal position, and the perchlorate is heated gently until effervescence ceases. A somewhat stronger heat is then applied, until, in from ten to fifteen minutes, the chloride is thoroughly fused. When cool, the contents of the tube, including the plugs, are washed on a Gooch crucible with hot water, and the chloride in the filtrate determined in the usual manner. A correction must be made, if necessary, for chloride in the asbestos used, and in the most exact work 0·1 mgrm. may be added to the weight of silver chloride found, as a correction for the loss with the final wash liquors. Without this last correction, the worst result of eight recorded by the authors is only 0·05 per cent. below the theoretical.

G. C. J.

Estimation of Chromium in Bronzes containing Tin and Antimony. H. Schilling. (*Chem. Zeit.*, 1910, **36**, 697.)—The following rapid modification of von Knorre's method is recommended: Two grms. of the finely-divided turnings are dissolved in 25 c.c. of hot *aqua regia* (1HNO_3 to 4HCl), and the solution mixed with 40 c.c. of sulphuric acid (1:1), and evaporated until white fumes appear. Complete removal of the *aqua regia* is essential. When cold, 200 c.c. of water are added, and the precipitated sulphates dissolved by boiling, with the exception of the lead sulphate. The copper and antimony are now precipitated by means of iron wire in the metallic form, the liquid filtered after five minutes, and the precipitate washed. The filtrate and washings are made up to 500 c.c., heated to boiling, and treated first with a few drops of silver nitrate solution (1 : 20) as a catalytic agent, and then with 10 c.c. of a cold saturated solution of ammonium persulphate. By vigorous boiling the chromium is oxidised to chromic acid, whilst the bulk of persulphate is meanwhile decomposed. The remainder, together with any permanganate that may have been formed, is decomposed by adding 5 c.c. of hydrochloric acid (sp. gr. 1·12) and boiling the liquid for a short time. When completely cold, the chromium is estimated by titration in the usual way. The presence of tin does not affect the accuracy of the results. C. A. M.

Iodimetric Estimation of Copper. K. Sugiura and P. A. Kober. (*J. Amer. Chem. Soc.*, 1912, **34**, 818-822.)—Though the iodimetric method for the estimation of copper is capable of yielding results of a high order of accuracy, this is only the case when the thiosulphate is standardised under conditions very closely resembling those prevailing in actual assays. In consequence of this, many papers have been published on the influence of various amounts of acid, salts, water, etc., the most recent being that of Peters (ANALYST, 1912, 277). Instead of trying to secure uniformity in all the conditions by the methods advocated by Peters and others, the authors think it far more easy to precipitate the copper as hydroxide, to dissolve the washed precipitate in acetic acid, and to titrate the resulting solution with thiosulphate after addition of potassium iodide. One advantage of the method is the stable end-point with starch indicator (no return of the blue colour). The only point in the method requiring close attention is the precipitation as hydroxide. To the solution, containing phenolphthaleïn, 33 per cent. alkali is added drop by drop until a slight precipitate of copper hydroxide remains undissolved. $\frac{N}{5}$ caustic soda free from carbonate (containing baryta) is then added from a burette until a change of colour is observed. Any excess of alkali containing carbonate would hold some copper in solution, whilst a large excess even of caustic alkali would prolong the operation of washing the precipitate. If the precipitation be performed as described, three or four washings suffice. The precipitate with the filter-paper is returned to the flask in which the precipitation was carried out, the precipitate is dissolved in 25 c.c. of 10 per cent. acetic acid, 3 or 4 grms. of potassium iodide are added, and the titration with thiosulphate conducted as usual. The thiosulphate is standardised by precipitating a measured volume of a standard copper solution with subsequent solution of the precipitated hydroxide and titration as described. Obviously, the concentration and nature of the acids and salts in the original solution are without influence on the results, if the washing of the hydroxide be sufficiently prolonged. The amount of washing which the authors give the precipitate cannot remove the whole of the salts, but the test numbers given in the paper show that no sensible error is introduced from this cause. G. C. J.

Estimation of Oxygen and Occluded Gases in Copper. G. L. Heath. (*J. Ind. Eng. Chem.*, 1912, **4**, 402-404.)—The loss in weight on heating copper drillings in hydrogen is not due entirely to oxygen from cuprous oxide and sulphurous acid, but also includes gases derived by the metal from the fuel and refining in the furnace and, in addition, any trace of moisture. In recognition of this fact it is now customary to heat the drillings to constant weight in a current of carbon dioxide before proceeding to the determination of oxygen. The loss in weight during the preliminary heating in carbon dioxide is returned as "absorbed gases," and includes hydrogen, and traces of carbon dioxide, carbon monoxide, and nitrogen. The author finds that the subsequent loss of weight by heating in hydrogen does not express the true oxygen of the cuprous oxide present in the cast metal, for the metal may take up so much hydrogen during the process that the amount of oxygen may be underestimated by more than 20 per cent. An accurate determination of oxygen may be made by passing a current of carbon dioxide through the heated tube for twenty minutes after reduction by hydrogen is complete.

In the author's laboratory the carbon dioxide is purified by treatment successively with a saturated solution of permanganate, solution of silver sulphate, concentrated sulphuric acid, anhydrous calcium chloride, dry chromous chloride, stick phosphorus, phosphoric anhydride, and anhydrous calcium chloride. The hydrogen is purified by means of a 10 per cent. solution of caustic potash saturated with permanganate, concentrated sulphuric acid, heated palladium asbestos, a 5 to 10 per cent. solution of pyrogallol in 50 per cent. caustic potash, and anhydrous calcium chloride. The clean drillings (50 grms.) are placed in a hard-glass tube, 30 cm. long and 6 mm. diameter, with one long bulb or two round ones; and if the copper is very porous or of unknown origin, the sample is dried at 100° C. while passing a current of carbon dioxide, and the tube with its contents re-weighed after cooling and replacing the carbon dioxide by air. Air is once more expelled by carbon dioxide, and this gas continuously passed while the tube is heated to full redness for twenty minutes. After cooling and replacing carbon dioxide by air, the tube is re-weighed, the loss being due to occluded gases in the copper. Hydrogen is now passed through the tube, which at its forward end is connected to a gas-washing device containing 10 c.c. of an ammoniacal solution of cadmium chloride (2 per cent.). According to the fineness of the drillings, from one to two hours at a red heat is required to reduce the cuprous oxide. Finally, hydrogen is expelled from the tube and from the copper by replacing the stream of hydrogen by one of carbon dioxide while maintaining a red heat. After twenty minutes, the tube is cooled by an air blast, the carbon dioxide replaced by air, and the final weighing of the tube made. The loss since the previous weighing represents oxygen and sulphur, and the latter is determined by iodine titration of the contents of the cadmium chloride bulbs after addition of hydrochloric acid and appropriate dilution. Proof of the accuracy of the method is given by a careful electrolytic assay of the reduced drillings. The sum of the copper (and silver) thus found, plus the percentage of arsenic and foreign metals found by complete analysis, should amount to 100 per cent. without any oxygen or occluded gases. In three sets of test numbers given, the totals are 100·0007, 99·9998, and 99·9901. Such check-work implies the use of refined electrolytic methods such as those described by the author (ANALYST, 1911, **36**, 172), which permit of the determination of copper with an error not exceeding 0·001 per cent. (see also ANALYST, 1900, **25**, 253; 1905, **30**, 385).

G. C. J.

Precipitation of the Copper-Arsenic Group and Separation of its Divisions. J. I. D. Hinds. (*J. Amer. Chem. Soc.*, 1912, **34**, 811-812.)—The method of precipitation described has regard to the fact that a fairly high concentration of acid is necessary for the complete precipitation of quinquevalent arsenic, whereas cadmium, antimony, and tin are not completely precipitated unless the acid concentration is kept low. To 50 c.c. of the solution, if approximately neutral, 5 c.c. of concentrated hydrochloric acid and 10 drops of nitric acid are added, or a less amount of hydrochloric acid if the original solution is strongly acid. The solution is concentrated to half bulk, whereby not more than one-thousandth part of the arsenic is lost. The nitric acid serves to oxidise all the tin to the stannic condition, which is desired, because stannous sulphide is not readily soluble in colourless ammonium sulphide; at the same time, some arsenic is oxidised to the quinquevalent condition. Arsenic is now precipitated by passing hydrogen sulphide for ten minutes through the hot solution, which is heated once or twice until it actually boils. About 80 c.c. of water are added, and the current of hydrogen sulphide continued until the liquid is cold, or for fifteen minutes. The precipitate, which contains the sulphides of all the metals of the group, is filtered, washed, and transferred to a beaker, where it is covered with strong ammonia. Hydrogen sulphide is passed through the mixture for two minutes, after which the other sulphides are separated by filtration from those of arsenic, antimony, and tin, which pass quantitatively into the filtrate with only a trace of copper. G. C. J.

Qualitative Analysis without Hydrogen Sulphide. H. Trapp. (*Zeitsch. anal. Chem.*, 1912, **51**, 475-480.)—Higher oxides are first reduced by passing sulphur dioxide through the solution. If insoluble sulphates separate at this stage, they are filtered off and examined separately. After boiling off excess of sulphur dioxide, hydrochloric acid is added, and any precipitate formed is filtered off and examined in the usual manner.. To the solution, or filtrate from insoluble chlorides, nitric acid is added to peroxidise the iron, then ammonia until a precipitate begins to form or until the solution is no longer acid, and finally ammonium sulphide in excess. Any insoluble sulphides are filtered off, and the filtrate is acidified to throw down the sulphides of tin, antimony, and arsenic, if present. These metals, as well as the alkali metals, alkaline earth metals, and magnesium, which pass into the filtrate, are separated and identified in the usual manner.

The ammonium sulphide precipitate, which may contain mercury, lead, bismuth, chromium, aluminium, zinc, iron, manganese, copper, cadmium, cobalt, and nickel is treated with nitric acid, and any undissolved mercuric sulphide is filtered off. Lead is precipitated as sulphate, and bismuth tested for by diluting a portion of the solution. If bismuth is present, it is next separated, after expelling the excess of acid in the solution. On addition of caustic soda and a little bromine and warming, all the remaining metals are precipitated as hydroxides except chromium, aluminium, and zinc, which pass into the filtrate as chromate, aluminate, and zincate, except when iron is also present, when chromium will be found in the precipitate. The filtrate is divided into three portions, in one of which aluminium is precipitated by ammonium chloride; in another, zinc is detected as sulphide, whilst the third is reduced with sulphur dioxide, and any chromium precipitated as hydroxide.

The hydroxides of iron, manganese, copper, cadmium, cobalt, and nickel are digested with ammonium sulphide and washed. From the mixed sulphides iron and manganese are extracted by dilute hydrochloric acid and separated from each other.

by means of sodium acetate. The sulphides of copper, cadmium, cobalt, and nickel, are dissolved in hot concentrated sulphuric acid, and the solution is neutralised with ammonia. Copper and cadmium are precipitated by shaking with zinc dust, the solution of cobalt and nickel is filtered, and these metals precipitated as hydroxides by boiling with excess of caustic soda. The residue of zinc dust with any copper or cadmium is treated with hydrochloric acid, which dissolves the zinc and cadmium, and the latter may be separated from the zinc by boiling the filtrate from the undissolved copper with excess of caustic soda.

An alternative method of analysis, also dispensing with the use of hydrogen sulphide, is described in the paper. G. C. J.

Determination of Iodides by Direct Titration. J. W. Turrentine. (*J. Ind. Eng. Chem.*, 1912, 4, 435-436.)—The method, an empirical one, is intended for the rapid estimation of small amounts of iodide in presence of much chloride, such as is required in a laboratory where large numbers of kelp samples have to be reported on. The solution (10 to 100 c.c.) containing the iodide to be estimated is transferred to a 250 c.c. separator, into which 15 c.c. of dilute (1 : 10) sulphuric acid and 15 c.c. of carbon tetrachloride are also introduced. A solution of permanganate, containing about 1 grm. per litre and standardised in an exactly similar manner on known amounts of iodide, is next added from a burette with shaking after each addition. With the decrease in the concentration of iodide, the solubility of the iodine decreases until, as the end of the titration is approached, the solution appears colourless. The easiest end-point to work to, however, is the persistence for one minute of the pink tint due to excess of permanganate. From the reading, an empirically determined deduction of 0·2 c.c. is made, and the remainder is then the measure of the iodide present. In standardising the permanganate, measured volumes (10 to 100 c.c.) of an exactly 0·1 per cent. solution of potassium iodide are treated in the manner described. By taking varying volumes, not only is the iodine value of the permanganate determined, but also the empirical correction already referred to. A series of numbers is given showing that in the author's hands this correction is about 0·2 c.c. permanganate, and that with this correction the method enables the analyst to determine small quantities of potassium iodide with an error not exceeding 6 per cent. with as little as 10 mgrms. present, nor exceeding 3 per cent. with quantities of 20 to 100 mgrms. The application of the method may be extended by effecting the standardisation in presence of large quantities of any salt, in presence of which the analyst is called upon to determine traces of iodide; but where this other salt is sodium chloride, such procedure is unnecessary. The author frees his carbon tetrachloride from reducing substances by prolonged treatment with iodine, subsequently removing the excess of iodine with thiosulphate and washing the carbon tetrachloride with water. G. C. J.

Potassium Iodide and Mercurous Nitrate as Sensitive Reagents for Tungsten and Molybdenum. E. Kafka. (*Zeitsch. anal. Chem.*, 1912, 51, 482.)—To the neutral solution of tungstate or molybdate, 1 drop of a saturated solution of mercurous nitrate is added, and this is followed by 1 c.c. or more of concentrated hydrochloric acid and excess of potassium iodide. The mixture is shaken vigorously until the green mercurous iodide first formed redissolves. In presence of much tungstate or molybdate, the solution assumes a blue colour at once. With little tungstate or molybdate present, the colour develops more slowly. As little as 0·2 mgrm. of sodium tungstate gives a distinct reaction. To distinguish between tungsten and molybdenum, potassium thiocyanate is added to the blue solution, which will change to blood-red in presence of molybdenum. Solutions containing so little molybdenum as to develop no blue colour in the first reaction may give a distinct red with thiocyanate. The function of the mercurous nitrate in the reaction first described is to increase the reducing power of the hydrogen iodide by forming a stable complex with the liberated iodine. G. C. J.

Separation of Nickel and Palladium by Means of Dimethylglyoxime. W. Wunder and V. Thuringer. (*Ann. Chim. anal.*, 1912, **17**, 201.)—The solution of the two metals is slightly acidified, preferably with hydrochloric acid, and treated with an excess of a 1 per cent. solution of dimethylglyoxime in 2 per cent. hydrochloric acid. After standing for thirty minutes on the hot-water bath the precipitated palladium is collected, washed with boiling water, ignited, and weighed in the metallic form. The filtrate is boiled and rendered slightly alkaline with ammonia, and the precipitated nickel dimethylglyoxime is collected in a Gooch crucible, washed with boiling water and then with 20 per cent. alcohol, and dried at 100° C. until constant in weight. The weight multiplied by the factor 0·2031 gives the amount of nickel. In solutions containing 0·025 grm. of palladium and 0·0846 grm. of nickel, the amounts thus found in six estimations were 0·0248 to 0·0252, and 0·0840 to 0·0843 grm., respectively. C. A. M.

Use of Oxygen under Pressure for Estimating Carbon in Ferro-Alloys. P. Mahler and E. Goutal. (*Compt. rend.*, 1912, **154**, 1702-1705.)—The use of the calorimetric bomb in the estimation of carbon in steel (ANALYST, 1911, **36**, 562) has been extended to the most refractory ferro-alloys. With these alloys, not only must one use litharge as a flux as in the case of very hard steels, but an auxiliary combustible is required. As auxiliary combustible the authors use iron of known carbon content. From 0·5 to 3 grms. of the alloy, according to its supposed carbon content, is taken for combustion, together with two or three times its weight of iron. With alloys very high in carbon, of which only 0·5 grm. can conveniently be taken, the proportion of iron must be increased, as there is some difficulty in effecting complete combustion of charges with a total weight of less than about 3 grms. Of litharge a weight equal to half that of the combustible charge is taken. A second experiment is made under identical conditions, save for the omission of the ferro-alloy. This second experiment provides the correction for the carbon in the soft iron and for any constant errors of the method. The authors now employ caustic soda for absorbing the carbon dioxide, and estimate the amount of the latter by titration before and after combustion, using phenolphthaleïn as an indicator. The test numbers given in the paper show that, when the method does not give results in close agreement with those of the ordinary direct dry combustion method, it gives higher results. In these cases—high-grade ferro-chromes and ferro-silicons—the authors think their higher numbers must be preferred. The following numbers serve to illustrate the difference in results by the two methods. A 69 per cent. ferro-chrome showed 10·6 per cent. carbon by the bomb, and 9·7 per cent. by ordinary direct dry combustion. A 75 per cent. ferro-silicon showed 0·20 per cent. carbon by the bomb, and 0·11 per cent. by the ordinary method. Results by the two methods with ferro-vanadium and ferro-molybdenum agree very closely. G. C. J.

Separation of the Rare Earths. C. James. (*J. Amer. Chem. Soc.*, 1912, **34**, 757-771.)—The paper states in a compendious form the best methods available for the separation of La, Ce, Pr, Nd, Sm, Eu, Gd, Tr, Dy, Ho, E, Tm, Yb, Lu, Ct, Yt, and Sc, in mixtures where all may occur. The methods are suited to large scale operations rather than to analytical practice, one method requiring a few thousand fractional crystallisations. But, though several of these elements can be determined with fair accuracy in minerals or mixtures of oxides in which they are the chief constituents, exact methods for the separation of others are not yet known. Where spectroscopic examination shows one or more of the rarer earths to be present in notable proportion, reference to this paper will show the analyst whether an approximate estimation of these elements is reasonably practical, and, if so, will indicate the necessary steps to be taken. G. C. J.

Improvements in the Ludwig-Sipöcz Method for the Estimation of Water in Silicates. M. Dittrich and W. Eitel. (*Zeitsch. anorg. Chem.*, 1912, **75**, 373-381.)—The method referred to in the title of the paper is that in which the powdered mineral is mixed with dry fusion mixture in a platinum boat, heated in a current of dry air in a combustion tube, and the water absorbed in appropriate drying tubes and weighed. The authors propose to replace fusion mixture by sodium carbonate, chiefly because it is easily obtained anhydrous by three hours' heating below 300° C., and can be mixed with the powdered mineral without risk of the absorption of more than a few tenths of a mgrm. of moisture. They also agree with Hillebrand ("Analysis of Silicate and Carbonate Rocks," p. 87) that the higher melting-point of sodium carbonate makes its use preferable to that of a mixture of sodium and potassium carbonates. The other innovations of the authors relate to the apparatus employed. They use a quartz combustion tube 45 cm. long by 22 mm. diameter, and 0·5 mm. in the wall. The platin-iridium boat, which is 12 cm. long, is provided with a cover and enclosed in a cylinder of thin platin-iridium foil, just fitting the combustion-tube, to protect the latter in case of frothing. The forward end of the combustion-tube is drawn out and connected by a ground joint to the first tared drying-tube. The other end of the combustion-tube is also ground to receive a quartz plug carrying a tube of small diameter, which is connected by rubber tubing to the apparatus for drying the current of air. Sulphuric acid is used for drying the air and for absorbing the moisture given up by the mineral. Heating is effected by a multiple Bunsen burner, supplemented as a rule by five to ten minutes heating with a multiple blowpipe, or an electric furnace may be used with advantage. In the latter case the temperature is raised to 850° to 900° C. in about twenty minutes, maintained at this point for fifteen minutes, and then raised to 1000° to 1050° for ten to fifteen minutes. One grm. of the substance with 6 grms. of sodium carbonate is a suitable charge, and the residue in the boat is immediately available for the determination of silica, alumina, etc. Duplicate determinations of moisture seldom differ by more than a few tenths of a milligram. G. C. J.

Volumetric Estimation of Sulphuric Acid, Nitric Acid, and Nitrous Acid, in Nitrating and Waste Acids. G. Finch. (*Zeitsch. Schiess- u. Sprengstoffwesen*, 1912, 7, 113.)—A wad of cellulose fibre is placed in 50 c.c. of the diluted mixture of acids, excess of barium carbonate added, and stirring continued until the evolution of carbon dioxide nearly ceases, when the liquid is boiled for five minutes. The precipitate of barium carbonate and sulphate is well washed, the filtrate boiled for several minutes with a wad of cellulose and 50 c.c. of $\frac{N}{5}$ sodium carbonate, filtered, the precipitate washed until no reaction is obtained with phenolphthaleïn, and the excess of sodium carbonate in the filtrate titrated back with $\frac{N}{5}$ hydrochloric acid and methyl orange. The cellulose, prepared by steaming ash-free filter-paper cut into small pieces for two days, and kept for use in alcohol, ensures the precipitation of the barium sulphate in an easily filtered condition. The barium carbonate is prepared by precipitating barium chloride solution with sodium carbonate in the cold, and washing thoroughly by decantation.

If $\frac{N}{10}$ barium hydroxide solution is used instead for the neutralisation, the acids may be estimated simultaneously; the total acidity is given by the amount of barium hydroxide used, and the nitric acid, present in the filtrate as barium nitrate, is estimated as before. Nitrous acid, if present, is titrated with permanganate, and deducted from the total acidity. The nitrometer may show a higher total nitrogen than the volumetric method; this is attributed to the presence of lower nitric-acid esters of glycerol, not removed in the after-separation. The error is usually negligible. O. E. M.

Rapid Method of Purifying Sulphuric Acid. G. Bressanin. (*Gazz. Chim. Ital.*, 1912, 42, 456-458.)—The principle of the method of separating arsenic, etc. (ANALYST, 1912, 206), may be applied to the purification of sulphuric acid for toxicological work. The acid is first concentrated to sp. gr. 1·52, then cooled, and treated with 10 c.c. of a 30 per cent. solution of hydriodic acid. After standing for twelve hours it is filtered through glass-wool and purified asbestos, and the iodine eliminated from the filtrate by boiling. Acid containing as little as 0·0005 mgrm. of arsenic per c.c. gives a precipitate with the reagent after some time. The purification must be carried out in vessels of Jena glass, since ordinary glass or porcelain may yield further traces of arsenic to the acid. Tin, copper, cadmium, lead, antimony, and selenium, are also precipitated—the last in elementary form; whilst nitric and nitrous acids are reduced to nitrogen peroxide. Mercury and bismuth are not precipitated, and no precipitate is given by the members of the third and following groups of metals. G. A. M.

New Reagent for Thorium. M. Koss. (*Chem. Zeit.*, 1912, **36**, 686.)—The solution to be tested is rendered strongly acid with hydrochloric acid, and a few drops of a solution of sodium hydrogen hypophosphate ($NaHPO_3$, $2H_2O$) added. With considerable quantities of thorium a white flocculent precipitate forms at once; with small quantities heating or long standing is necessary. Less than 0·0001 grm. of thorium oxide in 1 c.c. of solution may thus be detected. Titanium and zirconium are simultaneously precipitated. Previous treatment with hydrogen peroxide converts the titanium into pertitanic acid, which is not precipitated by the reagent. To remove zirconium, the mixed precipitate, after washing, is oxidised with sulphuric and nitric acids, and the solution precipitated with oxalic acid; zirconium remains in solution. O. E. M.

Quantitative Determination of Yttrium. C. F. Whittemore and C. James. (*J. Amer. Chem. Soc.*, 1912, **34**, 772-774.)—Precipitates of yttria are apt to be contaminated with salts of sodium, potassium, lithium, and magnesium, and with ferric oxide and alumina, if the corresponding elements are present in the solutions from which the yttria is precipitated. Thus yttrium may be overestimated by 5 per cent. if precipitated by caustic soda, ammonia, or oxalic acid, in presence of salts of sodium or potassium. The ammonium salts of several organic acids were tried as precipitant, with unsatisfactory results; but it is found that ammonium sebacate precipitates yttria quantitatively and free from sodium even when large quantities of sodium are present. In presence of potassium, a second precipitation as sebacate is necessary to obtain exact results. In presence of iron, aluminium, magnesium, or lithium, the whole of the yttria may be precipitated free from any trace of these elements by means of oxalic acid, provided the precipitation be made in the cold, and that excess of ammonium chloride is present. G. C. J.

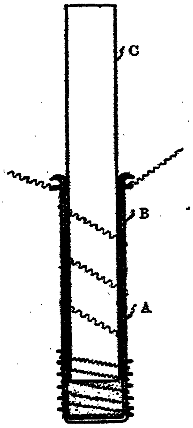
APPARATUS, ETC.

Estimation of the Concentration of Colloidal Solutions with the New Interferometer for Liquids. R. Marc. (*Chem. Zeit.*, 1912, **36**, 537.)—The interferometer described by F. Löwe (*Phys. Zeitsch.*, 1910, **11**, 1047) was sensitive with true solutions to 0·003 per cent., with a 4-cm. cell; it is found to be nearly as sensitive with solutions of dextrin, albumin, and other colloids. The ageing of such solutions on standing was almost without effect on the concentration as determined by the instrument. For small ranges the concentration was found to be nearly enough proportional to the readings to render a calibration curve unnecessary. With colloidal solutions the difficulty of matching the right pairs of lines is increased, and methods for overcoming this are given. As an example of the application of the instrument to concentration determinations in colloidal solutions, adsorption experiments (albumin and dextrin by barium carbonate) are described. The method may be extended to the examination of water: at the waterworks, by examining before and after filtering; for potable waters, before and after shaking with a substance capable of adsorbing colloids, but not affecting substances in true solution. The method is not usually applicable to dyes. O. E. M.

New Apparatus for the Coking Test of Coal. R. Lessing. (*J. Soc. Chem. Ind.*, 1912, 31, 465-467.)—This apparatus is devised to show, more markedly than the usual "crucible method" can, the difference in the coke produced from various coals. The apparatus is also useful for quantitative determinations of the volatile matter, in which respect it gives, generally speaking, results similar to those obtained by the old method. The sources of error of the crucible test are stated to be—

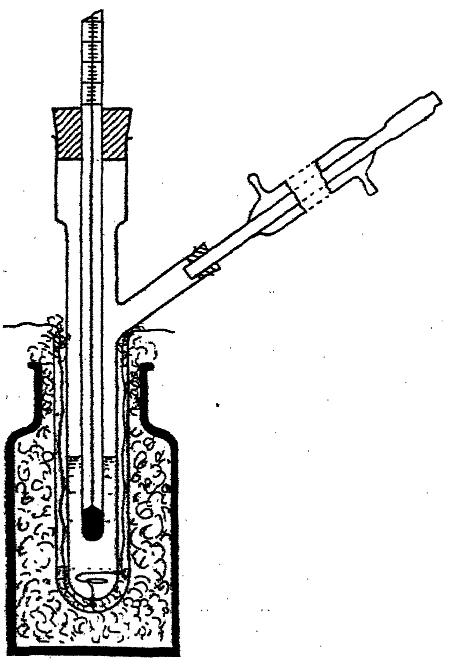
1. *Factors tending to Increase the "Volatile" Value.*—(*a*) Burning of coke in the more or less oxidising atmosphere; (*b*) "spitting" of coal-dust due to the explosive character of gasification of some coals, or rush of currents produced by the flame.

2. *Factors tending to Decrease the "Volatile" Value.*—(*a*) Insufficient coking of the coal; (*b*) secondary catalytic decomposition of volatile products on the walls of the crucible; (*c*) decomposition of volatile products by radiation in the waste space of the crucible; (*d*) deposition of carbon during coking by too rapid primary decomposition of volatile coal substance.



These factors are at work concurrently, and may compensate each other, but their presence explains the difficulty of obtaining agreement under slightly altered working conditions. In order to avoid the drawbacks due to the waste space above the coal, and to the excessive amount of heated surface in contact with the gas and vapours in the crucible test, the author uses a cylindrical vessel, as shown in the figure. *A* is the heating-tube of quartz glass, round which an electric resistance coil of platinum wire is wound. A number of quartz pin-points are fused on this tube to keep the turns of the coil apart. To concentrate the heat where required, the wire is first wound to a coil about 3 mm. in diameter, and this coil is then wound round the heating-tube. The reacting vessel *B* is a flanged quartz tube about 10 mm. in internal diameter, fitting loosely into the heating-tube. (Platinum tubes may be used instead of quartz tubes.) One grm. of the powdered sample of coal is placed in this tube *B*, and a third quartz tube *C*, fitting closely into the reacting chamber *B*, is placed on top of the coal before the commencement of the test. The pressure on the coal may be altered if desired by filling the piston-tube *C* with varying quantities of quartz powder. The outer tube *A* is permanently fixed in an insulating material, such as kieselguhr. Suitable resistance is provided according to the voltage of the supply current, and a rheostat is combined with the furnace itself, so that the temperature can be controlled. When the current is turned on, the different stages of carbonisation can be observed as the temperature rises; moisture goes off quickly, as a rule, some of the occluded gases follow, and, shortly after this, tarry vapours are evolved, increasing in volume according to the coal used for the test, and, finally, the heavier tars and pitchy matter make their appearance, the latter condensing on the cool parts of tube *C*. The test takes from five to seven minutes, and the tubes are then allowed to cool, when the tar at the mouth of *B* may be burnt off without interfering with the coke. The apparatus brings out the peculiarities of cokes from coals, although in the crucible test little or no difference is to be seen. The same kind of coal also gives the same characteristic coke. The paper is illustrated with photographs showing the appearance of the cokes produced by coals in this apparatus, together with their analytical figures. A. R. T.

Modification of the Beckmann Apparatus. E. Knecht and J. P. Batey. (*J. Chem. Soc.*, 1912, **103**, 1189-1193.)—For the determination of the boiling-points of aqueous solutions of certain sparingly soluble dyestuffs, the ordinary types of Beckmann apparatus failed to give satisfactory results owing to superheating effects caused by cohesion of the liquid on the glass walls of the vessel. The authors were therefore led to devise a method of electrical heating by means of a platinum wire in direct contact with the solution. The apparatus (see figure) consists of a tube with a platinum heating coil inside, and somewhat thicker wires fused through the glass for making the connections. When in use the apparatus is supported in an outer cylindrical glass jacket placed in a wide-mouthed bottle, packed at the bottom and round the neck with cotton-wool. With this arrangement the boiling-point of the liquid was found to remain constant to 0·001° C. In employing this method precautions must be taken to avoid any appreciable electrolytic action. The electrolytic effect will depend on the drop in potential across the heating-coil, and when this is reduced below a certain point no electrolysis should take place. In the above apparatus the resistance of the heating-coil at 100° C. was 0·47 ohm; the current used was 6·5 ampères, hence the drop in potential was only 3 volts. In another apparatus the coil had a resistance of only 0·32 ohm. With a current of 7·5 ampères, the drop in potential was 2·2 volts. With a 10 per cent. solution of potassium chloride in this apparatus, no chlorate was formed after boiling for half an hour, and the electrolysis of potassium iodide was very small. Measurements of molecular elevations of boiling-point made in this apparatus were in satisfactory agreement with published results. The authors found the molecular weight of tannic acid in aqueous solution to be between 3000 and 4000. Results have also been obtained for various dyestuffs, including benzopurpurine and indigo white. With the electrical heating constant readings are readily obtained without special precautions.



J. P. B.

Drying Oven. J. H. Coste. (*J. Soc. Chem. Ind.*, 1912, 31, 471.)—This oven can be maintained at a constant temperature, and throughout its area a stream of hot air, or other gas of the desired temperature circulates. As shown in the figure, a horizontal cylindrical copper vessel, *a*, contains a suitable quantity of a pure liquid, the boiling-point of which is near that of the temperature required. This vessel is heated by a series of gas-jets, and the vapour is condensed at *b*, and returned. The muffle-shaped drying-chamber, *cc*, is surrounded by the boiling liquid, or its vapour, with the exception of about one-thirtieth of its external surface (the door). Air which has passed through a flattened tube, *dd*, lying under, but not in contact with, the drying-chamber, enters it at the bottom of the end in the vapour, and leaves through a slit, communicating with the chimney *f*, in the door which is fixed tightly against the end of the chamber by means of steam rubber jointing and a screwed hinging bar against the end of the oven. The area of the drying chamber is small, relative to that of the total heated surface. If desired, the air may be dried before it enters the pre-heater at *h*, or other gases may be used. The drying-chamber will hold six watch-glasses or flat weighing-bottles placed on a copper tray, allowing several determinations of water to be simultaneously carried out, and the substances to be dried rapidly attain a temperature within 1° of that of the vapour. A. R. T.

REVIEWS.

Allen's Commercial Organic Analysis. Vol. V.: Tannins and the Analysis of Leather. By W. P. Dreaper. 1911. London: J. and A. Churchill. Price 21s. net.

Remembering the painstaking work which distinguished the first edition of this well-known book, the perusal of the sections on Tannins and Leather Analysis has been one of disappointment to the writer. The author has failed to render himself familiar with much recent work, and as a compilation, the chapters must be pronounced uncritical and in places unreliable, and containing much obsolete and useless matter. In several cases work is incorrectly described, and in more than one is attributed to the wrong author.

Such charges are not to be made lightly; and, at the risk of being tedious, they must be supported by detailed instances. On the very first page the tannins as a class are characterised as "notably soluble in ethyl acetate." In fact, their solubility in this reagent is very varied, and in some cases almost nil, and this peculiarity has been used by Stiasny in the separation of different members of the group. Tannins are spoken of as "powerful reducing agents," "especially in alkaline solution," while it is only under the last condition that they show any marked affinity for oxygen. On p. 7 gallotannic acid is mentioned as a glucoside, which is contrary to the modern view. Sumach-tannin is described as "possibly identical with gallotannic acid," while Strauss and Schwendner have shown that this is not the case. Hemlock-tannin is stated to contain phloroglucol, which is incorrect. The tannin of horse-chestnut bark is spoken of as "chestnut tannin," which is misleading, since the very important chestnut extract of commerce is made from the wood of the true Spanish chestnut, *castanea vesca*, which is not even mentioned in the table. The same remark is also to some extent true of "ulmo-tannic acid," since the "ulmo" bark of South America, which is now much used in tanning extract manufacture, is probably not a true *ulmus*.

On p. 8 the Stiasny formaldehyde test for catechol tannins is incorrectly given, and completely misunderstood. The Seyda test with gold chloride on the following page is merely the formation of colloidal gold, and the reaction is produced by any feeble reducing agent. On p. 14 the phloroglucol test with deal-shaving is stated in a note to be given also by catechol. Procter ("Lab. Book," p. 152) has shown that this is an error, though a blue violet is given by resorcinol, which is often present in commercial catechol; and this correction is quoted by the author himself on p. 54 without remark!

Schiff's reputed syntheses of digallic acid, both with phosphorous oxychloride and with arsenic acid, are now generally discredited, as it has been found impossible to free the product from the reagents without reconverting it into gallic acid. Hunt's attempted synthesis with monobromo-proto-catechuic acid and potassium gallate (which is mentioned on p. 17 without the name of its author) has never been successfully repeated, though tried by Schiff, and is now assumed to have been an error. The formula for ellagic acid, which on pp. 19 and 23 is attributed to Nierenstein, was proposed long ago by Graebe, and proved by Kostanecky, Perkin, Herzig, and others. On pp. 29 and 30 all the information as to the chemistry of catechins is more or less obsolete; the work of A. G. Perkin is not quoted, and the constitution according to Kostanecky is not given, though this is one of the few formulæ in the chemistry of the tannins which deserves credit.

On p. 31 chestnut wood extract is said to contain 14 to 20 per cent. of tannin, though 30 per cent. is nearer the modern standard, and this criticism applies to nearly all the tabular information given on the strength of tanning materials, the analyses quoted being mostly by obsolete methods giving far too low results. In fact, the information on tanning materials, occupying pp. 31 to 55, is very sketchy and incomplete; for instance, oak-wood extract, which is now one of the most important materials, is mentioned only in a table of 1883 attributed to Simand, which gives the total tannin as 14·47, and the part of this soluble in cold water as 15·09! On pp. 42 and 43 qualitative tables attributed to Procter are really due to

Andreasch, and no mention is made of the fact that they are only applicable to alcoholic solutions, though the original source is referred to on p. 55 with apparently no idea that the tables are identical with those given. No mention is made of the frequent use of extract of mangrove bark as adulterant of quebracho, nor of methods for its detection.

The modern quantitative methods are correctly given, mostly in the words of the official prescriptions of the I.A.L.T.C. and the A.L.C.A., but are not critically discussed; and a good deal of space is occupied by the description of antiquated processes, most of which are known to give incorrect or unreliable results.

In the section on the analysis of leather the von Schroeder method of glucose estimation is very briefly described, but the necessary glucose table is omitted both there and in the section on glucose estimation in tanning materials, and in place of it a single factor is given. No mention is made of the ordinary volumetric method, which, if carried out with proper precautions, gives results of considerable accuracy, and is very useful as a rapid process of preliminary investigation, and will usually decide whether or not artificial loading has taken place. Sucrose is now sometimes used in place of glucose, and, of course, is not estimated by either process without previous inversion. No mention is made of Fahrion's method of determining a tannage value by boiling with water, and in the formula for calculating hide-substance from the Kjeldahl determination of nitrogen, + is written instead of ×. Further remarks seem unnecessary. HENRY R. PROCTER.

DYES AND COLOURING MATTERS, DYESTUFFS OF GROUPS 6 TO 12, COLOURING MATTERS OF NATURAL ORIGIN AND ANALYSIS OF COLOURING MATERIALS. By J. T. HEWITT.

A very valuable feature of this fourth edition of Allen's well-known treatise is that the analytical examination of the various organic products under consideration is preceded by thoroughly up-to-date descriptions of the systematic chemistry of these materials, each section being dealt with by competent experts. In the chapter on dyes and colouring matters a brief résumé is given of the modern development of artificial colouring matters and of the relations of dyes to the textile fibres. A consideration of the nitro-, nitroso-, and *iso*nitroso-colouring matters is included in this section, which also deals very fully with the important azo-dyes. Very comprehensive tables are given, showing the mode of formation and the specific reactions of the azo-dyes. In some instances, however, the abbreviations employed have almost ceased to be intelligible. For example, Fast Acid Scarlet $(4)SO_3Na.C_{10}H_6.N_2(6).C_{10}H_6.OH$ is said to be obtained from beta-acid, and Acid Ponceau from α and γ naphthylamines (*sic*). There are also a few orthographical errors, such as "unsoluble," "phenatidine," and "dinitrosoresorcnol."

The remaining synthetic dyes are arranged in seven groups (groups 6 to 12 inclusive), a separate section being devoted to indigo.

The prevailing views on the constitution of the di- and tri-phenylmethane colouring matters are critically examined and the properties of the principal commercial dyes of these series are arranged in tabular form. The azine, oxazine, quinoline, and acridine dyes are similarly treated.

Indigo is classified under colouring matters of natural origin, and, possibly on this account, very little space is devoted to the important subject of synthetic indigo. The estimation of indigotin is, however, dealt with in greater detail, especially as regards the oxidation and reduction tests, reference being made to such modern developments as the production of indigotintetrasulphonic acid and the reduction of sulphonated indigotin with titanous chloride. A survey of such natural dyestuffs as logwood, fustic, turmeric, cochineal and the red woods is followed by a chapter on the analysis of colouring materials, giving methods for the examination of commercial colouring matters and their detection of the dyed fibres. The detailed information contained in a very concise form in this section of the treatise should prove of the greatest service to analysts called upon to examine fabrics dyed with the colouring matters employed in modern practice. G. T. MORGAN.

FOODS: THEIR ORIGIN, COMPOSITION, AND MANUFACTURE. By WILLIAM TIBBLES, M.D., LL.D., etc. London: Baillière, Tindall and Cox. 1912. Price 18s. net.

This work is a veritable encylopædia of foods, and of substances used in the preparation of food. It would, indeed, be difficult to mention any food material, from the most important and necessary to the most trivial condiment or colouring matter, which does not here find a place and adequate description.

The hard-worked scientific man must always feel a sense of gratitude towards his more leisured confrère, when that leisure is employed in the collection and compilation of the widespread information which to-day forms so important an adjunct to the analytical armoury.

In order that such a work should fulfil a really helpful and useful purpose, it is necessary that the author should possess sufficient scientific insight to enable him to judge of the value of the different sources of information at his disposal and sufficient discrimination to sift them adequately. When these dicta are applied to the work under review, one is compelled to admit that they are fulfilled.

The selection of authorities is excellent, and the "drawing from opposing authorities the pith of their knowledge," described in the preface by the author as "a source of delight," has, in nearly all cases, been happily carried out.

It is almost unnecessary to say that no man can be an authority on all branches of the widely diverse subjects here presented, nor does it seem that the author makes any special claim to have any special knowledge of any one of them. It is, therefore, inevitable that the expert in any of these subjects may have cause to find fault with some of the statements, etc., made, particularly if his pet theories happen to be omitted, or inadequately mentioned. In actual fact there are numerous errors, but these do not militate against the intrinsic value of the work. The author is happiest in those sections which deal with processes which are not closely interwoven with trade secrets and methods, for which one will look in vain in this, as in any other book; but in the general composition of the final products, and in trade descriptions of these products, there is much sure ground.

One notes with pleasure the great use which has been made of the invaluable bulletins of the U.S. Department of Agriculture, and the large collection of these will be useful to many. It would be quite impossible to deal with the various chapters one by one, as the before-mentioned diversity of subject-matter precludes personal criticism as much as it precludes comprehensive expert treatment in its composition.

Part I. deals with the "chemical constitution of foods and the classification and character of their proximate principles." The matter dealing with this intricate subject is well put together, and displays knowledge of the latest work, though some references to the conclusions of older investigators might well have been omitted in view of more recent findings. The chemical presentation is somewhat crude in expression in many cases and this is true of the work as a whole, though there is never any real doubt as to the meaning intended. There are some curious and oft repeated errors which are difficult to understand, such as the description of "cholesterin" as a nitrogenous fat, though in its proper place it is correctly described. "Protagon" is also spoken of as a separate entity. The carbohydrates are fully dealt with, and the section has been compiled from reliable sources.

In the chapters on the Mammalia, Pisces, and Aves, the author is probably at his best, as the scientific descriptions and classification are from excellent authorities, and are presented in a concise and thorough manner, with full details as to distribution on the earth's surface, and to the use made of them as food. There is also a useful chapter on meat inspection and regulations, and on the composition of meat as eaten and its digestibility. The properties of meat extracts, soups, etc., are given, and from the remarks appended there is evidently considerable personal knowledge of these aliments.

The care which the author has expended in the sifting of available data is nowhere better seen than in the sections dealing with such debatable matters as milk and milk products. In addition to the general consideration of the subject, he has succeeded in disentangling from the masses of conflicting evidence which have gathered round such points as the influences which affect the composition of milk, the effect of feeding, period of lactation, etc., the more vital and probably correct conclusions. One notices, however, with a slight feeling of amusement, the list of constituents of milk which is given, and which, if all had to be determined, would render the analysis a rather titanic task, very different from the usual "total solids and fat" beyond which few analysts appear to venture.

The bacteriology of milk-souring is, on the other hand, very inadequately described, and the latest work is not mentioned.

Under milk preparations, cheese, both in its aspects of manufacture and subsequent ripening, is adequately dealt with, and nearly every milk preparation known finds notice, and, in general, correctly, except in the case of condensed milk, for which only one or two quite out-of-date methods are referred to.

The chapters on Cereals, Vegetables, and Fruits are excellent and most complete, the botanical descriptions being quite reliable. Full details are given of the preservation of fruit, and it is to be wished that the description of "jam" manufacture was applicable to more of our jams than it can possibly be. The Public Analyst will be fully in accord with the author in his remarks under "What is jam?" A comprehensive list of colouring matters is appended, and it is noticeable that some common errors in regard to these are avoided.

Even in such a difficult subject as that of oils, the information is reliable and trustworthy, though some of the processes stated to be used are somewhat obsolete. A few of the trade descriptions in this section are not quite correct, such as the information that "nucoline" is palm-kernel oil.

The other chapters which deal with tea, coffee, chocolate, spices, condiments, sugar, honey, confectionery, wines, spirits, and malt liquors may be passed over without comment.

The only serious mistake that the author has made is the inclusion of analytical methods, as in nearly all cases these are hopelessly impossible or badly described. As they are quite out of place, it would have been much better if they had been omitted. In spite of the condensed nature of the book, the matter is always in most readable form, and the proof-reading, with a few exceptions, carefully done.

There is not the least doubt that this work would be of much assistance to the general analyst as a concise book of reference. C. REVIS.

VOLUMETRIC ANALYSIS FOR STUDENTS OF PHARMACEUTICAL AND GENERAL CHEMISTRY. By C. H. HAMPSHIRE, B.Sc., A.I.C. Pp. vi + 104. London: J. and A. Churchill. 1912. Price 3s. 6d. net.

As its title indicates, this book is not intended for the use of analysts, but for the instruction of students, particularly pharmaceutical students, and it must be judged accordingly. For example, anyone who attempted to use this book as a book of reference, and followed the directions given on p. 98 for the analysis of a mixture of boric acid and borax, would soon find himself in difficulties, unless he already knew all that this book has to teach. But the student who has steadily worked through the book up to this point would be in no difficulty, for in earlier pages the principles underlying mixed titration are clearly explained. The whole book is a model of lucidity, and one can only regret that the author did not suppress some redundant paragraphs, such as the titration of sodium bicarbonate after that of potassium carbonate had been described, and so have found room for a short description of methods of standardising apparatus. Criticism on many points which at first sight seem to invite criticism, is silenced by the reflection that the author's students are mainly concerned to determine whether certain drugs comply with the requirements of a Pharmacopœia which, in addition to other demerits, is fourteen years old. There are very few misprints, but presumably the direction on p. 23 to determine the strength of lime-water by titrating 25 c.c. with "normal" acid must be reckoned as one, and one would like to believe that the word "better" on p. 6, line 4, was a misprint for "necessary." The former is scarcely a strong enough word with which to back a recommendation to make use of a desiccator for cooling ignited sodium carbonate, which is to be the ultimate standard in all the acidimetric and alkalimetric work which is to follow. G. CECIL JONES.

SEPTEMBER, 1912 Vol. XXXVII., No. 438.

THE ANALYST.

OBITUARY.

BENJAMIN EDWARD REINA NEWLANDS.

Benjamin Edward Reina Newlands, youngest son of the Rev. William Newlands, was born in Southwark on January 23, 1842. On his mother's side he was of Italian descent. Both he and his brother John received their early education at home with their father, and subsequently at St. Saviour's Grammar School. The brothers studied chemistry under Professor A. W. Hofmann, and at an early age started an analytical practice in Great St. Helen's, London. Benjamin became assistant to Professor C. W. Heaton at Charing Cross Hospital, in 1862, and to Professor Way, of the Royal Agricultural Society, in 1863. His bent was always, however, towards technology, and at the end of 1863 he was appointed chemist to Messrs. James Gibbs and Co., manure makers, Victoria Docks, and from 1869 to 1873 he was manager at these works. In the latter year, he was made manager of Mr. James Duncan's Sugar Refinery, Clyde Wharf, Victoria Docks. This refinery was contiguous to Messrs. Gibbs's works, and while at the latter Newlands had had the *entrée*, and from time to time had given Mr. Duncan advice. He remained as manager, with his brother John as chemist, until the refinery, then the largest in the United Kingdom, closed in 1887, when the brothers once more embarked upon a professional career as analytical and consulting chemists at 27, Mincing Lane, London, and subsequently at 2, St. Dunstan's Hill, London. Well known as they were in the sugar trade, the brothers Newlands soon built up a good practice, mostly connected with sugar technology. Their consulting work was not confined to this country, their services being retained in India and the Colonies. A new edition of their treatise on "Sugar" has just been published. After the death of John Newlands in 1898, the writer was in partnership with Benjamin for five years. Benjamin Newlands was a Fellow of the Institute of Chemistry of Great Britain and Ireland, and had served on its Council and as a Vice-President. He was also a Fellow of the Chemical Society, and a member of our own Society. Of all scientific societies, he cared most for the Society of Chemical Industry, of which he was an original member, and served from the first on its Publication Committee, and, with a few intervals, on its Council. He was several times elected a Vice-President of the Society of Chemical Industry, and was Chairman of the London Section from 1895-96. He will be remembered by his professional brethren, not only by his wide practical knowledge, but no less by his sound common-sense, which was tempered by a characteristic geniality of manner. His fund of humour was wellnigh inexhaustible, and earned for him the reputation of the best *raconteur* in chemical circles. He died at his residence at Hayling Island on August 7.

Arthur R. Ling.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE ESTIMATION OF CARBON IN STEEL.

By A. G. LEVY, B.Sc., F.I.C.

THE direct combustion method for determining carbon in steel is now used so largely —many analysts using this method to the exclusion of all others, except for checking purposes—that it may not be amiss to point out one source of error hitherto apparently overlooked.

Whenever the direct process has been compared with the solution methods, it has been noticed that, except in cases where combustion appears to have been not quite complete, there is a tendency to slightly high results. Thus, many of the values quoted by Blount and Levy (ANALYST, 1909, **34**, 94) show a small excess over those obtained by the solution method. In the discussion on this paper, L. Archbutt (*ibid.*, p. 97) mentioned this tendency; and, more recently, Helen Isham (*J. Ind. and Eng. Chem.*, 1911, 3, 577) states that the values given by the direct method are usually 0·007 per cent. higher than those obtained by the use of the solution method. She also shows that there is no loss of carbonaceous gases during the dissolution of the steel in acidified potassium cupric chloride solution at *ordinary temperatures*.

It is obvious that if the sample of steel contains *dissolved carbonaceous gases*, such as carbon monoxide and dioxide, their carbon content will be included in its entirety in the values given by the direct combustion method; whilst it seems almost equally certain that it will not affect the solution process, since, even if the gases liberated are not expelled from the solution, they will pass with this into the filtrate from the insoluble carbonaceous residue, and leave the latter free from all but a possible trace of the double compound of cuprous chloride and carbon monoxide.

At first sight one might think that the quantities of gases involved are too small to affect the carbon determination. During the last few years, however, a good deal of work has been done on the amount and composition of the gases dissolved in steel, and it appears that errors of up to 0·02 per cent., or even more, may easily be due to this source. For the present purpose, by far the most valuable is a paper by E. Goutal (*Rev. Métallurgie*, Mémoires, 1910, vol. vii., p. 8). Goutal's method consisted in dissolving the sample in carefully boiled out acid potassium cupric chloride solution in a current of nitrogen, finally raising the solution to the boiling-point, and determining carbon monoxide, carbon dioxide, and sometimes other gases, in the gases evolved, and carbon in the residue. Proceeding in this way, he obtained the following results:

	CO_2. Per Cent.	CO. Per Cent.	C in Residue. Per Cent.	C (corresponding to Carbonaceous Gases). Per Cent.
Soft steel	0·0254	0·0063	0·160	0·0096
Medium steel	0·0210	0·0120	0·295	0·0108
Hard steel	0·0678	0·0137	0·596	0·0244
Extra hard steel	0·0792	0·0142	1·334	0·0277
Nickel steel (Ni, 2·04 per cent.)	0·0530	0·0060	0·340	0·0170
Chrome steel (Cr, 5·10 per cent.)	0·0510	0·0115	0·360	0·0188
Basic open hearth iron ...	0·1890	0·0132	4·110	0·0571

The values in the last column are not given by Goutal.

He also shows that, if the solution contains not more than 10 per cent. of HCl, and the temperature is not raised above 45° C., the CO_2 remains wholly in the liquid, whilst the CO is partly disengaged. Thus, working with 10 grms. of a steel containing 0·95 per cent. carbon, he found:

	CO_2. Per Cent.	CO. Per Cent.	C (corresponding to Carbonaceous Gases). Per Cent.
During dissolution	0·0000	0·0068	0·0029
In filtrate (on boiling) ...	0·0075	0·0070	0·0050
In residue (boiled with very dilute HCl)	0·0751	0·0015	0·0211
Total	0·0826	0·0153	0·0290
Check by first method ...	0·0829	0·0153	—

The carbon dioxide here found to remain with the residue would probably be largely, if not wholly, expelled during the drying usual before burning the residue, and hence would be lost in the solution method.

In another series of experiments he obtained the following values:

	Medium Steel. Per Cent.	Hard Steel. Per Cent.	Extra Hard Steel. Per Cent.

C in cases not identified ...	0·0009	0·0171	0·0158
C total	0·3067	0·6375	1·3775

As far as my reading goes, Goutal is the only author who mentions the influence of the dissolved gases on the two methods of estimating carbon. Thus, on p. 13 (*op. cit.*) he states quite incidentally that he prefers his own method of determining carbon (to the direct combustion method), because it enables one to distinguish between two forms of carbon (that in the residue and that evolved as gas), which influence the properties of the steel in quite different ways. This general silence is all the more striking when one reflects that the same consideration applies to all the numerous *wet* methods of combustion.

Further proof of the existence of appreciable quantities of dissolved carbonaceous gases in steel and iron is found in several other papers by different authors, all of whom determined the gases evolved on heating the samples *in vacuo*. A number of recent determinations are collected in the table following, in which I have calculated in the last column the percentage of carbon corresponding to the carbonaceous gases evolved:

Reference.	Nature of Sample.	C.	Weight of Sample	Gases evolved on Heating *in vacuo*.							Corresponding to Carbonaceous Gases.
				Total.	CO_2.	CO.	H.	N.	CH_4.	Not determined.

With the exception of the two results due to Baker, all the determinations were carried out on planings or thin wire and foil. Hence, gas evolved from large blowholes is excluded, and the results apply directly to samples as usually taken for direct combustion. It will be seen that plus errors of 0·03 per cent. carbon, due to this source alone, are easily possible, even if four higher values (up to 0·08) are rejected as abnormal. Incidentally, the presence of small quantities of hydrogen in the metals supplies a reason for the insertion of a drying tube between combustion tube and potash bulbs, which precaution is occasionally omitted. Regarding the accuracy of the determinations quoted, it may be mentioned that Baker found a small furnace blank of about 3 c.c. total gas, consisting largely of hydrogen and nitrogen, due probably to the walls of the heated porcelain tubes not being perfectly impervious to gases at high temperatures under the high *vacua* used.

Finally, to sum up, when working to a close carbon specification, it may not be a matter of indifference to the maker of the steel whether the analyst uses a solution or a direct combustion method.

THE BACTERIOLOGY OF AERATED WATER.

By G. D. ELSDON, B.Sc., A.I.C., and NORMAN EVERS, B.Sc., A.I.C.

During the past few years attention has been drawn to the bacteriological examination of commercial soda-water, and a number of results have been published by Public Analysts and others—*e.g.*, Klein, Report of the Medical Officer of Health for the City of London (Analyst, 1911, 36, 16). Thirty-seven samples of commercial soda-water have recently been completely analysed in this laboratory, with the following bacteriological results: In no case has typical *B. coli* (flagniac) been found in 50 c.c. In two cases fermentation was obtained in glucose taurocholate with 50 c.c., in two cases with 10 c.c., and in 1 case with 1 c.c.; but in all these cases further examination showed that these were not typical *B. coli*. The number of organisms growing on jelly in three days, found in twenty-five samples stored in siphons, varied from 1 to 150 per c.c.; whilst the number found in waters stored in bottles, all precautions being taken to prevent the access of bacteria during opening, was found to be in some cases 1,000 to 3,000 per c.c.

It seemed desirable to find out how far these bacteriological results, obtained in many cases probably several days (and possibly weeks) after bottling, are of value as an indication of the purity or otherwise of the original water, for it seemed probable that the presence of carbon dioxide under pressure would have a deleterious action on the micro-organisms present in the water. For the purpose of carrying out these experiments, the apparatus known as the "Prana Sparklet" siphon was used. The siphons were thoroughly cleaned and steamed for one hour, with careful heating and cooling to prevent breakages, on each of two successive days, the siphon-head being plugged with wool. The water to be experimented upon was then run in by means of a sterile funnel, and carbonated in the usual manner. Small quantities were withdrawn from the siphon from time to time for the purpose of bacteriological examination, estimations being also carried out on the water itself as a control.

Such experiments were carried out on—(1) the number of organisms growing on jelly at 21° C., counting after three days; (2) the number of organisms growing on neutral-red lactose taurocholate agar (Rebipel agar) at 37° C., counting after two days; and (3) the power of fermenting glucose taurocholate broth.

1. *The Number of Organisms growing on Jelly at 21° C.*—Various samples of water were taken and aerated as described above, and the number of organisms per c.c. growing on jelly at 21° C. estimated after various lengths of time in both the carbonated and uncarbonated water. The results obtained are given in the following table:

TABLE I.

Source of Water.	Number of Bacteria growing on Jelly in Three Days at 21° C.				
	Original Water.	After Three Days.		After Seven Days.	
		Control.	Carbonated.	Control.	Carbonated.
Filtered river	950	910	125	867	93
Filtered upland surface... ...	19	845	15	4,200	1
Unfiltered upland surface ...	391	Liq.	3	5,500	1
,, ,, ,, ...	3,400	7,300	53	7,400	44
,, ,, ,, ...	290	2,650	63	1,700	51
,, ,, ,, ...	10,000	36,800	397	33,900	142
Deep well	Liq.	240,000	950	—	—

These results, obtained from different types of water, show that the total number of organisms is rapidly reduced by carbonation, and in well-filtered waters, where the number of organisms is small originally, carbonation prevents these organisms from multiplying. In the case of the polluted water, it will be observed that the number of organisms was very rapidly reduced.

2. *Number of Bacteria growing on Rebipel Agar at 37° C. in Two Days.*—Sterile tap-water was in two cases inoculated with a small number of *B. coli* (flaginac) grown in peptone water for two days. Part of the water was aerated, and the effect of aeration observed as before.

TABLE II.

Original Water.	After Three Days.		After Seven Days.		After Fourteen Days.	
	Control.	Carbonated.	Control.	Carbonated.	Control.	Carbonated.
63	62	58	57	25	46	5
7,000	—	—	6,200	38	6,100	5

Experiments were then undertaken on the number of organisms growing on Rebipel agar which are naturally present in waters. The method used was similar to the one used under Section I. The results were as follows:

TABLE III.

Source of Water.	Number of Bacteria growing on Rebipel Agar at 37° C.				
	Original Water.	After Three Days.		After Seven Days.	
		Control.	Carbonated.	Control.	Carbonated.
Deep well water	275	1,820	66	—	—
" " "	108	44	19	8	7
River water	347	714	23	905	2

3. *Effect of the Addition of Sodium Bicarbonate on the Fermentation of Taurocholate.*—Fifty c.c. of sterile carbonated water were added to taurocholate, and then inoculated with a little cultivated *B. coli* (flaginac) and incubated at 37° C. After twenty-four hours a vigorous acid and gas production was observed.

Fifty c.c. of sterile carbonated water containing 10 grains per pint of sodium bicarbonate were added to taurocholate and inoculated as above. After twenty-four hours a vigorous growth was observed.

Fifty c.c. of a well-water known to contain *B. coli* were taken, and sufficient sodium bicarbonate added to make the alkalinity equal to 10 grains per pint. The water was then added to taurocholate, and after incubating at 37° C. for twenty-four hours, a similar growth was obtained to that given by the original water.

Fifty c.c. of carbonated water containing sodium bicarbonate equal to about 5 grains per pint were put into taurocholate; after twenty-four hours a vigorous growth was observed.

These results show that the growth of bacteria in glucose taurocholate is prevented neither by an alkalinity of 10 grains per pint of sodium bicarbonate, nor by carbonation, nor by both together.

4. *Organisms producing Acid and Gas in Glucose Taurocholate.*—The results given below were obtained by growing natural waters in glucose taurocholate with and without carbonation. In the table, (*a*) signifies the carbonated water, whilst (*b*) signifies the uncarbonated or control water.

TABLE IV.

Well Water A.

		50 c.c.	10 c.c.	1·0 c.c.	0·1 c.c.
Original		+	+	+	−
After four days	(*a*)	+	+	−	−
	(*b*)	+	+	−	−
After seven days	(*a*)	+	−		
	(*b*)	+	−		

Well Water B.

		50 c.c.	10 c.c.	1·0 c.c.	0·1 c.c.
Original		+	+	+	
After four days	(a)		+	+	
	(b)		+	+	
After seven days ...	(a)	+	+	+	
	(b)	+	+	+	
After twelve days	(a)				
	(b)		+		

Well Water C.

		50 c.c.	10 c.c	1·0 c.c.	0·1 c.c.
Original		+	+	+	+
After four days	(a)		+	+	+
	(b)		+	+	+
After seven days	(a)		+	+	+
	(b)		+	+	+
After twelve days	(a)		+	+	+
	(b)		+	+	+

It will be seen that except in the case of the well water B the carbonation did not sensibly affect the organisms fermenting glucose taurocholate in the time given.

Conclusions.—The general conclusions to be drawn from these experiments seem to be the following:

(*a*) The total number of organisms growing on jelly at 21° C. is considerably reduced by carbonation, and a water containing originally a large number of organisms may, after a week's standing under pressure, contain only a number such as would be found in a very good water.

(*b*) *B. coli* are not so rapidly reduced as other organisms, but die off rather more rapidly than in ordinary water.

(*c*) The number of organisms growing on Rebipel agar are much reduced by carbonation, especially those which do not produce the typical *B. coli* red appearance. This latter fact was shown by the appearance of the plates after incubation.

(*d*) Ten grains per pint of sodium bicarbonate does not affect the growth of organisms in glucose taurocholate; neither does excess of carbon dioxide, such as is found in carbonated waters.

It follows, therefore, that bacteriological results obtained on a water which has been carbonated for more than twenty-four hours are of little value as an indication of the source or purity of the original water, except in the case of growth in glucose taurocholate. In this latter case correct results may probably be obtained for a week after carbonation.

SOLUBILITIES OF THE LEAD SALTS OF THE HIGHER FATTY ACIDS IN ETHER AND IN PETROLEUM ETHER.*

By G. B. NEAVE, M.A., D.Sc.

Owing to the fact that the solubility of lead oleate in ether is employed in estimating the amount of oleic acid in a mixture, and the possibility that errors may arise from the solution of the lead salts of saturated acids, the latter were prepared and their solubilities in ether and petroleum ether determined.

Preparation of the Lead Salts.—The pure acid was neutralised with ammonia, and the lead salt precipitated by addition of a saturated solution of lead acetate. The lead salt was filtered, washed, and recrystallised from alcohol.

Lead caproate	m.pt.	73-74° C.	Pb found	47·23 %	Pb calculated	47·37 %
Lead heptylate	„	90·5-91·5° C.	„	44·27 %	„	44·51 %
Lead caprylate	„	83·5-84·5° C.		—		—
Lead nonylate	„	94-95° C.	„	39·68 %	„	39·73 %
Lead caprate	„	100° C.	„	37·59 %	„	37·70 %
Lead laurate	„	103-104° C.	„	34·16 %	„	34·21 %
Lead myristate	„	107° C.	„	31·34 %	„	31·32 %
Lead palmitate	„	112° C.		—		—
Lead stearate	„	125° C.		—		—

Lead Oleate.—This salt was obtained as a white powder, m.pt. 45-50° C., which is considerably lower than that quoted by Gottlieb (*Annalen*, 1845, 57, 38). Other preparations were made, but all the specimens gave approximately the same m.pt. The lead oleate thus obtained was extremely soluble in ether and in petroleum ether.

Attempts were also made to prepare the lead salts of other unsaturated acids. These, however, were very rapidly oxidised on exposure to the air.

Determination of Solubilities of the Lead Salts.—The ether employed was purified by distillation over sodium; the petroleum ether was the fraction collected from 40-60° C. The flask containing the lead salt and the solvent was placed in a thermostat maintained at a temperature of 20° C., and was fitted with a stirrer driven by a small motor. Since filtration by the ordinary method was slow and involved a loss of solvent, a special pressure-filtering apparatus was used. The flask containing the solution and excess of lead salt was closed with a cork, through which passed, in addition to the stirrer, two tubes, one terminating just below the cork, the other at the bottom. The second tube, communicating with a weighed flask, was widened at the end, on which was the filter, consisting of two layers of Swedish filter-paper, with an outer layer of thin silk. After the solution was saturated, dry air was forced into the flask, and any convenient volume collected in the weighed flask and evaporated to complete dryness. The solubilities at the boiling-points of the solvents were determined in the same manner, the first flask being attached to an efficient condenser.

---

* This work was carried out under the conditions of the Analytical Investigation Scheme.

The solubilities in the following table are expressed in grms. per 100 c.c. solution:

	Ether.		Petroleum Ether.	
	20° C.	Boiling-Point.	20° C.	Boiling-Point.
Lead caproate ...	—	1·3640	—	0·0608
Lead heptylate...	0·2397	1·4900	0·0200	0·0528
Lead caprylate...	0·0938	0·5460	practically insoluble	0·0384
Lead nonylate ...	0·1115	0·2404	practically insoluble	0·0450
Lead caprate ...	0·0290	0·4285	practically insoluble	0·0170
Lead myristate...	practically insoluble	0·0555	practically insoluble	0·0210
Lead laurate ...	practically insoluble	0·0205	practically insoluble	practically insoluble
Lead palmitate...	practically insoluble	0·0261	practically insoluble	practically insoluble
Lead stearate ...	practically insoluble	practically insoluble	practically insoluble	0·0170

It will be seen from the table that the solubilities are very small, while that of lead oleate, as stated previously, is very great.

I desire to thank Messrs. E. Anderson. A.I.C., A. P. Clark, D. Hamilton, A.I.C., and J. Porter, A.I.C., for their assistance in this work.

THE ROYAL TECHNICAL COLLEGE,
GLASGOW.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

ANALYSIS OF FOOD AND DRUGS.

Micro-Chemical Tests for the Identification of Some of the Alkaloids. E. B. Putt. (*J. Ind. and Eng. Chem.*, 1912, 4, 508-512.)—In the method described, a fragment of the alkaloid was dissolved on a microscope slide in a drop of dilute hydrochloric acid, a drop of the reagent was added, and the nature of the precipitate examined under the microscope. In many cases distinct types of crystals were formed successively by the same precipitate. Some forty different alkaloids and other substances were thus tested, and a description is given of the crystalline or amorphous precipitates obtained. The paper is illustrated with photo-micrographs.

W. P. S.

New Method of Estimating Caffeine. G. Costes. (*Ann. Chim. anal.*, 1912, **17**, 246-249.)—The method is based upon the fact that caffeine is not destroyed by three hours' heating with sulphuric acid, and after the destruction of the bulk of the accompanying organic matter, the alkaloid may be extracted from the neutralised solution with chloroform. Twenty grms. of the ground coffee (or more in the case of samples containing only about 0·1 per cent. of caffeine) are mixed little by little with 15 to 20 c.c. of pure sulphuric acid (sp. gr. 1·835), and the flask placed for ten to fifteen minutes on the water-bath at 100° C., after which the mixture is extracted with three successive portions (about 200 c.c., 150 c.c., and 100 c.c.) of boiling water, the extraction being continued about ten minutes the first time and five minutes the second and third time. After each extraction the liquid is filtered into a porcelain basin containing a little sodium hydroxide (insufficient to neutralise the whole of the acid). The united filtrates are rendered slightly alkaline with sodium carbonate, concentrated to about 200 c.c., filtered if necessary, and extracted three times with chloroform (50 c.c., 35 c.c., and 30 c.c.). The chloroform extracts are united and distilled, and the residue of caffeine purified by heating it for ten minutes with 2 c.c. of sulphuric acid on the water-bath, and adding just sufficient water to render filtration possible. The filter is washed five or six times with a little boiling water, and the filtrate and washings rendered slightly alkaline with ammonia, cooled, and extracted with three successive portions of chloroform (25 c.c., 20 c.c., and 15 c.c.). The extracts are evaporated in a tared basin on the water-bath at about 80° C., and the residue is dried for thirty minutes at 100° C. and weighed. However white the crystals appear, the residue will not contain more than about 93 per cent. of pure caffeine, and it is therefore advisable to estimate the nitrogen by Kjeldahl's method, and to calculate the corresponding amount of caffeine. For industrial purposes results in close agreement with those given by the methods of Granval and Lajoux and of Helger and Juckenack may be obtained by omitting the neutralisation of the liquid after the initial treatment with sulphuric acid and filtration, extracting the caffeine with (1) 100 c.c., (2) 100 c.c., and (3) 75 c.c. of chloroform, evaporating the extracts, and weighing the residue.

C. A. M.

Comparative Value of the Catalase, Reductase, and Leucocyte Tests in Detecting Mastitis. O. Gratz and A. Náray. (*Milchwirtschaftl. Zentralb.*, 1912, **41**, 225-232, 257-263, 289-303; through *Chem. Zentralb.*, 1912, II., 287.)—The milk of 153 individual cows was examined, re-examined after ten or twelve days, and the examination repeated several times in all doubtful cases. As a result the reductase test, whether in Barthel's original form or Schardinger's modification of it, is declared to be too uncertain to be of value. The catalase test is said to be five to ten times as sensitive as the leucocyte test, but the latter is necessary to control the results of the former in cases where the abnormal catalase number is due to blood. In such cases the blood will usually be detected by the reddish colour of the sediment in the capillary of the tube used for collecting the sediment for a leucocyte count. For the catalase test the authors use Koestler's apparatus, 10 c.c. of milk, and 5 c.c. of 1 per cent. hydrogen peroxide solution, and allow two hours at [illegible] to

24° C. They find that the test readily fixes suspicion on the mixed milk of ten to twenty cows, only one of which is suffering from mastitis. G. C. J.

Estimation of Husk in Cocoa Powders. L. Kalusky. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **23**, 654-661.)—The method proposed depends on the difference between the sp. gr. of the cell tissue of the inner portion of the cocoa bean and that of the husk. The sp. gr. of the cell tissue of the inner portion (obtained by treating the fat-free substance with diastase, and subsequently with hydrochloric acid) varies from 1·1131 to 1·3503, and is usually less than 1·25; whilst that of the husk lies between 1·4324 and 1·9337, and in the majority of cases is upwards of 1·50. The authoress found that it was possible to separate the two tissues by means of a mixture consisting of chloral hydrate, glycerol, and water, and having a sp. gr. of 1·415 at 17° C., and to estimate within narrow limits the quantity of husk which had been added to cocoa powders, when both the powder and the husk had been prepared by herself from cocoa beans. When commercial cocoa powders were examined it was found, however, that the sp. gr. of the cell tissue of the inner portion was somewhat higher than the above-mentioned figures, and it was found necessary to employ a medium having a sp. gr. of 1·5 in order to separate the two kinds of tissue. The details of the process as applied to the estimation of added husk in cocoa powder are as follows: About 5 grms. of the cocoa are extracted with ether until the fat has been removed completely. One grm. of the fat-free, dry powder is boiled for five minutes with 500 c.c. of water, then cooled to 65° C., and maintained at this temperature for one hour after the addition of a small quantity of diastase. Twenty-five c.c. of 25 per cent. hydrochloric acid are next added; the mixture is boiled for thirty minutes, when the insoluble tissue is collected on a weighed filter, washed with hot water, dried for two hours at 100° C., and weighed. The dry tissue is detached from the filter, ground as finely as possible in a mortar, again dried, and a weighed portion of it mixed in a suitable tube with 20 c.c. of the medium, and submitted to centrifugal action for five minutes. The medium is prepared by mixing 210 grms. of chloral hydrate, 50 grms. of glycerol, and 35 grms. of water, and should have a sp. gr. of 1·50 at 17° C.; if this is not the case, more chloral hydrate or water is added, as required. The portion of tissue which is at the bottom of the tube is now separated, mixed with 100 c.c. of water, collected on a filter, washed with hot water, dried, and weighed. A convenient form of tube for use in the centrifugal operation is described; it consists of a glass tube which is drawn out to a narrow point at the lower end, a small opening in this end being closed by a glass rod passing down the centre of the tube. The end of the rod is ground to fit the opening, and the sediment may be discharged from the tube by raising the rod slightly. The weight of heavy tissue thus obtained is calculated as a percentage quantity of the original cocoa, and the result is multiplied by 3 in order to give the percentage of husk present. This factor is obtained as the result of estimations of heavy tissue in samples of cocoa husk, the latter yielding on an average 30 per cent. of the tissue. When husk is absent, the whole of the tissue is found floating on the surface of the medium after the mixture has been submitted to centrifugal action. W. P. S.

Detection of Formic Acid in Fruit Products. F. L. Shannon. (*J. Ind. and Eng. Chem.*, 1912, 4, 526-528.)—The authors find that numerous substances, known to be free from formic acid, yield, when submitted to steam distillation, a distillate which reduces both silver nitrate and mercuric chloride. From none of these substances, however, could formic acid be isolated and identified as such. For the identification of formic acid the authors recommend that the acid be converted into formaldehyde by means of magnesium and dilute sulphuric acid; the acid may also be neutralised with lead hydroxide, when characteristic crystals of lead formate are obtained. In testing fruit juice or fruits, about 500 grms. of the sample are submitted to steam distillation, until the distillate ceases to give an acid reaction towards litmus (usually about 2,500 c.c. must be collected). The distillate is then neutralised, evaporated to 50 c.c., transferred to a flask provided with a long tube, to act as an air-condenser, and treated at the ordinary temperature with magnesium and sulphuric acid. The mixture is now distilled, and the first 10 c.c. of distillate tested for the presence of formaldehyde. Another portion of the sample may be distilled as before, and the distillate collected in a flask containing lead-cream (prepared by treating lead nitrate solution with potassium hydroxide until the mixture is faintly alkaline to phenolphthaleïn). The distillate is then evaporated to 50 c.c., filtered, and the filtrate set aside to crystallise. Any crystals obtained are washed with alcohol, to remove lead acetate, and then examined for formic acid by the usual tests (reducing reactions, conversion into formaldehyde, etc.). W. P. S.

Bromine Absorption of Certain Vegetable Oils and Fats. H. Sprinkmeyer and A. Diedrichs. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, 23, 679-687.)—The following percentage quantities of insoluble bromine compounds were obtained on subjecting various oils and fats to the process described by Hehner and Mitchell (ANALYST, 1898, 23, 315): Linseed oil, 28·9; candlenut oil, 8·8; hempseed oil, 8·82; walnut oil, 2·22; soja bean oil, 3·62; sesame oil, 0·14; mustard oil, 1·30; rape oil, 1·92. Poppy-seed oil, sunflower-seed oil, maize oil, cottonseed oil, castor oil, tea oil, earthnut oil, cocoanut oil, palm oil, palm-kernel oil, cacao butter, stillingia tallow, tulucuna fat, dika fat, and malukang butter, did not yield an insoluble bromine compound. In the case of shea butter, different specimens of the fat yielded from 5·2 to 8·6 per cent. of bromine compound, whilst mowrah butter gave 0·82 per cent., enkabang tallow 0·17 per cent., and adjab fat 2·2 per cent. As regards the four last-mentioned fats, the bromine compound appears to be formed from the unsaponifiable matters present, the fatty acids derived from the fats yielding no bromine compound after they have been freed from unsaponifiable matter. W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Estimation of Lactic Acid in the Presence of Proteins. J. Mondschein. (*Biochem. Zeitsch.*, 1912, 42, 105-123.)—Lactic acid is an important constituent of animal organs, but the greater part of this acid found in extracts of the organs is produced by post-mortem changes in the tissue, only a small quantity being a constituent of the living organ. Experiments carried out by the author show that when animal tissue is boiled with water only about two-thirds of the quantity of the lactic acid passes into the aqueous solution, the remaining third combining with the coagulated albumin. The following method is proposed for the estimation of the total amount of lactic acid present in an animal tissue or serum: In the case of muscular tissue, 50 grms. of the finely-divided substance are suspended in about 80 c.c. of water, the mixture is heated to boiling, and the coagulum is collected on a filter and washed with hot water until free from acidity. The filtrate is then titrated with $\frac{N}{10}$ alkali solution, using phenolphthaleïn as the indicator, and the acidity is expressed in terms of lactic acid. The coagulum is now removed from the filter, mixed in a beaker with 50 c.c. of water and 10 c.c. of a 10 per cent. sodium hydroxide solution, and the mixture is heated until fluid. One hundred c.c. of saturated sodium chloride solution are then added, the whole is again heated to boiling, and the hot mixture is saturated with sodium chloride. The precipitated proteins are collected on a filter and washed with hot saturated sodium chloride solution; the filtrate is rendered slightly acid with sulphuric acid, diluted to 500 c.c., filtered through a dry filter, and the lactic acid estimated in 250 c.c. of the filtrate by the method described by von Furth and Charnass (ANALYST, 1910, **35**, 445). The quantity of lactic acid thus found is added to that obtained by titration in the first part of the process, in order to give the total amount of the acid present in the substance under examination. Before applying von Furth and Charnass's method, it is advisable to boil the acid filtrate for ten minutes, in order to expel any hydrogen sulphide which may be present. The small quantity of protein which is precipitated on the addition of the sulphuric acid does not interfere with the estimation.

W. P. S.

Application of the Quantitative Precipitin Reaction in Honey Analysis —II. J. Thöni. (*Mitt. Lebensmitteluntersuch. u. Hyg.*, 1912, **3**, 74-94; through *Chem. Zentralbl.*, 1912, II., 151-153; *cf.* also ANALYST, 1911, **36**, 456.)—The author has studied the effect of heating the honey on the results of the precipitin reaction. Honey may be heated for various reasons—*e.g.*, for removing air-bubbles (temperature 35° C.), melting the honey out of the combs (temperature 50° C.)—and comparatively high temperatures are used in clarifying foreign crude honeys. The precipitin reaction depends on protein constituents which only begin to change at temperatures above 50° C., so that only such temperatures come into account. Experiments made at 60° to 98° C. showed that only temperatures a few degrees below 100° C. caused a diminution in the quantity of the precipitate, and then only if maintained for a certain length of time (ten to sixty minutes). Complete absence of the precipitate is only observed when the honey has been heated for longer than one hour at 100° C. At such a temperature the aroma and enzymes are destroyed, and such honey could not be regarded as normal. In the quantitative precipitin reaction the values obtained have only a relative significance, since they may vary according to the equivalent of the antiserum; only results obtained at the same time with the same serum are comparable among themselves. With a large number of samples of genuine honey of different origins no considerable differences in the variations of the precipitate values were established; these variations amounted to about ± 40 per cent. of the mean value. In the case of abnormal samples the serological method permitted an accurate identification of the honey. For the estimation of the catalase value of honey, 7·5 c.c. of honey solution (50 per cent.) were mixed with 7·5 c.c. of a 1 per cent. solution of hydrogen peroxide, and the volume of oxygen was observed after twenty-four hours. The author agrees with Witte that the catalase value alone is only of use in extreme cases as an indication of large adulteration, or incipient fermentation, or strong heating. As regards the effect of heating on the diastase value, the author considers that the original honey should be heated, not its solution, and in such cases a deficiency in diastatic activity only occurs at temperatures above 90° C., a higher limit than is found when the diluted honey is heated. For carrying out Fiehe's reaction, about 7 or 8 grms. of honey are dissolved in an equal quantity of water, extracted with ether; the clear, filtered ethereal solution is evaporated in a porcelain dish at 40° to 45° C., and the residue tested in the usual manner. Genuine honey does not give Fiehe's reaction; adulterated honey does; so that this is a reliable test for certain kinds of adulteration (*cf.* ANALYST, 1911, **36**, 456). J. F. B.

Determination of the Digestive Value of Papain. J. R. Rippetoe. (*J. Ind. and Eng. Chem.*, 1912, **4**, 517-518.)—Graber (ANALYST, 1912, 57) described a method for testing the digestive value of papain, using finely-ground steak suspended in 0·3 per cent. hydrochloric acid, and criticised the use of egg albumin in an alkaline medium. The author describes a process he has long employed for testing papain, in which 10 grms. of egg albumin is subjected to the action of 0·1 and 0·2 grm. of papain in 40 c.c. of 0·1 per cent. sodium hydroxide solution for six hours at 52° C. in a stoppered bottle, shaking every ten minutes. The whole is then washed into a graduated cylinder, made up to 70 c.c., and the volume of the deposit read at the end of one and sixteen hours. The following figures show the comparative effects of acid and alkali on the same sample of papain:

	Deposit in c.c. after standing.	
	One Hour.	Sixteen Hours.
Blank	52	43
0·1 grm. papain, 0·1 per cent. NaOH	26	18
0·2 ,, ,, 0·1 ,, ,, ...	8	8
0·2 ,, ,, 0·1 per cent. HCl	16	20
0·2 ,, ,, 0·2 ,, ,, ...	30	30
0·2 ,, ,, 0·3 ,, ,, ...	32	30

The inhibitory effect of the acid on proteolysis is clearly shown. H. F. E. H.

Laboratory Studies of Rennin. A. Zimmerman. (*J. Ind. and Eng. Chem.*, 1912, **4**, 506-508.)—Rennin precipitated with sodium chloride at 40° C. is sold in powder form mixed with lactose, and so prepared gives a much smaller yield than with sodium sulphate, but its activity is from five to six times greater. It has, when thus diluted, an activity of 1 : 30,000 or 40,000 within twelve minutes, contains more or less albumose, and is acid in reaction. Scale rennin is prepared by scaling the whole clarified rennet solution at a temperature of 43·5° C., and has a strength of 1 : 30,000 or 40,000. Scale rennin contains peptones and albumoses formed during the process of the digestion of the rennets with hydrochloric acid which it retains, having thus an acid reaction. The former product is the less permanent, this quality being apparently dependent on phosphoric acid, originally present in the rennets as the calcium salt, and set free by the hydrochloric acid when employed. The scale preparation, but not the sodium chloride product, gives the reaction of phosphoric acid, and the addition of this acid in the proportion of ·075 per cent. to new milk greatly accelerates the action of rennin. As milk gets older, rennin acts more readily. The curd in milk four to eight hours old forms very gradually, and when complete is not nearly so firm as that produced in the presence of phosphoric acid which materially reduces the time of action. Lactic acid has about one-fifth, and hydrochloric and oxalic acids one-tenth, the activity of phosphoric acid in this connection. Milk which is slightly acid curds more readily, and can be modified to require a longer time by addition of small quantities of alkali. To control the variability of milk for the assay of rennin, a standard rennin is required to show whether the milk is fast or slow. The action of the rennin is tested in not less than twelve different samples of milk. If the rennin is standardised to 1 : 30,000 in eight minutes, its use as a control with the rennin to be assayed shows whether the milk is fast or slow, and allowance is made accordingly. The rennin should be added to the milk as soon as the temperature is 40° C. Aqueous solution of rennin of sp. gr. 1·010 and containing 0·20 per cent. by volume of hydrochloric acid lost 30 per cent. of its activity in twenty-four hours at 21° C. Stronger solutions with more acid proved more permanent. The author's results point to the use of granular scale rennin and phosphoric acid in place of lactic acid in the preparation of essence of pepsin.

H. F. E. H.

Trommer's Test for Sugar in Urine. E. Salkowski. (*Zeitsch. physiol. Chem.*, 1912, 79, 164-170.)—The author agrees with the statements by Schulz (*cf.* ANALYST, 1912, 264) regarding the behaviour of urine when treated with copper sulphate and sodium hydroxide solutions, but points out that urine containing sugar behaves somewhat differently from urine free from sugar when the two are treated with copper sulphate and then rendered alkaline, and that it is still possible to detect sugar in urine by Trommer's test when the order of adding the reagents is reversed. The following manner of carrying out the test is, however, recommended: Five c.c. of a 30 per cent. sodium hydroxide solution and 8 drops of a 10 per cent. copper sulphate solution are mixed and heated to boiling; a clear blue solution is thus obtained containing a few particles of black copper oxide which do not interfere with the test. To the hot solution are now added 2 c.c. of the urine, and the mixture is again boiled. Urine containing as little as 0·2 per cent. of sugar reduces the copper much more than does urine free from sugar. The test is rendered more sensitive by allowing hydrochloric acid to flow on the surface of the hot mixture; in the presence of sugar a yellow zone of hydrated cuprous oxide is obtained.

The urine may also be clarified by means of mercuric acetate before being tested. Twenty c.c. of the sample are treated with a 20 per cent. mercuric acetate solution, this being added drop by drop as long as a precipitate is formed, but a large excess is to be avoided. The mixture is then neutralised with sodium carbonate, filtered, the filtrate acidified with hydrochloric acid and warmed gently after the addition of a quantity of zinc-dust. When all the mercury has been precipitated, the mixture is again filtered, and the filtrate tested for sugar by Trommer's test, the sodium hydroxide being added before the copper sulphate. In the case of normal urine the solution retains its blue colour, but becomes bright yellow if 0·2 per cent. of sugar is present. Subsequent addition of hydrochloric acid also renders this test more sensitive. W. P. S.

ORGANIC ANALYSIS.

Colour Reaction of Alcohols and Alcoholic Hydroxyl Groups. L. Rosenthaler. (*Chem. Zeit.*, 1912, **36**, 830.)—A red coloration is obtained when an alcohol is heated with its own volume of a 0·5 per cent. sodium nitrite solution and 4 volumes of a 0·5 per cent. sulphanilic acid solution (prepared by dissolving 1 grm. of sulphanilic acid in a mixture of 5N hydrochloric acid and 150 grms. of water). With 0·25 grm. of ethyl alcohol or glycerol, the colour develops within thirty seconds; it fades after a time and is discharged on the addition of an acid. The reaction is not very sensitive, but may be obtained with 2·5 mgrms. of ethyl alcohol or 0·01 grm. of glycerol. The coloration develops slowly at the ordinary temperature; this is especially the case with malic acid, whilst citric and tartaric acid yield but a slight reaction even when the mixture is heated. Other acids containing a hydroxyl group or groups give the coloration, as do also the higher alcohols, certain carbohydrates, etc. W. P. S.

Differentiation between Natural and Petroleum-Residue Asphalts. J. Marcusson. (*Chem. Zeit.*, 1912, **36**, 801-803.)—As an approximate means for differentiating between natural and petroleum-residue asphalts, the proportion and nature of the oily constituents afford a guide, but is not in itself a conclusive test. If an asphalt on distillation yields over 34 per cent. of oil of a thick, ointment-like consistence, it is probably a petroleum residue; the oily matters from natural asphalt are relatively thin, but it must be borne in mind that many petroleum residues yield less than 34 per cent. of oil. Further, if the oil contains over 2 per cent. of paraffin-wax, the presence of petroleum residues is very probable, but certain petroleum residues yield oils poor in paraffin—*e.g.*, from Roumanian petroleum 3·1 to 3·6 per cent. and from Californian 2·2 to 2·9 per cent. Further methods of differentiation have been investigated by the author. For instance, natural asphalts, on distillation, yield distillates with a comparatively high acid value. A quantity of the sample representing 30 grms. of bitumen is distilled in a small retort and two fractions of 4 to 5 c.c. each are collected. These are dissolved in ether and shaken with water to remove any mineral acid. Neutral alcohol is then added and the acid value of both fractions determined, using alkali-blue as indicator. In the case of natural asphalt the acid value of the first fraction is over 1, and the second fraction still shows a distinct acid value, whereas the acidity of the distillates from petroleum residues is very small, generally *nil* in the second fraction. The separation of solid paraffin from the distillates is also an indication of petroleum residues. A further criterion is the saponification value of the bitumen soluble in benzene: 5 grms. of the soluble bitumen are dissolved in 25 c.c. of benzene free from thiophene and boiled for an hour with 25 c.c. of $\frac{N}{1}$-alcoholic potassium hydroxide, cooled, diluted with 200 c.c. of alcohol and titrated with repeated heating until all the alkali is extracted from the precipitate of pitch. Natural asphalts show saponification values of 28·5 to 34 for the extracted bitumen; petroleum residues show values from 7·6 to 13·5. J. F. B.

Bromine and Iodine Methods for the Volumetric Estimation of Cresol. C. M. Pence. (*J. Ind. and Eng. Chem.*, 1912, **4**, 518-520.)—The usual bromine methods for the estimation of cresol depend upon fixed conditions (*cf.* ANALYST, 1900, **25**, 78), and whilst they may be of service they do not satisfy the demand for a suitable method. Tribromo-*o*- and *p*-cresol bromides cannot be formed in a manner analogous to the production of tribromophenol bromide (*cf.* ANALYST, 1910, **35**, 218); dibromocresol bromide compounds are formed and finally tribromophenol bromide, but *o*- and *p*-cresols cannot be estimated volumetrically by conversion into these compounds. *m*-cresol may be estimated by conversion into tribromo-*m*-cresol; if the *m*-cresol solution is in contact with bromine for 1·5 hours and potassium iodide is then added and the mixture allowed to stand for two hours, all the cresol is converted into tribromo-*m*-cresol.

O- and *p*-cresols form di-iodo compounds, and this reaction is made the basis of a method for their estimation. Five grms. of the cresol are dissolved in water, 10 c.c. of $\frac{N}{2}$ sodium hydroxide solution being added to aid in the solution, and the mixture is diluted to 1 litre. Twenty-five c.c. of this solution are treated with 9 grms. of sodium acetate and 50 c.c. of $\frac{N}{10}$ iodine solution. After the lapse of one hour, 100 c.c. of water are added and a few c.c. of chloroform to dissolve the precipitated di-iodocresol, and the excess of iodine is titrated with thiosulphate solution. As *m*-cresol does not yield di-iodo compounds under the same conditions, a mixture containing this cresol cannot be analysed by a volumetric iodine method. W. P. S.

Compounds of Ferric Salts with Albumoses. F. Rohmann and T. Shmamine. (*Biochem. Zeitsch.*, 1912, **42**, 250-254.)—When an aqueous solution of Witte's peptone is treated with either ferric chloride or ferric sulphate, a precipitate containing primary albumoses is obtained, which may be collected on a filter and washed without difficulty. It contains sulphuric acid in addition to iron, when ferric sulphate is used, but the ratio of Fe : SO_4 is greater than in the precipitant. When the precipitate is suspended in water and an alkali is added cautiously, complete solution is obtained, but on the addition of an excess of alkali ferric hydroxide is precipitated and the albumoses remain in solution. If barium hydroxide be used as the alkali, the sulphuric acid is also precipitated. After removing the excess of barium hydroxide by means of carbon dioxide, the barium-albumose compound may be decomposed with dilute sulphuric acid; a portion of the albumoses remains in solution whilst the remainder separates out together with the barium sulphate. The insoluble portion is soluble both in alkali solutions and in very dilute sulphuric acid. This behaviour of the albumoses recovered from the iron precipitate indicates the presence of a mixture of proto- and hetero-albumose. W. P. S.

Estimation of Lactic Acid and β-Hydroxybutyric Acid in Mixtures of the Same. J. Mondschein. (*Biochem. Zeitsch.*, 1912, 42, 91-104.)—When lactic acid in 1 per cent. sulphuric acid is heated to boiling and $\frac{N}{10}$ potassium permanganate solution is added drop by drop, the lactic acid is converted quantitatively into acetaldehyde, carbon dioxide, and water, according to the equation :

$$CH_3.CHOH.COOH + O = CH_3.CHO + CO_2 + H_2O.$$

On the other hand, β-hydroxybutyric acid in 4 per cent. sulphuric acid solution is converted into acetone, carbon dioxide, and water, by adding to the boiling solution a 0·5 per cent. potassium bichromate solution; in this case the reaction proceeds according to the equation :

$$CH_3.CHOH.CH_2.COOH + O = CH_3.CO.CH_2.COOH + H_2O = CH_3.CO.CH_3 + CO_2 + H_2O,$$

the acetoacetic acid being an intermediate product. Should both lactic acid and β-hydroxybutyric acid be present together in a solution, the former yields a small quantity of aldehyde when the mixture is oxidised with bichromate, and the latter acid a small quantity of acetone during the permanganate oxidation, the conditions necessary for the complete oxidation of one acid not being suitable for the complete decomposition of the other. The two acids may, however, be estimated separately by a combination of these methods, the oxidations being carried out in an apparatus described previously by von Furth and Charnass (ANALYST, 1910, 35, 445). A definite volume of the solution containing the two acids is oxidised with permanganate as described (*loc. cit.*), and the distillate obtained, measuring 400 c.c., is divided into two equal portions, and the total aldehydic content is estimated in one portion by means of potassium bisulphite as described by Ritter (ANALYST, 1901, 26, 131). The other portion of the distillate is then boiled under a reflux condenser after the addition of hydrogen peroxide and sodium hydroxide in order to destroy the aldehyde. The mixture is now distilled, and the distillate again examined by Ritter's method. The difference between the results of the two estimations corresponds with the amount of aldehyde present, from which the lactic acid may be calculated.

Another portion of the original solution is then oxidised with potassium bichromate, and distilled. The distillate in this case contains the whole of the acetone derived from the β-hydroxybutyric acid together with a quantity of aldehyde from the lactic acid. After this aldehyde has been destroyed by boiling the solution with sodium hydroxide and hydrogen peroxide under a reflux condenser, the solution is again distilled and the acetone estimated in the distillate by Messinger's iodoform method (*cf.* ANALYST, 1908, 33, 98). Experiments with solutions containing known quantities (about 0·2 grm. each) of the two acids show that the method is trustworthy, 99·2 per cent. of the amount lactic acid, and 97·8 per cent. of the β-hydroxybutyric acid actually present being obtained. W. P. S.

Method of Examining Chinese Wood Oil. P. C. McIlhiney. (*J. Ind. and Eng. Chem.*, 1912, **4**, 497-498.)—The following method of estimating the proportion of this oil which is solidified when treated with iodine is proposed in the hope that the estimation may be of value in distinguishing between genuine oils and those which have been adulterated with other oils. The author refrains from giving any figures at present, as he has not been able to obtain authenticated specimens of Chinese wood oil, and has only applied the method to commercial samples. Broadly speaking, Chinese wood oil yields only a small fraction of liquid oil when subjected to the process, whilst other oils remain entirely liquid and soluble in petroleum spirit. The details of the method are as follows: Five grms. of the oil are heated with 10 c.c. of 99·5 per cent. acetic acid until a clear solution is obtained, and 50 c.c. of a 1·5 per cent. iodine solution in 99·5 per cent. acetic acid are added. This iodine solution should be warmed so that it does not cool the oil solution. After the lapse of thirty minutes, 50 c.c. of petroleum spirit are added, mixed thoroughly with the mass, and then decanted into a separating funnel; the extraction with petroleum spirit is twice repeated, and the united extracts are washed with water until free from acid, then with potassium iodide solution to remove free iodine, and finally with water. The petroleum spirit is next evaporated and the residue weighed in order to obtain the portion of the oil which is not solidified by the action of iodine.

W. P. S.

Heat Test for Chinese Wood Oil. F. Browne. (*Chem. News*, 1912, **106**, 14-15.)—The author advocates a standardised form of apparatus and method of working for the observation of the time required to produce "setting" or jelly formation on heating the oil to 540° to 560° F. The addition of 10 per cent. of other vegetable, or of mineral, oils causes an appreciable lengthening of the time required, which for 5 c.c. of a genuine wood oil is about eleven to twelve and a half minutes under the stated conditions of the experiments. If the time required is thirteen minutes or more, the author employs the iodine and chloroform test (ANALYST, 1898, **23**, 43). Genuine oils "set" in from forty to fifty-five seconds. The following range of constants is given: Sp. gr. at 15·5° C., 0·9402 to 0·9431; saponification number, 191 to 194; iodine number (Wijs), 173 to 174. A. R. T.

Refractive Index of Chinese Wood Oil. L. E. Wise. (*J. Ind. and Eng. Chem.*, 1912, **4**, 497-498.)—The refractive indices of fifteen samples of commercial Chinese wood oil were found to lie between 1·5099 and 1·5186, the values being determined at a temperature of 25° C. Gross adulteration of the oil with other drying oils can be detected readily by means of the refractometer as the refractive index is lowered. W. P. S.

Effect of Free Fatty Acid on Specific Gravity of Some Fatty Oils. A. O. Ransome. (*J. Soc. Chem. Ind.*, 1912, **31**, 672.)—The author's results support the statement of Allen ("Commercial Organic Analysis," II., part i., pp. 126-127) that in the case of olive oil the presence of free fatty acids lowers the sp. gr. Each 5 per cent. of free acid was found by the author to diminish the gravity by

0·00082, Allen's figure being "about 0·0007." From a consideration of the results of other observers, the author shows that the sp. gr. of the fatty acids of various oils is invariably lower than that of the oil itself, the differences being from 0·0037 to 0·0258. It is further shown that the iodine number of Menhaden oil is increased by the presence of free fatty acids, and it is assumed that many or all constants of an oil will vary progressively with the proportion of free acids present. In the case of oils containing a sufficient quantity of free acids to vitiate the constants, it is thus considered desirable to isolate the fatty acids and make the analysis on them instead of on the original oil.

The following figures may be quoted:

ANALYSIS OF SIX AUTHENTIC SPECIMENS OF OLIVE OIL.

Three Menhaden oils showed a decrease of sp. gr., for each 5 per cent. of free fatty acid, of 0·00054, 0·00084, and 0·00063. A. R. T.

Glycerides Occurring in Fats and Oils: Heptadecoic Acid and its Glyceride. A. Bömer and R. Limprich. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, 23, 641-653.)—Considerable doubt having arisen as to the actual presence of a glyceride of heptadecoic acid in fats and oils (*cf.* ANALYST, 1904, 29, 259; 1905, 30,

---

* The acids contained about 7 per cent. of glyceride calculated on the difference between the neutralisation and saponification values. The figures for acids were corrected on this basis.

212), the authors have prepared this acid and its glyceride synthetically for the purpose of comparison with the acid isolated from fats and oils; the results of this comparison will be published later, the present paper dealing with the preparation and properties of the acid. Krafft's method (*Ber.*, 1879, **12**, 1668) was used for this purpose; it consists in distilling a mixture of barium stearate and barium acetate under reduced pressure, separating the resulting ketones by fractional solution in alcohol, oxidising the heptadecyl ketone with bichromate and sulphuric acid, and crystallising the heptadecoic acid repeatedly from alcohol. The pure acid obtained melted at 60·5° C., and boiled, in an absolute vacuum, at 143·6° C. One hundred c.c. of absolute alcohol dissolve 1·15 grms. of the acid at 0° C., and 3·48 grms. at 15° C. The zinc salt is practically insoluble in cold alcohol. The triglyceride of the acid was prepared by heating the potassium soap for two hours with the theoretical quantity of tribromhydrin, extracting the mass with ether and evaporating the ethereal solution; the residue obtained was dissolved in benzene, and the glyceride precipitated by the addition of alcohol. After crystallisation from ether it yielded masses of needle-shaped crystals which melted at 62·7° C. One hundred c.c. of anhydrous ether dissolve 0·0288 grm. of the glyceride at 0° C., and 0·322 grm. at 15° C. W. P. S.

New Oxygen Absorption Method for Oils. L. P. Wilson and G. S. Heaven. (*J. Soc. Chem. Ind.*, 1912, **31**, 565-568.)—About 0·2 grm. of the oil is mixed in a flask with 1 grm. of kieselguhr, and, after the flask has been cooled to a definite temperature, a side-tube provided on the neck of the flask is sealed. The flask is now heated to 100° C. for one hour, again cooled, and the side-tube is connected with graduated levelling tubes filled with water; the height of the water is noted and the seal is broken, the resulting difference in the water-level (after the water surfaces have been brought to the same level) being a measure of the amount of oxygen absorbed by the oil. The volume of oxygen absorbed is then calculated into a percentage quantity on the oil. The side-tube of the flask may be provided with a bulb to prevent water entering the flask. The following percentage amounts of oxygen were absorbed by various oils examined: Linseed oil, 17·2 to 21·2; poppyseed oil, 17·4; cottonseed oil, 11·1; sesame oil, 5·8; olive oil, none. W. P. S.

Notes on Serger's Reaction for Vegetable Oils. Utz. (*Chem. Rev. Fett.- u. Harz.-Ind.*, 1912, **19**, 128-131; 151-153.)—Serger has suggested the use of a solution of 0·1 grm. of sodium molybdate in 10 c.c. of strong sulphuric acid as a means of distinguishing between vegetable and animal oils, the former when dissolved in ether giving colorations varying from yellow to blue or green, whilst in the case of the latter no colorations are produced in less than thirty to forty-five minutes. Comparative tests here described show that the reaction is slower and no more sensitive than Bellier's test, whilst treatment of the oils with bleaching agents such as benzoyl peroxide ("lucidol") or the action of heat prevent the appearance of the colorations. Oils giving only faint reactions in this test may be mixed with lard without risk of detection by Serger's test, and the phytosterol test is then the only method of proving the addition of vegetable oils. C. A. M.

Comparison of Methods for Determining the Viscosity of Pitch. B. Weinberg and H. Smirnow. (*J. Russ. Phys.-Chem. Soc.*, 1912, **44**, 3; through *Chem. Zentralbl.*, 1912, II., 4.)—The investigation was confined to methods in which the motion reaches a limit, and in which alteration of form, but not of volume, takes place (*cf.* Weinberg, *J. Russ. Phys.-Chem. Soc.*, 1907, **38**, 202). The torsion method, the Legel method, and the strata-displacement method, were particularly examined. The torsion method is the best for substances having viscosities of the order of $10^8 \frac{\text{g.}}{\text{cm. sec.}}$; it may be used for substances from 10^6 to 10^{10}, but the external friction of the apparatus must be accurately determined. The Legel method possesses the advantage of direct transmission of the force to the examined substance, but secondary phenomena must again be taken into account. The third method has a low degree of accuracy, and for substances of viscosity below 10^9 requires the application of the law of Archimedes; this applies also to the first method when the viscosity is below $10^{10} \frac{\text{g.}}{\text{cm. sec.}}$ O. E. M.

Separation and Estimation of Pyridine and Ammonia. A. Bayer. *J. f. Gasbeleuchtung*, 1912, **55**, 513-514; through *Chem. Zentralbl.*, 1912, II., 281.)—In the titration of pyridine and ammonia, ferric thiocyanate is a better indicator than methyl orange or ferric chloride. The solution of pyridine or ammonia is acidified with $\frac{N}{10}$ hydrochloric acid, ferric chloride and ammonium thiocyanate are added, and then $\frac{N}{10}$ caustic alkali, until the red-brown liquid becomes quite colourless. For the estimation of pyridine in presence of ammonia, the pyridine is first concentrated by distilling the solution after the addition of sulphuric acid until it is almost neutral to litmus. The whole of the pyridine, with very little ammonia, passes over with the first third of the distillate. The ammonia is titrated with $\frac{N}{10}$ hydrochloric acid, using litmus as indicator, excess of acid is then added, and the pyridine estimated in the manner already described. Where the utmost accuracy is desired, the ammonia is best eliminated as ammonium magnesium phosphate.

G. C. J.

Detection of Pyridine Bases in Ammonia and Ammonium Salts. A. Wöhlk. *Ber. deutsch. pharm. Ges.*, 1912, **22**, 285-288; through *Chem. Zentralbl.*, 1912, II., 286-287.)—If an ammonium salt containing pyridine bases be triturated in a mortar with twice its bulk of borax, the impurity may be detected by its odour, which is pronounced if so little as 0·4 mgrm. be present. For the examination of liquid ammonia, the latter is mixed with a small excess of acid and evaporated to dryness on the water-bath, the dry residue being used for the test. Ammonium salts can be freed from pyridine by dissolving them in water and leading a current of pure ammonia gas through the solution. G. C. J.

A Critical Study of Sugar Analysis by Copper Reduction Methods. A. W. Peters. (*J. Amer. Chem. Soc.*, 1912, **34**, 928-954.)—The investigation described by the author arose from the need for a rapid and accurate method of determining sugar in urine, and led to his standardising a volumetric method applicable to any sugar. No new principle is involved, the experimental work recorded mainly dealing with the effect produced by variations in the rate of heating the alkaline copper solution with sugar. To an aliquot portion of the residual copper solution after filtration sulphuric acid and excess of potassium iodide are added, and the liberated iodine titrated against thiosulphate. This "residual" method the author considers very rapid and accurate. An examination in detail is described of the rate of reduction with pure dextrose under varying conditions of time and heating, and curves are given showing the percentage of the total sugar reduced for each interval of time at different temperatures. It is important to employ a mechanical heating device to insure uniformity in this connection, and the standard heating power arbitrarily selected was such as to produce a rise from 35° to 90° C. in 120 seconds, when acting on 60 c.c. of distilled water. The duration of heating was always calculated from the moment the temperature of 90° C. was reached, and was fixed at exactly 20 seconds. Reasons are given and figures quoted supporting the contention that this is the best length of time for the reduction process, the much longer period usually taken being without justification. The total volume of the solution employed is 60 c.c., 20 c.c. of "Fehling-Soxhlet" copper sulphate solution, 20 c.c. of "Allihn alkaline tartrate solution," containing 346 grms. of Rochelle salt and 250 grms. caustic potash per litre, and 20 c.c. of sugar solution. The heating is conducted in an Erlenmeyer flask, closed with a doubly-bored stopper, a thermometer passing through one of the holes, the other being left free for the escape of steam. The flask stands on an asbestos plate, which must be 3 to 5 cm. away from the burner. At the end of the 20 seconds' heating, the whole is cooled for a few seconds under the tap to just below the boiling-point, and then filtered through a Gooch crucible packed very heavily with two layers of asbestos containing pure talcum powder between them. The total volume of filtrate, including washings, must not exceed 75 to 80 c.c.; and the thiosulphate finally employed should have a value between 12·5 and 13 mgrms. of copper per c.c. The dextrose-copper ratio so obtained falls from 0·833, when 1 mgrm. of dextrose is employed, to 0·522 for 25 mgrms. dextrose, at which point it remains constant till 110 mgrms. of dextrose is reached, when it rises to 0·572 at 200 mgrms. dextrose. From 1 to 10 c.c. of urine may be employed, 2 c.c. being usually taken in the case of urine from diabetic subjects.

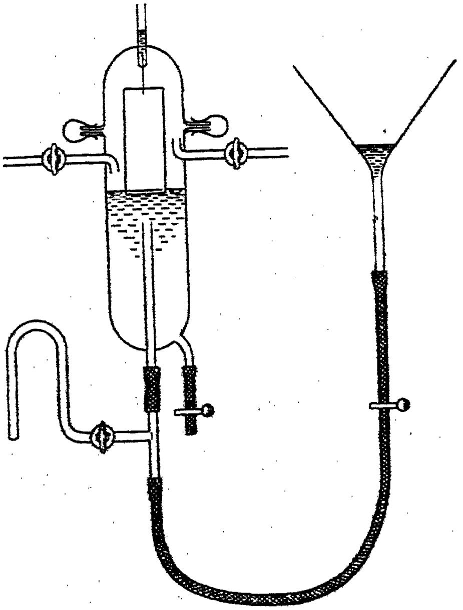
INORGANIC ANALYSIS.

Separation of Arsenic from Antimony and Other Metals by Means of Methyl Alcohol in a Current of Air. L. Moser and F. Perjatel. (*Monatsh.*, 1912, 33, 797-820.)—The authors have worked out a method for the estimation of arsenic by distillation in presence of methyl alcohol and strong hydrochloric acid with a current of air at the temperature of the water-bath (*cf.* Friedheim and Michaelis, *Ber.*, 1895, **28**, 1414; S. W. Collins, ANALYST, 1912, 229). A portion of the arsenic distils as the trichloride, and a portion as methyl arsenite, which is immediately hydrolysed by the water in the receiver. If the arsenic is present in the pentavalent form, it must be reduced before distillation, preferably by means of a ferrous salt. The methyl alcohol has no reducing action under the conditions adopted. The usual method of oxidising the arsenious acid, in preparing ores for analysis, by potassium chlorate and hydrochloric acid is unsatisfactory, and leads to a loss of arsenic; but oxidation by means of chlorine in alkaline solution is complete. Arsenic acid is not volatilised with hydrochloric acid. The general arrangement of the apparatus used for distillation is similar to that described by Thaddeeff for the estimation of boric acid with methyl alcohol. It consists of a wide-necked flask, with rubber stopper having three holes. Through one passes a tube for the introduction of air, extending to some height; through the other a dropping funnel; and through the third a simple bulb distillation-head. To this is joined a tube 60 cm. long, bent at one end, and dipping to the bottom of a beaker cooled by water. The flask is immersed in a water-bath; the current of air is regulated by a screw-clip, and passes through drying towers. About 200 c.c. of water are placed in the beaker. For the separation of arsenic from antimony, etc., the quantity of arsenious acid taken must not exceed 0·22 grm. If the substance has to undergo a preliminary treatment, this may be carried out in the flask, and any residues of nitric acid or water must be removed; small quantities of sulphuric acid are immaterial. In the case of pentavalent arsenic, 5 to 8 grms. of ferrous sulphate are added; then 40 to 50 c.c. of hydrochloric acid, sp. gr. 1·19, and the contents of the flask are brought to the boil in the water-bath, and kept at the boil for five to ten minutes. By that time the reduction of the arsenic acid is complete, and the first addition of 30 c.c. of methyl alcohol is made, air being passed through for a few seconds to prevent the sucking back of water in the beaker. The liquid is then boiled for a quarter of an hour without the air-current, and for half an hour with a vigorous current. Next, a further 20 c.c. of methyl alcohol are added, and boiled for a quarter of an hour; the same operation is repeated, and the liquid boiled for another quarter of an hour. The total time of boiling is one and a half hours, of which one hour is with the air-current. The separation of the arsenic is complete, and this element is estimated in the distillate either gravimetrically or volumetrically by iodine or permanganate. Th antimony and other metals are estimated in the residue; the method is not applicable for the separation of arsenic from mercury, since the latter is also volatile as chloride.

J. F. B.

Estimation of Arsenic. E. Rupp and F. Lehmann. (*Arch. Pharm.*, 1912, **250**, 382-389.)—The following method has been devised more especially for the rapid estimation of arsenic from salvarsan in animal tissue. It depends upon the destruction of the organic matter by means of potassium permanganate or persulphate and sulphuric acid, and the distillation of the arsenic as trichloride in a current of hydrochloric acid gas evolved from the solution itself. From 5 to 20 grms. of divided moist material are intimately mixed with 10 grms. of powdered potassium permanganate (or persulphate) and 10 c.c. of dilute sulphuric acid, and the mixture heated for fifteen minutes, with continual stirring, on the water-bath, after which it is gradually treated with 25 c.c. of concentrated sulphuric acid, followed by 30 c.c. of hydrogen peroxide solution. As soon as frothing has stopped, the liquid is transferred to a Kjeldahl flask, into which is also introduced 5 grms. of anhydrous (or 10 grms of crystalline) ferrous sulphate to reduce the arsenic acid, and 50 grms. of sodium chloride, the flask then connected with a receiver containing 40 grms. of sodium bicarbonate and 100 c.c. of water, and heated on a sand-bath. The receiver is frequently shaken, and as soon as the whole of the bicarbonate has dissolved the distillation is stopped, and the distillate cooled, rendered alkaline, if necessary, with sodium bicarbonate, filtered, and titrated with standard iodine solution, 0·05 c.c. of $\frac{N}{10}$ solution being deducted as a correction. C. A. M.

Electrometric Determination of the Reaction of Liquids containing Carbon Dioxide. K. A. Hasselbalch. (*Compt.-rend. des Travaux du Lab. de Carlsberg*, 1911, **10**, 69-84.)—The exact electrometric determination of the reaction of liquids containing carbon dioxide is rendered difficult by the tendency of the solution to part with some of its dissolved gas, and become appreciably more alkaline before the determination can be completed. Michaelis and Rona (*Biochem. Zeitsch.*, 1909, **18**, 317) have proposed to obviate this difficulty by superimposing an atmosphere of hydrogen above the liquid, and by preventing the electrode from dipping in the liquid any more than is necessary to make contact. Their method has advantages, but does not give exact results, and it is now shown that an atmosphere of hydrogen does not prevent loss of carbon dioxide, and that the increased accuracy of their results compared with those of earlier workers is entirely due to the electrode not being submerged in the liquid.



The author has adopted this principle of slight immersion of the electrode, and has evolved a method which makes it possible to obtain exact results in a very short time (half an hour). The method depends on putting some of the solution in equilibrium with hydrogen in an appropriate apparatus, and then, since the liquid has lost carbon dioxide in the process, replacing it by a fresh portion of liquid, and proceeding to the electrometric measurement. The illustration shows a convenient form of apparatus. The electrode is seen just touching the surface of the liquid, which half fills a vessel of about 15 c.c. capacity. A current of hydrogen is passed through the empty vessel for half an hour to saturate the hydrogen electrode at the prevailing barometric pressure. The liquid is then introduced through the funnel and pinchcock, and the apparatus rocked from the vertical to a horizontal position and back again some 200 times. Blood may require nearly three times as much agitation. The liquid, which has lost carbon dioxide, is now run out of the apparatus and replaced by a fresh portion, and the E.M.F. determined in the usual manner.

G. C. J.

Estimation of Arsenious Acid with Permanganate in Presence of Hydrochloric Acid. L. Moser and F. Perjatel. (*Monatsh.*, 1912, **33**, 751-758.) —The titration of arsenious acid by permanganate in acid solution sometimes presents difficulties, owing to the fact that reduction to the manganous stage is only complete and rapid under certain conditions. If the permanganate be added too quickly to a too concentrated solution of arsenic, yellow to brown colorations, due to the intermediate stages of reduction of the manganese, occur, and the titration is spoilt; the concentration of free acid is also an important factor. The authors have worked out the following generally satisfactory method: 0·1 to 0·3 grm. of arsenious acid is dissolved in not very concentrated caustic soda lye, containing about 1 grm. of solid sodium hydroxide, in a porcelain dish, and the solution is diluted with 100 to 200 c.c. of water. The liquid is acidified by the addition of 10 to 15 c.c. of hydrochloric acid, sp. gr. 1·19, per 1 grm. of sodium hydroxide used. Permanganate is then added drop by drop in the cold with continuous stirring. Under these conditions no brown coloration ensues, and the end-point is sharply recognisable by a pink colour lasting for two to three minutes. The volume of the arsenious chloride solution should be between 50 and 200 c.c. If the solution to be tested is already acid, it is advisable to neutralise it first exactly with sodium hydroxide, and then to add 5 to 10 c.c. of concentrated hydrochloric acid. If a yellow coloration develops on titration, the addition of the permanganate has been too rapid. The results are accurate.

J. F. B.

Reaction of Hydrazine and Hydroxylamine with Ferricyanides, and New Methods for Estimating Hydrazine and Ferricyanides. P. R. Rây and H. K. Sen. (*Zeitsch. anorg. Chem.*, 1912, **76**, 380-386.)—Hydrazine and potassium ferricyanide in alkaline solution react as follows:

$$N_2H_4 + 4K_3Fe(CN)_6 + 4KOH = N_2 + 4K_4Fe(CN)_6 + 4H_2O.$$

In presence of excess of alkali, the reaction is quantitative until either the whole of the hydrazine or the whole of the ferricyanide has disappeared. The reaction proceeds rapidly at room-temperatures, and is unaccompanied by any secondary reactions. It therefore affords a basis for the estimation of hydrazine or ferricyanide.

For the estimation of hydrazine, the substance for analysis is weighed out from a weighing bottle into the cup of a Crum's nitrometer, and washed into the latter by means of a little water and 4 to 5 c.c. of 15 per cent. caustic potash. A solution of the substance may be used, since considerable dilution has no influence on the course of the reaction; but the presence of a deep aqueous layer above the mercury in the nitrometer reduces the space available for gas, and the larger the gas volume, the less the percentage error of the method. A large crystal (an excess) of potassium ferricyanide is introduced by the open end of the nitrometer, which is immersed in the mercury bath, and the tube is shaken to hasten the reaction, which is complete in three or four minutes.

Since Stolle's iodine method (*J. Prakt. Chem.*, 1902, **66**, 332) for the estimation of hydrazine leaves nothing to be desired, the new method is recommended rather for the estimation of ferricyanide, especially in presence of ferrocyanide. In this application, a "pill" of hydrazine sulphate (an excess) is introduced into the nitrometer from below, and the ferricyanide is weighed out into the cup of the nitrometer, covered with water, and drawn in. Caustic potash solution is then added through the cup, and the analysis completed as before. The accuracy of the method is limited only by the accuracy with which the gas volume can be read. The test numbers show that the authors make no attempt to read this volume more closely than 0·05 c.c., and their greatest error corresponds exactly to a misreading of the gas volume of 0·05 c.c. The excess of hydrazine always present in ferricyanide determinations keeps the mercury clean, but mercury which has been exposed to excess of ferricyanide in hydrazine determinations needs purification with dilute nitric acid before being used for other purposes.

Phenyl-hydrazine reacts with ferricyanide similarly to hydrazine, but hydroxylamine gives rise to a mixture of nitrogen, ammonia, and nitrous oxide, the proportions of which depend on the exact conditions under which the reaction is brought about. G. C. J.

Determination of Iodine in the Presence of Other Halogens and Organic Matter. E. C. Kendall. (*J. Amer. Chem. Soc.*, 1912, **34**, 894-909.)—For the determination of iodine, when present as a soluble iodide or in the uncombined form, the author employs a modification of Hunter's method (Analyst, 1910, **35**, 483), in which about 200 c.c. of the cold neutral or slightly alkaline solution, containing the iodine to be estimated, is treated slowly with sodium hypochlorite in slight excess in the presence of 5 c.c. of 42 per cent. phosphoric acid. Any iodine present is oxidised to iodic acid. To prevent loss of iodine, if more than 0·1 grm. is present, a few c.c. of benzene are floated on the surface of the liquid. Ten c.c. of a colourless 5 per cent. solution of phenol are then rapidly and forcibly blown into the flask. This removes all traces of chlorine without the formation of coloured compounds. The whole is now made just alkaline with 30 per cent. sodium hydroxide, and then acidified by the addition of 10 c.c. of 50 per cent. phosphoric acid. Potassium iodide is next added in excess, about eight times the weight of the iodine originally present being required; and the liberated iodine, of which one-sixth part is that originally present, is titrated with thiosulphate. Working with quantities of iodine lying between 5 and 350 mgrms., over fifty results are recorded, showing a maximum error of −0·76 per cent., a minimum error of +0·02 per cent., and an average error of about ±0·1 per cent.

Bromine or bromides, if present, do not interfere, and there is no oxidation of the bromine. Hydrobromic acid, when present in large amount, will reduce iodic acid, but all the former may be removed by the addition of sufficient hypochlorite. The procedure is that already described, except that 10 c.c. of benzene are added, sufficient hypochlorite being used to liberate all the bromine and oxidise the iodine.

A little pumice is added, and the solution is boiled. The benzene reacts with the hypobromite and hypochlorite, forming bromo- and chloro-benzene. The free bromine is boiled out of the solution. A precipitate of bromo-benzene may form, but does not interfere. When colourless, the solution is cooled, and potassium iodide is added directly, no neutralisation and acidification being necessary. The presence of chlorides has no effect, and there is no need to boil the solution.

To remove organic matter, enough material to contain about 60 mgrms. of iodine is fused with special precautions, at a temperature below dull redness, in a nickel crucible, with 5 grms. of solid caustic soda. Potassium nitrate is finally added in small quantity, and the melt, which should be clear, is cooled and extracted with water. At this stage, silver, copper, iron, or mercury, if present, are removed, and the solution, which contains sodium hydroxide, carbonate, and iodide, potassium nitrite and nitrate, is acidified slowly with 10 c.c. of 50 per cent. sulphuric acid, after the addition of 2 c.c. of a 10 per cent. solution of sodium bisulphite, to prevent loss of iodine with the escaping carbonic acid, and a few c.c. of chloroform. The iodine, which is now present as hydriodic acid, is oxidised with hypochlorite to iodic acid, as already described, phenol and potassium iodide being added as before. If bromine is present, the modifications required in its presence mentioned above are introduced. The author was unable to modify Hunter's method (*loc. cit.*) satisfactorily for the estimation of iodine in such small quantities as those present in preparations of thyroid gland. A better method is the fusion treatment already described, but with numerous detailed modifications, gallic acid being added after the potassium nitrate to effect the reduction of the excess of nitrate and nitrite. Bromine is next added in slight excess, and then removed with sodium salicylate. When this method is employed with all the refinements described, as little as 0·005 mgrm. of iodine can be detected with certainty, 1 grm. of thyroid gland substance and 10 grms. of caustic soda being suitable amounts to employ for the preliminary fusion. Three commercial samples of thyroid gland preparation contained respectively 1·899, 1·950, and 1·716 mgrms. of iodine per grm. of material.

H. F. E. H.

Electrolytic Estimation of Manganese and its Separation from Iron. H. Golblum and H. Gunther. (*Compt. rend.*, 1912, 155, 166-168.)—The presence of iron in a solution from which manganese is to be deposited as MnO_2 is a positive advantage, as the deposit is then much more adherent. In solutions containing iron and manganese, the latter may be deposited completely as MnO_2 as follows: The solution, which may conveniently contain 0·1 grm. of manganese and 10 grms. of ammonium oxalate in 100 c.c., is placed in a platinum Classen dish, which serves as an anode, the rotating cathode consisting of a smaller slotted dish suspended from the rotating device by a platiniridium rod of sufficient rigidity. The cathode is rotated at about 700 revolutions per minute, and a current of 2 ampères at 3 volts employed, the solution being maintained at 80° C. An hour suffices for the deposition of the whole of the manganese as MnO_2 on the anode, and, under the above conditions, the deposit will contain not more than 0·5 mgrm. nor less than 0·2 mgrm. of iron. The exact correction corresponding to any particular conditions may be readily determined by solution of the weighed deposit and colorimetric determination of the iron. Lower current densities reduce the amount of iron deposited on the anode, but a current of at least 0·5 ampère is necessary to make the deposition of manganese quantitative. Some iron, but comparatively little, is deposited on the cathode, which may be weighed, and the solution freed from manganese may then be electrolysed in other suitable apparatus for the estimation of the iron. G. C. J.

Electrolytic Estimation of Molybdenum. Part I. A. Fischer and J. Weise. (*Zeitsch. anal. Chem.*, 1912, **51**, 537-550.)—The authors are unable to confirm the statement of Exner (ANALYST, 1903, **28**, 328) and of Wherry and Smith (*ibid.*, 1907, **32**, 341) that molybdenum is deposited quantitatively from a molybdate solution as hydrated sesquioxide when following the directions of those authors. On the other hand, the quantitative deposition of molybdenum is found to be practicable under the following conditions: When speed is no object, or the complication of a rotating anode is undesirable, the molybdate solution is acidified with 0·15 c.c. sulphuric acid, diluted to 120 c.c. in a platinum dish with matte surface, heated to an initial temperature of 75° C., and electrolysed for fourteen hours with a current of 0·02 to 0·03 ampère at 1·8 to 2 volts. The deposit is converted quantitatively into MoO_3 by heating for two hours in an electrically-heated furnace maintained at 400° C. For rapid work, hydrochloric acid must be substituted for sulphuric acid and, with from 0·05 to 0·2 grm. MoO_3 present, the amount of hydrochloric acid should not be much less than 0·2 c.c., nor more than 0·25 c.c. of concentrated acid (sp. gr. 1·19). If no more than 0·13 c.c. of acid be present, the deposit is not adherent, whilst high concentrations lead to incomplete deposition. With as much as 0·33 c.c. acid present, the results are always low but never more than 0·5 mgrm. low; but two or three times this amount of acid gives rise to errors of from 10 to 50 per cent. A current of 3·5 to 4 ampères is employed, the voltage varying from 18 to 30 according to the temperature of the electrolyte and the speed at which the anode is rotated. A convenient speed is 600 to 800 revolutions. Deposition is complete in less than twenty-five minutes. The deposit is transformed into MoO_3 in the manner already described. A current of 2·5 ampères gives equally good results, but thirty-five minutes are required for the deposition of 0·2 grm. The authors have been unable to get good results when working with larger quantities than correspond to 0·2 grm. MoO_3, and they show that the error depends mainly, if not entirely, on the difficulty of oxidising large deposits quantitatively to MoO_3. The success of this operation, even with small deposits, is shown to depend on precise regulation of the temperature. At temperatures much below 400° C., the conversion of Mo_2O_3 to MoO_3 is never complete, whilst higher temperatures may result in loss by volatilisation. G. C. J.

Analysis of Platinum Alloys. H. Arnold. (*Zeitsch. anal. Chem.*, 1912, **51**, 550-554.)—The analysis of platinum alloys can be accomplished more quickly by the following method than by methods which depend on the separation of platinum as metal or as sulphide. The method depends on the separation of platinum as potassium platinic chloride. The alloy (1 grm.) is dissolved in *aqua regia*, and the solution evaporated to dryness three times with hydrochloric acid. The soluble chlorides are taken up in 10 c.c. of hydrochloric acid (sp. gr. 1·12), 1 grm. of caustic potash dissolved in a little water is added and the solution evaporated to dryness on a not too vigorously boiling water-bath. The residue of silver chloride and potassium platinic chloride is washed four or five times by decantation with 50 c.c. of alcohol, and, the bulk of the precipitate is dried in the evaporating basin whilst the filter is ashed. The dried precipitate is next transferred to the crucible containing the ash, and the potassium platinic chloride decomposed by ignition in a current of hydrogen. The contents of the crucible are then transferred to a beaker and heated successively with dilute nitric acid and dilute ammonia. The platinum is filtered off, washed with hot dilute ammonia and then with hot water, and the filter ashed and the residue ignited, treated with hydrofluoric acid to eliminate silica derived from glass vessels, re-ignited and weighed. In the filtrate from platinum, silver is precipitated —preferably as sulphide, since silver chloride is appreciably soluble in solutions of alkali chlorides—and is finally weighed as chloride.

The alcoholic filtrate is evaporated to dryness, the residue moistened with dilute hydrochloric acid and the solution again evaporated. The residue is then taken up in 5 to 10 c.c. of hydrochloric acid (sp. gr. 1·1) transferred to a Rothe separator and iron removed by Rothe's ether process (*Mitt. Kgl. Techn. Versuchs-anstalt*, 1892, 123). The iron is obtained in aqueous solution by shaking the combined ethereal extracts with water, and is determined in any convenient manner.

The acid aqueous layers from the separator are united, warmed to expel dissolved ether and taken down to fuming after addition of 0·5 c.c. of sulphuric acid. The cooled residue is taken up in dilute sulphuric acid, the solution made alkaline with ammonia and any trace of ferric hydroxide filtered off, re-dissolved, and its solution added to the main solution of ferric chloride separated by the ether process. The solution of copper and nickel freed from the last trace of iron is next acidified so that it contains about 5 per cent. of sulphuric acid, and copper is precipitated by passing hydrogen sulphide through the hot (80° C.) solution. The copper is finally obtained as oxide or as copper, and usually carries a weighable trace of nickel which is best determined by the dimethylglyoxime method. The copper may also be accompanied by a trace of platinum, but this never exceeds 0·5 mgrm.

The filtrate from the copper sulphide is evaporated to small bulk, mixed with a saturated solution of ammonium sulphate and 50 c.c. of 25 per cent. ammonia and electrolysed for nickel, preferably using Frary's apparatus (*Zeitsch. Electrochem.*, 1907, 13, 308).

G. C. J.

Estimation of Radium in Minerals and Rocks. E. Ebler. (*Zeitsch. Electrochem.*, 1912, 18, 532-535.)—This paper includes an illustration and fuller description of the apparatus already described by the author (ANALYST, 1912, 323). The parts of the apparatus from the platinum boat *a* to the ground connection *f* can be identified by reference to the abstract of the earlier paper. The drying tube *e* is charged with sodium and not with phosphoric anhydride, which absorbs notable amounts of niton and sometimes gives off lower oxides of phosphorus which make the air a conductor. The use of the pump *g* to transfer the air and emanation to the vessel *h* is obvious from the drawing. Their further transference from *h* to *l* is effected by means of the balance vessel *m*, the tubulure of which is connected to that of *l* by flexible tubing not shown in the drawing. The gas is left in *l* some minutes to allow time for the complete decomposition of any possible thorium emanation and is then transferred to the ionisation chamber *n*, where the measurement of the maximum saturation current is made after four hours. The ionisation chamber carries a manometer, *q*, and rests on the ebonite supports *ss*, inside the metal casing *r*, which is earthed. The ionisation chamber itself consists of a double-walled brass vessel, the space between the walls being filled with tin. Its inner wall is galvanised with zinc.

Study on the Acidity of Soils. A. Gregoire. (*Bull. Soc. Chim. de Belg.*, 1912, **26**, 336-342, 362-375.)—The estimation of the acidity of a soil is a necessary preliminary for gauging its requirements in lime. The acid constituents of the soil exist largely in a condition in which they are not readily extracted, and the author gives an account of the principal methods which have been proposed for their estimation, and discusses the interpretation of their results in relation to the necessity of liming. He further proposes a method for the estimation of acidity based on the liberation of iodine from a mixture of iodide and iodate as applied by Kjeldahl for the estimation of feeble organic acids. The reagent employed contains 55·3 grms. of potassium iodide, 14·3 grms. of potassium iodate, and 99·2 grms. of crystallised sodium thiosulphate, per litre. The solution of iodine employed for titrating back the excess of thiosulphate contains 17 grms. of iodine and 25 grms. of potassium iodide per litre, and the solutions are standardised against each other by adding 20 c.c. of $\frac{N}{5}$ acid to the first, and titrating back with the iodine. The solution of iodide, iodate, and thiosulphate is called Kjeldahl's solution; it keeps very well. For the estimation, 10 grms. of soil, passed through a sieve with holes of 1 mm., are placed in a stoppered flask with 15 c.c. of the Kjeldahl reagent. After a sufficient time, the volume is made up to 105 c.c., the solution is filtered, and 100 c.c. are drawn off for titrating back the thiosulphate. If the soil be digested with the diluted Kjeldahl solution, the action is very much weaker than with the undiluted reagent. The action of the reagent upon the soil is not instantaneous, but iodine continues to be liberated for a very considerable time, so that it seems difficult to arrive at a final point. The results obtained in several experiments with the same soil are, however, very regular, and it appears desirable to neglect the slow ulterior action of the reagent, possibly on certain mineral constituents of the soil, and to confine the observations to the iodine liberated by the more pronounced organic acids in a period of twenty-four hours. Experiments have shown that the temperature of the digestion within moderate limits has no influence on the results. Further tests have also shown that a large number of inorganic substances behave as acids towards the Kjeldahl reagent; for instance, aluminium sulphate and chloride react with the whole of their acid, and in the case of ferrous ammonium sulphate about half of the sulphuric acid reacts, corresponding to that which is in combination with iron. J. F. B.

Estimation of Total Manganese in Soils. R. A. Gortner and C. O. Rost. (*J. Ind. and Eng. Chem.*, 1912, 4, 522-524.)—As repeated treatment with hydrofluoric acid and sulphuric acid is required in order to obtain in solution all the manganese present in soils, the author recommends the following method as being more rapid. One grm. of the soil is fused with 4 grms. of sodium carbonate, the melt is dissolved in 100 c.c. of water, acidified with 130 c.c. of 35 per cent. sulphuric acid, and diluted to a volume of 250 c.c. Should a precipitate of silica separate at this point it must be removed by filtration, but a slight opalescence does not interfere. One hundred c.c. of the solution are then treated with from 0·25 to 1 grm. of sodium bismuthate, and boiled until the manganese has been oxidised to permanganate. If there is any red coloration the boiling has not been continued long enough. The solution is now cooled, and the coloration compared against a standard permanganate solution which has been prepared by reducing a potassium permanganate solution (in 20 per cent. sulphuric acid) with sulphurous acid and reoxidising the mixture with sodium bismuthate. This standard solution should contain about 0·2 mgrm. of MnO per 10 c.c. Sodium bismuthate is preferred to ammonium persulphate as an oxidising agent as it gives a better oxidation, always giving the true permanganate tint whilst persulphate is liable to produce a reddish tint.

W. P. S.

Quantitative Estimation of Thorium, especially in Monazite Sand, by Means of Sodium Hypophosphate. A. Rosenheim. (*Chem. Zeit.*, 1912, 36, 821.)—The sample (100 grms. in the case of a 5 per cent. monazite sand) is decomposed with concentrated sulphuric acid at 180° to 200° C. in the usual manner, the sulphate dissolved in cold water, and the solution made up to 1,000 c.c. When the undissolved matter has settled, 100 c.c. of the clear solution is pipetted off and mixed with 50 c.c. of concentrated hydrochloric acid and about 180 c.c. of water, and heated to boiling. A cold saturated solution of sodium hypophosphate is then added as long as continued addition gives rise to any further precipitate, and the thorium hypophosphate is filtered off and washed with water acidified with hydrochloric acid until the washings no longer give any precipitate (ceria, etc.) on addition of oxalic acid (or hydrogen peroxide) and ammonia. The precipitate of thorium hypophosphate always contains titanium, and zirconium if present in the sample, but only traces of cerium and other rare earths. Tetravalent cerium gives rise to a very insoluble hypophosphate, but the high acid concentration in which the above precipitation is made ensures the absence of tetravalent cerium. To free the thorium from titanium, zirconium, and traces of other earths, the precipitate and filter-paper are digested with sulphuric acid in a capacious platinum basin or a Kjeldahl flask with occasional addition of a crystal of nitre to hasten the oxidation of the paper. The acid is mostly boiled away, and the cooled mass taken up with water. Since anhydrous thorium sulphate dissolves with difficulty, it economises time to make the solution faintly alkaline with ammonia. When the finely-divided suspension of anhydrous thorium sulphate has given place to a flocculent precipitate of hydroxide, the mixture is made strongly acid with hydrochloric acid, boiled, and the solution of thorium chloride filtered from any trace of silica. In the hot filtrate, thorium is precipitated as oxalate, which is filtered off after twelve hours and washed with dilute hydrochloric acid until free from the last traces of cerium, zirconium, and titanium. The precipitate is finally ignited, and weighed as oxide as usual.

For purposes of works control, useful information may be obtained by igniting the original precipitate of $Th(PO_3)_2$ and weighing it as pyrophosphate, ThP_2O_7. Apart from the fact that the hypophosphate precipitate is never pure, this abbreviated method has another source of inaccuracy in that the oxidation of hypophosphate to pyrophosphate is never quite complete. As a check on manufacturing operations, however, the method is useful.

Sodium hypophosphate is not yet readily procurable, but it can be prepared by the method of Rosenheim and Pinsker (*Ber.*, 1910, **43**, 2003). It will shortly be obtainable in commerce, since a process for working up monazite sand on the large scale by its use has been described. G. C. J.

Analysis of High-Grade Tungsten Alloys. T. Kuczynski. (*Anzeiger Akad. Wiss. Krakau.*, 1911, 542-544; through *Chem. Zentralbl.*, 1912, II., 283.)—When the other constituents of the alloy form readily volatile chlorides, the alloy is conveniently opened up by heating in a current of chlorine. It need not be finely powdered. When the reaction is complete, and the tube in which it is conducted has cooled (in a current of chlorine), this tube and the Peligot tube are washed out successively with dilute hydrochloric acid and dilute ammonia. Excess of hydrochloric acid and about 5 c.c. of nitric acid are added to the liquid, which is heated to boiling, concentrated to about 60 c.c., and then allowed to cool. The separated tungstic acid is filtered off and washed, and the filtrate evaporated to dryness, to throw out of solution the last traces of tungstic acid. The residue is heated to 120° C., to render insoluble the tungstic acid, which is moistened with dilute (1 : 5) hydrochloric acid, filtered off, and washed. The combined tungsten precipitates are redissolved in ammonia, separated from a trace of iron, and the solution evaporated to dryness. The tungstic acid is transferred to a quartz crucible by the use of a little ammonia, excess of nitric acid is added, the liquid evaporated, and the residue ignited and weighed as WO_3. This method is especially useful when a determination of carbon has to be made simultaneously.

If only metals have to be estimated, decomposition of the alloy by means of nitric and hydrofluoric acids is quicker. The fragments of alloy, contained in a platinum dish, are covered with 5 c.c. of nitric acid, and 0·5 grm. of ammonium fluoride is added in small pieces at a time. The reaction, violent at first, needs the heat of a water-bath to sustain it towards the end. To the clear solution 2 or 3 c.c. of sulphuric acid are added, and the solution taken down to fuming. The cooled residue is diluted with water and 20 c.c. of hydrochloric acid, and the tungsten separated as already described. G. C. J.

Measurement of Concentration of Hydrogen Ions in Sea Water. S. Palitzsch. (*Compt.-rend. des Travaux du Lab. de Carlsberg*, 1911, **10**, 85-98.) —The concentration of hydrogen ions in sea water usually lies between $10^{-7\cdot95}$ and $10^{-8\cdot35}$. In a series of measurements made during a cruise from the Baltic to the Black Sea, the only exceptions to this generalisation were certain samples taken from great depths in the Black Sea, which contained hydrogen sulphide, but were still slightly more alkaline than pure water, the highest hydrion concentration noted being $10^{-7\cdot25}$, a number for which a lesser degree of accuracy is claimed than for the others given in the paper.

The method adopted was that of Sörensen (ANALYST, 1909, **34**, 498), in which comparison is made with a series of standard solutions, using an appropriate indicator. For the narrow range of concentrations covered by this inquiry, only two of Sörensen's fundamental standards are needed—namely, $\frac{N}{10}$ hydrochloric acid and a borate solution made by dissolving 0·2 gram-molecules (12·404 grms.) of boric acid in 100 c.c. of $\frac{N}{1}$ sodium hydroxide, free from carbonate, and diluting to 1,000 c.c. with boiled water. These two solutions are then mixed in varying proportions, to obtain a series of substandards. A mixture of 5·25 c.c. of the borate solution with 4·75 c.c. of the hydrochloric acid corresponds to a hydrion concentration of $10^{-7\cdot62}$, whilst 8 c.c. of borate and 2 c.c. of acid correspond to $10^{-8\cdot91}$. The paper includes a table showing the hydrion concentrations corresponding to many intermediate mixtures, together with the corrections to be applied for the influence on the indicator of the high saline concentration of sea water. For hydrion concentrations from $10^{-8\cdot91}$ to $10^{-8\cdot29}$, phenolphthalein is used as indicator; for higher concentrations up to $10^{-7\cdot62}$, a-naphtholphthaleïn is preferred, and is, indeed, necessary, when the concentration exceeds $10^{-8\cdot06}$, since water less alkaline than this is without influence on phenolphthaleïn.

As a general rule the hydrion concentration increases with the depth from which the sea is sampled. A series of samples taken at one spot in the Atlantic showed concentrations varying from $10^{-8\cdot22}$ at the surface to $10^{-7\cdot96}$ at 750 and 1,000 fathoms, and samples collected similarly in other seas yielded very similar results. G. C. J.

Estimation of Zinc in Ferruginous Minerals. E. Beyne. (*Bull. Soc. Chim. de Belg.*, 1912, **26**, 355-361.)—The method generally used for the assay of zinc ores in industrial laboratories is that of Schaffner. The mineral is opened up with nitric acid and hydrochloric acid, the metals of the copper and arsenic group are removed by sulphuretted hydrogen, the filtrate is collected in a 500 c.c. flask, the excess of sulphuretted hydrogen is removed by boiling, and the iron is oxidised by nitric acid. On cooling, 100 c.c. of ammonia (sp. gr. 0·92) are added, and 5 c.c. of hydrogen peroxide if manganese be present. The whole is shaken and allowed to settle until the next day, when it is filtered. Meanwhile a control solution is prepared containing approximately the same amount of pure zinc, the same amount of acid and ammonia, as the solution to be analysed. The titration of the two liquids with sodium sulphide is then conducted simultaneously, until a drop of each produces the same effect upon a strip of lead paper. The principal source of error in this procedure is caused by the co-precipitation of an appreciable amount of zinc with the ferric hydroxide, in spite of the large excess of ammonia employed. The amount of the error increases with the amounts of the two metals present. Various means have been recommended to avoid this error, and the author finds that the simplest consists in adding a comparatively large excess of ammonium chloride before precipitating the iron, a similar quantity of the salt being also added to the control solution. The actual quantity of ammonium chloride necessary has not yet been worked out for minerals containing various proportions of zinc and iron. The extent to which the error is eliminated under given conditions increases with the quantity of ammonium salt added. Thus, with a solution corresponding to 2·5 grms. of a mineral containing 40 per cent. of zinc and 20 per cent. of iron in 250 c.c., an addition of 35 to 40 grms. of ammonium chloride, before precipitating with ammonia and diluting to 500 c.c., gave the theoretical result in the titration for zinc. The addition of more than 40 grms. would begin to interfere with the sharpness of the end-point of the titration.

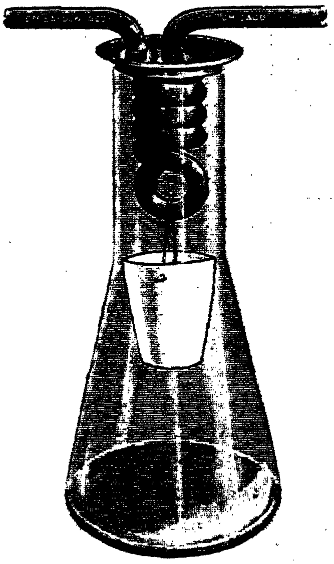
APPARATUS, ETC.

Porcelain Bunsen Burners. **E. Beckmann.** (*Zeit. angew. Chem.*, 1912, **25**, 1515-1518.)—Various forms of Bunsen burners with porcelain tubes are described and recommended for use in spectroscopic work. They may be obtained from Altmann, Luisenstrasse, 47, Berlin.

C. A. M.

Apparatus for the Detection of Carbon Monoxide. **M. A. Guasco.** (*Compt. rend.*, 1912, **155**, 282.)—Two bulbs, one of which is platinised, are carried at the extremities of a vertical U-tube, and are enclosed in a gas-tight envelope, to which the gas to be examined is admitted through a porous septum. The portion of the U-tube outside the envelope contains a coloured liquid, and is so arranged that very small differences of level, produced by differences in temperature of the bulbs due to occlusion of inflammable gases by the platinum, are readily observed. With the apparatus used, the difference in the levels in the two limbs produced by 1 volume of carbon monoxide per 1,000 was 13 mm., and by 2 in 1,000, 26 mm. The smallest quantity giving a distinct indication was 1 in 10,000. If mercury is substituted for the coloured liquid, the apparatus can readily be arranged to close a circuit, and thus release an alarm signal.

O. E. M.



Extraction Apparatus. H. J. Cary-Curr. (*J. Ind. and Eng. Chem.*, 1912, 4, 535-536.)—The apparatus described is for the determination of the constituents of rubber insulation material on wire or cord, and consists of a conical flask 6 inches high, fitted with a metallic spiral tube condenser, passing through a metal plate which forms the cover of the flask. The sample is placed in the suspended Gooch crucible, at the base of which is a disc of filter-paper. The whole is placed on a hot plate or other convenient heater, and works without need of attention, the solvent condensing at the base of the coil and dripping directly into the crucible. The increase in the weight of the conical flask is the weight of matter extracted.

H. F. E. H.

Use of the Zeiss Interferometer in the Technical Analysis of Flue Gases. O. Mohr. (*Zeitsch. angew. Chem.*, 1912, 25, 1313-1317.)—Haber and Löwe (*Zeitsch. angew. Chem.*, 1910, 23, 1393) have described a new interferometer by means of which Rayleigh's principle may be applied to problems of technical gas analysis. They confined themselves, however, to relatively simple problems, such as the determination of methane in mine air and the examination of technical hydrogen. The analysis of flue gases is complicated by the fact that they are not a mere mixture of carbon dioxide with air, nor are they air in which so much oxygen has been replaced by an equivalent amount of carbon dioxide. The sum of the percentages of oxygen and carbon dioxide is always less than the percentage of oxygen in normal air, mainly on account of the hydrogen in the fuel, and there is always the possibility that carbon monoxide may be present. The authors show, however, that the new method of analysis may be extended to flue gases. After being dried by means of sulphuric acid, the gas is passed through the interferometer chamber and a reading taken. It is then passed through a soda-lime tube to deprive it of carbon dioxide, and again through the interferometer, and another reading, which will be lower than the first, is taken. The difference between these first two readings is the measure of the carbon dioxide. With the Zeiss instrument used by the authors a difference of 0·01 scale division corresponds to 0·186 per cent. carbon dioxide. In the absence of carbon monoxide, the second reading also gives the relative proportions of oxygen and nitrogen, which are read off by reference to a straight line curve constructed from readings obtained with mixtures of oxygen and hydrogen in known proportions. From these values for oxygen and nitrogen, which together total 100 per cent., the percentage of oxygen and nitrogen in the original gas is calculated by reference to the percentage of carbon dioxide found. If the percentage of oxygen thus found plus the percentage of carbon dioxide is notably less than it should be, the presence of carbon monoxide is nearly certain. The authors have constructed several tables to facilitate the calculations. The final table is for determining whether carbon monoxide is present or not, and it gives the totals to which the percentages of carbon dioxide and oxygen should sum for four grades of fuel (from coke to brown coal), and with varying excesses of air above that necessary for combustion. G. C. J.

Determination of Melting-Points with the Aid of the Microscope. M. P. Cram. (*J. Amer. Chem. Soc.*, 1912, **34**, 954-956.)—In toxicological investigations the m.pt. of a substance too small in amount to be introduced into a capillary tube may be determined within a few degrees by the use of a compound microscope fitted with a ⅔-inch objective and magnifying 100 diameters. The diaphragm is removed, and beneath the table is clamped a section of brass tube, 3·1 cm. in diameter and 2·4 cm. long, fitted with glass windows at the end, and wound with a heating coil of "nichrome" wire through which is passed an electric current. The heating wire is impregnated with Bakelite varnish No. 2. Four yards of asbestos-covered ·020 nichrome wire are wound on, and the outside wrapped with four layers of asbestos paper. Squares of asbestos board with a hole in the centre are used above and below the tube to prevent loss of heat. The thermometer is introduced through a side-tube, the centre of which is 8 mm. above the bottom of the main tube, and the bulb is entirely within the centre of the coil, the stem extending horizontally to one side. Above the bulb of the thermometer is a wire bridge, upon which the microscope-slide which is to hold the substance is placed. Round cover-glasses 2 cm. in diameter are best adapted to hold the material to be tested. The temperature of the thermometer is not exactly that of the substance on the slide, but the true m.pt. can be found by noting the thermometer reading with substances of known m.pts. A current of 0·6 ampère gave a reading of 64° C., while a temperature of 200° C. was obtained with a current of 1·25 ampères. H. F. E. H.

New Sublimation Apparatus and its Application in Food Analysis. E. Philippe. (*Mitt. Lebensmitteluntersuch. u. Hyg.*, 1912, **3**, 41-53; through *Chem. Zentralbl.*, 1912, II., 82.)—The apparatus consists of a metal capsule of 7 cm. diameter, serving as a condenser, inverted with its lower edge resting on the convex surface of a watch-glass of 11 cm. diameter, with the interposition of a soft rubber ring about 12 mm. wide and 6 to 7 mm. thick, and held in position by three spiral spring clips. Through the top of the capsule pass two tubes of 8 mm. diameter, serving for the circulation of the cooling-water. The watch-glass is placed with its concave side on a flat glass dish with a ground edge, having a height of 3 cm. and a diameter slightly smaller, or at any rate not larger, than that of the capsule. The arrangement rests on a tripod with a double wire gauze. The apparatus is intended for quantitative sublimations, and is applicable for the estimation of salicylic and benzoic acids in foods. Tests made with various sublimable substances showed a yield generally of over 95 per cent. The greatest loss was experienced with vanillin —viz., 5·5 per cent. After each estimation the previously tared watch-glass is wiped on its under side, and the sublimate is dried in the desiccator for half an hour before weighing. In the estimation of salicylic acid in milk an error of about 33 per cent. was found, owing to the fact that some of the salicylic acid was carried down in the precipitation of the milk with copper sulphate and sodium hydroxide; in the estimation of benzoic acid in milk the yield ranged from 84·81 to 96·41 per cent. In fruit preserves and fruit juices the estimation of salicylic acid by sublimation of the ethereal extract gave results agreeing well with the bromine titration method. For the estimation of salicylic acid in a coffee substitute preparation, 10 grms. were freed from fat by petroleum spirit, treated with 10 c.c. of ammonia, extracted with chloroform, and the chloroform extract was submitted to sublimation. The results were in good concordance with the estimation by the Trillich-Göckel method. J. F. B.

Beckmann Thermometer with a Modified Arrangement for setting the Mercury Thread. A. Kuhn. (*Chem. Zeit.*, 1912, **36**, 843.)—The construction of the thermometer is shown in the illustrations. The excess of mercury is brought into the two side limbs by simply inclining the thermometer, and the capillary may be filled by a reverse movement, the lower reservoir of the instrument being at the same time warmed until the mercury thread reached the elongated point *a* of the capillary (Fig. 3). The opening at the point *a* is of such size that each drop of mercury flowing from it measures 1° C. on the scale. It is not necessary to tap the thermometer during these operations. W. P. S.

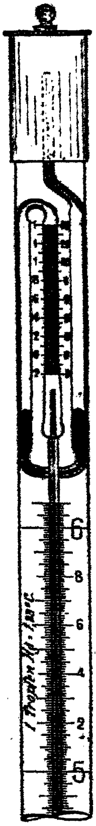


FIG. 1.

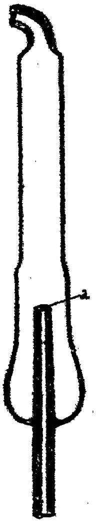

FIG. 3.

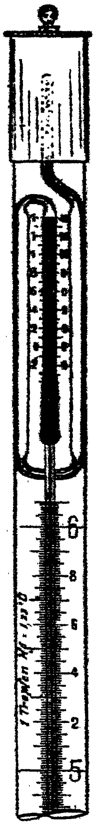

FIG. 2.

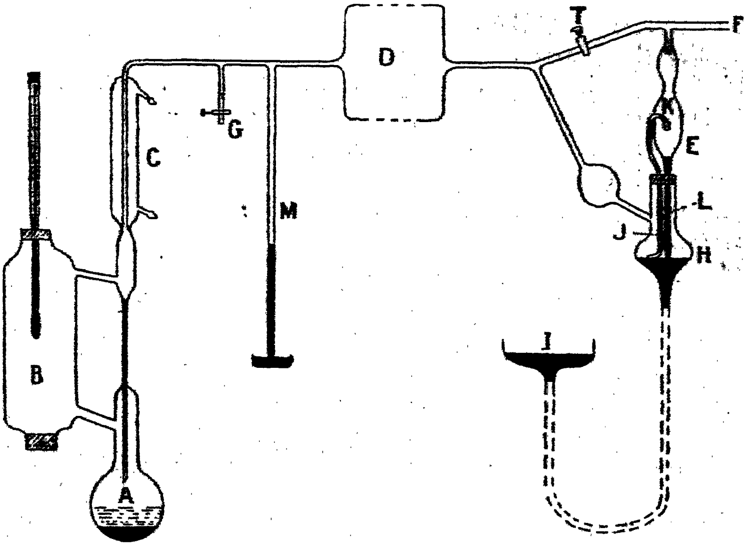
New Hand Photometer. W. J. Dibdin. (*J. Soc. Chem. Ind.*, 1912, **31**, 624-625.)—The present instrument is a development of the author's radial photometer described in 1884. It is a portable instrument, weighing 6 pounds, and measuring 17 × 5 × 5 inches, and may be used for comparison of lights in rooms, streets, etc. The instrument is designed to embrace three conditions: (1) Maximum open scale readings; (2) convenience and accuracy in comparing lights of different colours; (3) reliability, by reason of the facility with which its indications can be checked. The open scale readings are obtained by the employment of an electric incandescent lamp, the current to which (from a storage cell) is regulated by means of a rheostat giving an unusually lengthy movement of the contact-point, the position of which is read on a scale graduated in terms of "foot-candles." This arrangement allows of more delicate measurements than by direct readings of the voltmeter, which is also fitted in the instrument to check the working of the storage cell. The comparison of lights of different colours is secured by means of the author's improved form of Leeson's star-disc. Readings of this instrument compared simultaneously with those of a standard photometer show it to give accurate results, the figures differing by +0·01 to −0·04 foot-candles, with an average of −0·01 for twelve readings.

To ascertain the "illuminating power" of any radiant, the square of the distance in feet from the photometer disc is multiplied by the "foot-candle" power observed. As the instrument indicates up to 12 foot-candles, a light at 25 feet distance giving that degree of illumination would have an intensity of 7,500 candles; while if the power at the same distance was only 0·001 candle (lowest observable), the initial intensity would only be 0·625. The range of the instrument is thus wide enough for all ordinary purposes. A. R. T.

Easily Adjustable Vapour Thermostat. J. Fletcher and D. Tyrer. (*Proc. Chem. Soc.*, 1912, **28**, 189-192.)—The authors describe a vapour-bath which can be maintained constant with very little trouble to 0·005° C., and can be fixed at any desired point (say, between 30° C. and 130° C.) with the greatest ease. In principle it consists of a pure liquid boiling under a constant and adjustable pressure, which is controlled and maintained constant by an efficient manostat. Practically any liquid of suitable boiling-point may be used. The boiling liquid is contained in the flask *A* (see diagram). The vapour passes into the compartment *B*, which may be of any particular form suitable; *B* also contains a thermometer, as shown. The vapour is then condensed in *C*, and returns as liquid to the boiling flask *A*. The end of the condenser *C* is connected, as shown, with an air reservoir, *D*, of about 10 to 20 litres capacity (the larger the size of this reservoir the greater is the efficiency of the apparatus), and then to the manostat *E*. The manostat, being the most important part of the apparatus, is described at some length, and for the sake of



clearness has been drawn in the diagram on a rather large scale. The tube *F* is attached to an efficient water-pump. The degree of exhaustion is first roughly adjusted by allowing air to enter by the side-tube and pinch-cock *G*. The mercury rises into the bulb *H* out of the reservoir *I* until the level reaches the end of the tube *J*, when it stops and remains constant. If it passes this point, it closes off the rest of the apparatus from the pump; and as air is entering through the side-tube *G*, the pressure increases, and the level of the mercury in the manostat falls again. As soon as the end of the tube *J* becomes uncovered, the pump again comes into play, and rapidly reduces the pressure, causing the mercury level to rise again. When equilibrium is reached, the level of the mercury remains constant, and a continual current of air and mercury passes up the tube *J* into the compartment *K*, from whence the mercury falls back into the bulb *H* by the tube *L*, and the air passes off through the pump. It will be clear that the difference in the levels of the mercury in *H* and *I* represents the pressure in the apparatus, and the adjustment of this pressure is merely made by altering the height of the reservoir.

For the proper working of the manostat it is necessary to have a large air-supply to draw from, otherwise the mercury level in *H* rises and falls irregularly. This is the purpose of the air reservoir *D*. Although the level of the mercury in *H* may fluctuate slightly, the pressure recorded by the manometer *M* remains perfectly constant. In order to raise the temperature in *B*, the mercury reservoir *I* is raised, and to lower the temperature it is merely necessary to lower *I*.

For the efficient working of the apparatus the author insists that attention should be paid to the following details: The reservoir should be shallow, so that if the vessel *K* partly fills with mercury, as sometimes happens, the difference in the mercury levels in *H* and *I* is not appreciably altered. The end of the tube *J* should be a narrow slit not wider than 0·5 mm., and bent horizontally. The width of this slit insures that the greatest possible variation in the pressure is 0·5 mm., although the actual variation need not exceed 0·1 mm. In order to accelerate the initial exhaustion of the apparatus, the tap *T* is provided as a by-pass, which at all other times must be closed. The connecting tubes should be of wide bore, so that the pressure at all parts of the apparatus is absolutely the same. The boiling liquid used must be pure, and must boil quietly without bumping. It is found that bumping is prevented, however low the pressure, by placing in the flask *A* a layer of mercury as indicated. It is better to boil the liquid over a small free flame shielded from draughts. If the efficiency of the water-pump varies considerably, and if it is desired to have a very constant temperature, it is better to use two manostats connected together with an air reservoir and air inlet tube between them. The temperature can, however, be maintained constant to about 0·01° C. with one manostat.

If rubber stoppers are used, an alcohol should be employed as the boiling liquid, but with ground-glass connections lubricated with glycerol-dextrose mixture any liquid can be used. For temperatures ranging from 30° to 65° C. the authors recommended methyl alcohol, from 40° to 70° C. ethyl alcohol or benzene, and for higher temperatures toluene or xylene.

In experiments made with a Beckmann thermometer in *B*, and with a double manostat, it was found that for short periods of time the temperature remained constant to 0·001° C. For longer periods the variation is greater; but so long as the atmospheric pressure remains unchanged, the temperature remains constant to about 0·005° C.

It is claimed that this form of thermostat has many advantages over the usual large water-bath. It is more quickly adjustable, and need not be left going for long periods of time, as it is only a matter of a few minutes to start it again.

GOVERNMENT REPORTS.

Regulations under the Public Health (Regulations as to Food) Act, 1907.—Sir,—I am directed by the Local Government Board to advert to the Public Health (Regulations as to Food) Act, 1907 (7 Edw. VII., c. 32), under which the Board are empowered to make regulations authorising measures to be taken for the prevention of danger arising to public health from the importation, preparation, storage, and distribution of articles of food or drink (other than drugs or water) intended for sale for human consumption. In connection with the powers thus conferred the Board have for some time had under consideration and inquiry the danger to health which may be entailed by the addition of preservatives and other foreign substances to milk and cream and the importance of controlling such additions, and they have now made Regulations under that Act entitled "The Public Health (Milk and Cream) Regulations, 1912." Copies of an Order containing these Regulations are enclosed.

In making these Regulations due regard has been had to representations which the Board have received from local authorities under the Sale of Food and Drugs Acts, from representatives of the trades affected and from others concerned.

The Regulations are designed to secure that no preservatives shall be added to milk, or to cream containing less than 35 per cent. by weight of milk fat, at any stage from the place of production to that of delivery to the purchaser. In the case of cream containing over 35 per cent. of milk fat, the addition of boric acid, borax, or a mixture of these preservative substances, or of hydrogen peroxide, is not prohibited by the Regulations, but is subject to a system of declaration which is required to be followed by all persons dealing with such cream for the purpose of sale for human consumption. By this system (Part II. of the Regulations) it is intended that preserved cream as an article of commerce shall in all stages be differentiated from cream to which no preservative has been added. Further, Article IV. (*a*) prohibits the addition of any thickening substance to cream or preserved cream.

It will be seen that except as regards Part III. the duty of administering the Regulations has been placed upon those authorities in England and Wales who are Local Authorities under the Sale of Food and Drugs Acts.

Existing arrangements for the collection and examination of milk samples under the Sale of Food and Drugs Acts can readily be extended so as to enable the Council to receive such reports from the public analyst as are requisite. Arrangements will be required for the periodical examination of samples of cream for the purpose of ascertaining whether the requirements of the Order are being duly complied with.

In the case of any contravention of the Regulations, steps should be taken to ascertain the circumstances in which the default has arisen, with a view to any necessary action. Article VI. requires that before the Local Authority institute proceedings against any person for contravention of any of the Regulations in Part II. of the Order, the Local Authority shall afford him an opportunity of furnishing an explanation, and shall consider such explanation and all the circumstances of the case. It should be observed that the proceedings here in question are those authorised by the Public Health (Regulations as to Food) Act, 1907, and the enactments referred to in the Notice at the foot of the Order.

It will be desirable that the Medical Officer of Health should be instructed to exercise general supervision over the action taken in pursuance of these Regulations, and that the officer of the Council who directs sampling under the Sale of Food and Drugs Acts, should be instructed to confer with the Medical Officer of Health and with the Public Analyst as to the details of procedure necessary to secure the observance of the Regulations in the area over which the Council has supervision.

The Regulations will as regards their main provisions take effect on and after October 1 next, and as regards Article V. (1) on January 1, 1913. The Board are anxious to secure uniformity in the administration of the Regulations, and will be glad to have their attention drawn to any cases of difficulty which may hereafter arise.

Copies of the Regulations and of this Circular are enclosed for transmission to the Medical Officer of Health and Public Analyst.

The Regulations and this Circular will be placed on sale, so that copies may shortly be obtained, either directly or through any bookseller, from Messrs. Wyman and Sons, Limited, Fetter Lane, London, E.C.

I am, Sir,
Your obedient Servant,
H. C. MUNRO, *Secretary*.

THE TOWN CLERK *or* THE CLERK TO THE COUNTY COUNCIL.

The draft of the Regulations was published in the ANALYST, 1912, 109-115. In the final form the following alterations have been made:

Page 110 (March issue of the ANALYST), line 7 from bottom, *for* "40" *read* "35."

Page 110, line 4 from bottom, delete "in amount not exceeding 0·1 per cent. by weight."

	Inches. Inches.
Not exceeding 1 pint	¾ by 1¾
Exceeding 1 pint	3 by 5

Circular to Local Authorities in England and Wales for the Purposes of the Sale of Food and Drugs Acts, 1875 to 1907.—SIR,—I am directed by the Board of Agriculture and Fisheries to enclose herewith a copy of the Sale of Milk Regulations, 1912.

These Regulations amend the Sale of Milk Regulations, 1901, in so far as they relate to skimmed or separated milk, and replace the limit of 9 per cent. of total milk-solids on which, under Article 3 of those Regulations, a presumption that the milk is not genuine is based, by a limit of 8·7 per cent. of milk-solids other than milk-fat.

Representations have been received from time to time from Local Authorities of districts where there is a trade in skimmed and separated milk that considerable practical difficulties arise in instituting proceedings in cases in which water has been added to skimmed milk, but, owing to the fact that the milk has been imperfectly skimmed, the total solids have not fallen below 9 per cent. Thus a sample containing 1·5 per cent. of fat and 7·5 per cent. of milk-solids other than milk-fat would probably contain over 12 per cent. of added water, but the total solids are up to the limit of 9 per cent. The present Regulations are intended to obviate these difficulties and to facilitate the prevention of the adulteration of skimmed milk with water.

The fixing of the percentage at 8·7 may result in some hardship in cases where the milk is imperfectly skimmed. Thus, if milk containing 3 per cent. of milk-fat and 8·5 per cent. of milk-solids other than milk-fat is imperfectly skimmed, so that 1·5 per cent. of milk-fat remains, the proportion of milk-solids other than milk-fat will rise only to 8·63 per cent., and the Board would suggest that this point should be taken into account by your Local Authority in considering the question whether they should institute proceedings on the presumption of adulteration based on the Regulations in cases where the deficiency of milk-solids other than milk-fat is slight and the skimmed milk contains a considerable proportion of milk-fat.

I am to enclose duplicate copies of this Circular and of the Regulations for transmission to the Public Analyst, and to say that the Board will be glad to supply further copies of the Circular for distribution amongst the members of your Local Authority and the officers concerned in the administration of the Acts on being informed of the number you require.

I am, Sir,
Your obedient Servant,
T. H. ELLIOTT, *Secretary.*

THE CLERK TO THE LOCAL AUTHORITY.

BOARD OF AGRICULTURE AND FISHERIES,
August 20, 1912.

Statutory Rules and Orders, 1912, No. 687: Adulteration (Sale of Food and Drugs Acts)—The Sale of Milk Regulations, 1912. *(Dated June* 29, 1912.)—The Board of Agriculture and Fisheries, in exercise of the powers conferred on them by Section 4 of the Sale of Food and Drugs Act, 1899, do hereby make the following Regulations:

Skimmed or Separated Milk.—(1) Where a sample of skimmed or separated milk (not being condensed milk) contains less than 8·7 per cent. of milk-solids other than milk-fat, it shall be presumed for the purposes of the Sale of Food and Drugs Acts, 1875 to 1907, until the contrary is proved, that the milk is not genuine, by reason of either the addition thereto of water or the abstraction therefrom of milk-solids other than milk-fat.

Revocation of Existing Regulation.—(2) Regulation 3 of the Sale of Milk Regulations, 1901, is hereby revoked, but not so as to affect the validity of any certificate of analysis given before the commencement of these Regulations or any legal proceedings in respect of any sample to which any such certificate relates.

Commencement.—(3) These Regulations shall come into operation on the First day of September, One thousand nine hundred and twelve.

Extent.—(4) These Regulations shall extend to England and Wales.

Short Title.—These Regulations may be cited as the Sale of Milk Regulations, 1912.

In witness whereof the Board of Agriculture and Fisheries have hereunto set their official seal this twenty-ninth day of June, One thousand nine hundred and twelve.

(L.S.) T. H. ELLIOTT, *Secretary*.

REVIEWS.

PRINCIPES THÉORIQUES ET PRATIQUES D'ANALYSE MINÉRALE. G. CHESNEAU. Ch. Béranger, Paris. 1912. Price 25 francs.

The author describes this book as a guide for engineers to the analysis of industrial minerals, but it is more truly a comprehensive treatise on inorganic analysis; and though written from the standpoint of the works manager or the mining engineer, it will be of considerable value to the professional chemist.

The first part, which deals with theoretical principles and general methods of analysis, is exceptionally good. It sets forth the *rationale* of analytical manipulation with a completeness and lucidity all too rare in professedly "practical" handbooks. The theory of washing precipitates is fully discussed, and the relation of solubility to size of particles is considered, and the reason why digestion usually diminishes the fineness of a precipitate is indicated. Gelatinous precipitates and the precautions necessary in dealing with them receive full consideration. The equilibrium conditions of the reactions suitable for analytical purposes are discussed with a view to the elucidation of the two fundamental problems—to produce a precipitate as little soluble as possible, and to dissolve insoluble bodies.

Qualitative analysis is next considered; general methods and a complete scheme for the detection of metals are given.

The first part closes with an excellent chapter on the general processes of quantitative analysis. The degree of accuracy attainable in volumetric processes is discussed, and emphasis is laid upon the advantages of the comparative method, in which a "standard" is treated in exactly the same way as the sample.

In the second part the elements are studied separately. The principal sources and uses are first given for each element and its industrially valuable compounds; then its distinguishing characteristics and the analytical properties made use of for its detection and estimation are described. This is followed by an account of selected methods for the separation and estimation of the element in question, and the application of these methods to minerals and manufactured products.

On the whole, the methods chosen are authoritative and reliable, though some are rather unfamiliar to English practice. All are very carefully described, with due attention to such points as concentration of solutions, temperature, strength of acid, etc. Following the treatment of hydrogen, the general question of acidity is dealt with and the theory of indicators outlined. A section is also devoted to water analysis. Phosphorus and phosphoric acid are well treated. Under "Arsenic" the method of Fresenius and Babo is given. This allows of the detection of one-thousandth of a milligram of arsenious acid, and its differentiation from antimony. The consideration of carbon is followed by methods for the estimation of common hydrocarbons, elementary organic analysis, and the analysis of fuels. The chapter on the iron group opens with a clear discussion of the conditions necessary for the separation of the metals as sulphides and acetates. Somewhat surprising is the absence of any mention of the bichromate method for iron estimation.

The analysis of iron and steel is treated in considerable detail. Besides the usual dry and wet combustion methods for carbon, a volumetric method is described. The apparatus appears to be rather complicated, and, as only one determination can be made in two hours, its advantages are not very obvious. The Eggertz colour method is reviewed, with due warning as to its limitations. For sulphur, the only oxidation process described is the "Arnold" method, in which aqua regia is used together with bromine and potassium chlorate, and the precipitation with barium chloride is made in the cold. The molybdate method described for phosphorus, involving two precipitations of the phosphomolybdate, is decidedly tedious and complicated. No magnesia method is given. Several colour methods for manganese are described, including the persulphate process, which is certainly the simplest and most expeditious. In dealing with the "rare" elements, a preliminary treatment by the ether method of Rothe is recommended. This accomplishes a nearly complete separation of the iron from all the other elements except molybdenum. The estimation of nickel by means of dimethylglyoxime is described, but the cyanide titration in presence of ammonium citrate is not mentioned.

The metals of the copper and tin groups are well treated, and methods for the analysis of their alloys are given.

Like most French publications, the book lacks an index, but there is an alphabetical list of minerals of which the analysis is given.

The printing is good, and the diagrams are clear and well chosen.

F. W. HARBORD.

THE ANALYST'S LABORATORY COMPANION. Fourth Edition. By ALFRED E. JOHNSON, B.Sc. (Lond.), F.I.C., A.R.C.Sc.I. 1912. London: J. and A. Churchill. Pp. ix + 164. Interleaved with blank pages.

As a small work of reference for chemical and physical data, this edition of Mr. Johnson's book deserves commendation. The numerous tables have been revised where necessary, and some further tables have been added, the International Atomic Weights for 1912 being adopted. Considering, however, that refractometric methods of analysis are being employed to an increasing extent, it is rather surprising that space has not been found for tables showing the relation between refractive index and percentage content of solutions of various substances.

The notes on analysis have also been revised and amplified, some very useful additions being the standards for sewage effluents recommended by the Royal Commission on Sewage Disposal (Fifth Report, issued in 1908), and the chief provisions of the Draft of "The Public Health (Milk and Cream) Regulations, 1912," issued by the Local Government Board. In the section dealing with the cupric reducing power of the carbohydrates, a method for the gravimetric estimation of reducing sugars is described, but no mention is made of the volumetric method now so generally used.

Considerable space is devoted to chemical calculations. At p. 36, Mr. Johnson justly condemns the calculation of analytical results to an unwarrantable number of decimal places, but falls into the same error himself at p. 107, where the percentages of dextrose and maltose in a commercial "glucose" are given to the second decimal place.

On the whole, however, the revision has been done very carefully, the errors observed are few, and for the most part trivial, and the new material has been judiciously selected. The book is of a convenient size, and should prove very useful in the laboratory. LEWIS EYNON.

INSTITUTE OF CHEMISTRY.

PASS LIST: JULY EXAMINATIONS, 1912.

Of thirty-five candidates who presented themselves for the Intermediate Examination, eighteen passed: C. A. Adams, B.Sc. (Lond.), Miss D. J. Bartlett, L. O. Brekke, B.Sc. (Leeds), H. B. Brown, F. G. Conyers, E. D. Goddard, B.Sc. (Lond.), J. B. Gray, F. A. Hatch, M. Howie, D. W. Kent-Jones, E. Marsden, Miss E. G. Mocatta, B.Sc. (Lond.), E. A. Rayner, B.Sc. (Lond.), W. S. Ritchie, B.Sc. (Lond.), W. G. Saunders, D. E. Sharp, B.Sc. (Aberdeen), T. F. Smeaton, and W. A. Storey. Of thirty-seven candidates who presented themselves for the Final Examination, twenty-eight passed. In the branch of Mineral Chemistry: C. R. Chown, A.R.C.S. (Lond.), B.Sc. (Lond.), H. Gilmour, W. P. Harmsworth, J. G. King, H. Knight, P. G. Knapman, B.Sc. (Lond.), and R. H. Truelove, B.Sc. (Lond.), A.R.C.S. (Lond.). In the branch of Metallurgical Chemistry: E. O. Jones, B.Sc. (Lond.), A.R.C.S. (Lond.), W. A. C. Newman, B.Sc. (Lond.), A.R.C.S. (Lond.), and E. W. Yeoman, B.Sc. (Lond.), A.R.C.S. (Lond.). In the branch of Physical Chemistry: J. I. Crabtree, B.Sc. (Vict.), and Miss A. M. Finney, B.Sc. (Birm.). In the branch of Organic Chemistry: J. L. S. Allan, J. Crawford, G. J. Eastburn, J. H. Naylor, M.Sc. (Manc.), F. G. Rawling, M.Sc. (Leeds), S. Robertson, A. Wilson, T. A. Wilson, and T. Wright. In in the branch of the Chemistry of Food and Drugs, and of Water: S. W. Bunker, B.Sc. (Lond.), D. H. B. Cowman, B.Sc. (Lond.), A. Gemmell, B.Sc. (Edin.), C. L. Hinton, H. Raistrick, B.Sc. (Leeds), M. J. Robb, B.Sc. (Aberdeen), and S. B. Tallantyre.

OCTOBER, 1912 Vol XXXVII., No 439.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE IODIMETRIC TITRATION OF SULPHITES IN PRESENCE OF ALCOHOL AND SUGARS.

By JULIAN L. BAKER, F.I.C., and F. E. DAY, B.Sc., A.I.C.

In a paper published recently (*J. Inst. Brewing*, 1911, **17**, 465; Analyst, 1911, **36**, 495), dealing with the behaviour of sulphites added to beer for preservative purposes, we showed that the bulk of the sulphite combines with various constituents of the beer, with the formation of stable, chemically inert bodies. We based this conclusion partly on the differences between the results obtained by direct titration and by the distillation method. K. Farnsteiner (*Zeitsch. Untersuch. Nahr. Genussm.*, 1902, 5, 1124) employed a method for estimating sulphites in light-coloured liquids, such as lime-juice, which consisted in adding alkali and then acid previously to titration. We found that under these conditions a higher value for sulphurous acid is obtained than by direct titration.

Among several constituents of beer, whose action on sulphites we tested separately, was alcohol, industrial spirit, partially purified by repeated distillation, being employed. We have considered it desirable to repeat our experiments, using pure alcohol; and, contrary to our expectations, we have found that the results obtained by Farnsteiner's method were considerably lower than by direct titration.

Potassium hydrogen sulphite was made up to $\frac{N}{20}$ strength with (*a*) distilled water containing 5 per cent. by volume of pure alcohol, and (*b*) distilled water alone. Twenty c.c. portions diluted with water were titrated with $\frac{N}{10}$ iodine under varying conditions:

Time after Preparation of Solution	C c. Iodine used.		
	Direct Titration.	After Acidifying with HCl.	Farnsteiner's Method.
5 per cent. alcohol:			
½ hour	9·70	9·2	8·90
20 hours	9·55	—	9·10
70 ,, ...	9·40	9·0	8·95
No alcohol:			
At once	9·80	9·3	8·80
70 hours	9·40	—	8·65

Though the results are unaffected by the presence of alcohol, which plainly does not combine with the sulphite, yet the difference in the values of the second and third columns as compared with the first is marked, and in the opposite sense to that anticipated. The purity of the reagents was beyond question, and, if the acid and alkali were previously mixed and then added to the sulphite solution, a normal titration result was obtained. It seemed probable to us that the oxygen dissolved in the liquid might be the cause of this difference, and the following experiments were made to throw some light on the matter: A $\frac{N}{10}$ solution of potassium hydrogen sulphite was titrated with $\frac{N}{10}$ iodine under varying conditions, 70 c.c. of either distilled or tap water (both saturated with air, unless otherwise stated) being used to dilute the liquid before titration. In the table, the results obtained by diluting with distilled and tap water are recorded in separate columns, and the constituents of the mixture titrated are given in the order in which they were added. The total volume titrated in most cases was 80 c.c., which contains approximately 0·0007 grm. dissolved oxygen:

Mixture in Titration Flask.	Time between Mixing and Titrating.	C.c. Iodine used.	
		70 c.c. Distilled Water.	70 c.c.* Tap Water.
5 c.c. sulphite + 70 c.c. water	At once	5·0	4·9
5 c.c. sulphite + 2 c.c. concentrated HCl	At once	5·0	4·6
	7 minutes	—	4·6
5 c.c. sulphite + 70 c.c. water + 5 c.c. 6 per cent. NaOH + 2 c.c. HCl	At once	4·3	4·8
	3 minutes	—	4·3
5 c.c. sulphite + 70 c.c. freshly-boiled water and 5 c.c. 6 per cent. NaOH + 2 c.c. HCl	At once	4·8	—
5 c.c. sulphite + 70 c.c. freshly-boiled water + 5 c.c. concentrated HCl	At once	4·8	—
70 c.c. water + 5 c.c. 6 per cent. NaOH + 2 c.c. HCl + 5 c.c. sulphite	At once	5·0	5·0
	7 minutes	—	4·7

It is evident that in dilute acid solutions the sulphite rapidly combines with the dissolved oxygen, and it seems likely that the action is hastened by the act of neutralising the added alkali, thus exhibiting the phenomenon of an "induced reaction." The amount of oxygen dissolved in the solution is capable of oxidising 0·9 c.c. of $\frac{N}{10}$ sulphite. It will be noted that the addition of a considerable quantity of hydrochloric acid appreciably lowers the titration value. The experiments plainly show the inaccuracy of estimating the amount of sulphurous acid in liquids by Farnsteiner's method.

Having traced the source of the discrepancy in the previous results to the disturbing effect of dissolved oxygen, and having also shown that pure alcohol does not combine with sulphites, experiments similar to those described in our previous paper were carried out with alcohol derived from various sources. A $\frac{N}{10}$ solution of potassium hydrogen sulphite was prepared, containing 5 per cent. of the alcohol under examination, and titrated with iodine. In the table, the column headed "real loss" represents the difference between the amount of sulphurous acid actually present after four weeks, as determined by the distillation method, and that originally present. The "apparent loss" is the difference between the amount shown by direct titration and that originally present; this value includes the "real loss," together with the amount of sulphite in stable combination. The difference between the "apparent loss" and the "real loss" is a measure of the sulphite in combination:

---

* This water had a distinct alkaline reaction to methyl orange.

	C.c. $\frac{N}{10}$ Iodine Solution used.						Expressed as c.c. $\frac{N}{10}$ Iodine.			
	By Direct Titration after—				After 4 Weeks.		Apparent Loss.		Real Loss.	Combined SO_2.
	½ Hour.	4 Hours.	23 Hours.	50 Hours.	Direct.	Distilled.	23 Hours.	4 Weeks.	4 Weeks.	4 Weeks.
Pure alcohol ...	10·00	9·90	9·90	9·9	9·20	9·40	0·10	0·80	0·60	0·20
Alcohol distilled from old ale ...	9·70	9·95	9·95	9·8	9·35	9·55	0·05	0·65	0·45	0·20
Methylated spirit ...	9·45	9·45	9·25	9·2	9·10	9·60	0·75	0·90	0·40	0·50
Brandy	10·15	9·90	9·90	9·8	9·70	9·90	0·10 0·25	0·30 0·45	0·10 0·25 *	0·20

It would be expected that the "real loss" would be greater where least combination had occurred, but this idea is hardly borne out by the last column. For example, the "real loss" is far less in the case of brandy than in that of pure alcohol, whereas, according to the results, the amount of sulphite in combination is the same. As regards odour and flavour of sulphurous acid, the test solutions were arranged as above, most odour—and it is to be supposed least combination—occurring in the solution with pure alcohol, and least odour and most combination in the brandy solution. This was confirmed by blowing a litre of air, during a seven and a half minutes' period, through 10 c.c. of each. On titration with iodine the following figures were obtained:

	Pure Alcohol.	Alcohol from Old Ale.	Methylated Spirit.	Brandy.
Before	9·20	9·35	9·10	9·70
After	8·75	9·10	9·05	9·60
Loss	0·45	0·25	0·05	0·10

---

* The diluted brandy showed a slight initial absorption of iodine, which has been allowed for in the lower set of figures.

These figures confirm the previous "real losses," and from these experiments we infer that at least two states of combination exist between sulphites and some constituent of alcohols of commercial origin. One results in either decreased volatility of the sulphurous anhydride, or resistance to oxidation by molecular oxygen; the other, more stable, resists even oxidation by iodine. The latter state seems to occur but slightly in the case of pure alcohol, or alcohol derived from fermented liquids, but is exhibited in a marked degree even by good quality methylated spirit.

In our previous paper we showed that there was a considerable amount of combination between maltose and dextrin and sulphites. We have extended these observations by including glucose and cane-sugar. A 10 per cent. solution of the sugar was mixed with $\frac{N}{5}$ potassium hydrogen sulphite and titrated with $\frac{N}{10}$ iodine:

Sugar.	C.c. Sugar Solution.	C.c. $\frac{N}{5}$ $KHSO_3$.	Duration before Titration.	C.c. $\frac{N}{10}$ Iodine.
Glucose	5·0	10·0	—	19·4
"	10·0	10·0	10 minutes	19·4
"	50·0	10·0	10 minutes	19·3
Sucrose	10·0	10·0	—	20·0
"	40·0	10·0	—	20·0
"	50·0	10·0	5 minutes	20·0

The apparent loss of sulphite caused by the addition of glucose is striking, and can probably be correlated with its aldehydic constitution, which would explain why cane-sugar does not show any such effect.

The conclusions to be derived from the preceding experiments are, we consider, as follows:

1. That sulphurous acid is readily oxidised by dissolved oxygen in dilute acid solution.

2. That this action is greatly facilitated by the occurrence in the solution of a reaction between alkali and acid. This obviously affects the results obtained by the method of sulphite estimation proposed by Farnsteiner (*loc. cit.*).

3. That commercial alcohols and alcoholic liquids contain substances capable of combining with sulphites. These substances partially prevent the oxidation of sulphites by iodine.

4. That glucose, by virtue of its aldehydic structure, combines to a certain extent with sulphites, but cane-sugar does not.

STAG BREWERY, LONDON.

* * * * *

THE GRAVIMETRIC SEPARATION OF ZINC AND NICKEL.

BY T. COCKBURN, F.I.C., A. D. GARDINER, AND J. W. BLACK.

THE unsatisfactory results obtained by the commoner methods for the separation of zinc and nickel renders the analysis of German silver a matter of some difficulty.

For the purpose of our inquiry we selected a few of the better-known processes, omitting those involving the use of cyanides or fixed organic acids, whilst we directed special attention to obtaining zinc sulphide in a form in which it could be filtered—a desideratum which is frequently unattainable.

In order to obtain strictly comparable results, the same standard solutions of zinc and nickel and the same graduated glass apparatus were used throughout.

1. *Precipitation of Zinc as Zinc Sulphide from an Acetic Acid Solution.*—We found considerable difficulty in finding the correct conditions when employing this process. In many of our trials, either the precipitation of the zinc or the physical condition of the zinc sulphide proved unsatisfactory, but by adhering to the following details our best results were obtained:

To a faintly acid solution of the two metals a solution of sodium carbonate is added until a faint turbidity is produced, then 100 c.c. glacial acetic acid, the solution thoroughly cooled, and hydrogen sulphide passed into it for one hour at the rate of about 2 bubbles per second (*cf.* Lewis, *J. Soc. Chem. Ind.*, 1909, **78**, 587).

These conditions insure the production of zinc sulphide perfectly white in colour, and in a granular form permitting of easy filtration. The precipitated zinc sulphide is allowed to stand in the cold for some hours, and the clear supernatant liquid then completely decanted through a hardened Schleicher and Schüll No. 5 paper. The precipitate is washed with sulphuretted hydrogen water containing 2 per cent. ammonium acetate. After drying, the precipitate is separated from the paper, and ignition started at a low red heat, the temperature being gradually increased until a bright red heat is obtained. The duration of the ignition at a gradually rising temperature lasted one hour, when the zinc sulphide was entirely converted into zinc oxide.

The precipitates were tested for nickel by the exceedingly delicate reaction discovered by Tschugaeff (*Chem. Zeit. Rep.*, 1905, **29**, 247)—namely, the production of a dark scarlet nickel glyoxime when to the dilute hydrochloric acid solution of the precipitates, made slightly ammoniacal, was added an alcoholic solution of dimethylglyoxime:

TABLE I.

No. of Experiment.	Weight of Zinc taken.	Weight of Nickel taken.	No. of c.c. of Glacial Acetic Acid.	Total Volume of Solution.	Weight of Zinc found.	Difference.
1	0·1102	0·1934	40	210	0·1105	+0·0003
2	0·2203	0·1934	50	260	0·2211	+0·0008
3	0·3672	0·1934	100	260	0·3675	+0·0003
4	0·3672	0·1934	100	260	0·3668	−0·0004
5	0·6793	0·1934	100	260	0·6791	−0·0002

The results were negative in the instances shown in Table I., but we found that when using larger quantities of nickel there was a tendency for nickel to appear in the zinc precipitate, and consequently high results were obtained.

2. *Precipitation of Zinc as Zinc Sulphide in Presence of Formic Acid (Waring's Method).*—This process, which we prefer to the acetic acid method, was operated as described in Low's "Technical Methods of Ore Analysis," 5th ed., p. 294.

To the acid solution of zinc and nickel is added a drop of methyl orange, then from a pipette a very dilute solution of sodium hydroxide is run in until the pink colour barely but permanently changes to a light yellowish tint. Then sufficient formic acid (50 per cent. strength) is added drop by drop just to restore the permanent pink colour, and ½ c.c. is added in addition. The solution is diluted to about 250 c.c. (or so that 100 c.c. contains not more than 0·2 grm. of metallic zinc), and heated to about 80° C. Sulphuretted hydrogen is then passed through the solution under a slight pressure, and when the zinc has been completely precipitated the flask is disconnected, the precipitate allowed to subside, and the clear supernatant liquid passed through a hardened No. 5 filter or ordinary Swedish filter-paper, and the precipitate washed with hot water. As in the foregoing process, the zinc was weighed as zinc oxide:

TABLE II.

No. of Experiment.	Weight of Zinc taken.	Weight of Nickel taken.	Weight of Zinc found.	Difference.
	Grm.	Grm.	Grm.	
1	0·3672	0·0704	0·3684	+0·0012
2	0·1836	0·0704	0·1844	+0·0008
3	0·1836	0·1760	0·1827	−0·0009
4	0·0734	0·1760	0·0724	−0·0010
5	0·0734	0·3521	0·0730	−0·0004
6	0·2570	0·3521	0·2580	+0·0010
7	0·0734	0·7042	0·0769	+0·0035

The precipitates were tested for nickel by dimethylglyoxime. Positive results were obtained in Nos. 6 and 7. We found this method rapid and easily worked, whilst the separation, except in the case of No. 7, which contained a high proportion of nickel, was clean and sharp.

3. *Precipitation of Zinc as Zinc Sulphide from a Solution faintly Acidified with Hydrochloric Acid.*—The results obtained by this method were unsatisfactory, and after an extended trial it was abandoned. As we anticipated, the main difficulty was to determine the quantity of free acid to employ, whilst the constantly increasing proportion of highly ionised free acid militates against accurate results being obtained.

4. *Zimmermann's Process* (*Ann. d. Chem. und Pharm.*, 1879, **199**, 3; 1880, **204**, 226).—More was expected of this method, but notwithstanding the fact that we carried out the process exactly as described in Treadwell, vol. ii., p. 127, we were unable to obtain concordant results.

With a view to estimating the nickel in the filtrates from the above, we reviewed the recent work of L. Dede (ANALYST, 1911, **36**, 598), which promised to obviate the error arising from the well-known occlusion of alkali by nickel hydroxide. Dede employed potassium persulphate instead of bromine as the oxidising agent, and his results indicated an accuracy of ±0·2 mgrm. on weighings up to 0·3 grm.

The results obtained by us did not conform to this degree of accuracy, notwithstanding the fact that the amount of alkali required in each test was calculated, and great care taken to employ only the smallest possible excess. We found that the precipitates and the nickel reduced therefrom invariably contained alkali, the amount of occluded matter being approximately proportional to the concentration of the nickel. The following results, which are typical of many obtained, plainly indicate this:

TABLE III.

No. of Experiment.	Nickel taken.	Nickel found.	Difference.
	Grm.	Grm.	Grm.
	0·0704	0·0747	+0·0043
	0·1408	0·1516	+0·0108
	0·2464	0·2598	+0·0134

Separation of Nickel from Zinc.—In close connection with the foregoing work, we made an examination of the dimethylglyoxime method of separating nickel from zinc as detailed by O. Brunck (ANALYST, 1907, **32**, 431). To the solution, first neutralised with dilute ammonia and rendered faintly acid with dilute hydrochloric acid, is added a 1 per cent. alcoholic solution of dimethylglyoxime in amount equivalent to seven times the quantity of nickel present. This was followed by the addition of a few c.c. of 10 per cent. sodium acetate solution. The solutions were maintained at the boiling-point for half an hour, filtered through a Gooch crucible having an asbestos felt, and washed with hot water. The precipitate was weighed as $Ni(C_4H_7O_2N_2)_2$, after drying at 110° C.

TABLE IV.

No. of Experiment.	Weight of Nickel taken.	Weight of Zinc taken.	Weight of Nickel found.	Difference.
	Grm.	Grm.	Grm.	Grm.
1	0·0704	—	0·0714	+0·0010
2	0·0704	0·0734	0·0709	+0·0005
3	0·0704	0·3672	0·0712	+0·0008
4	0·0704	0·5508	0·0724	+0·0020
5	0·1408	—	0·1407	−0·0001
6	0·1408	0·1468	0·1406	[illegible]
7	0·1408	0·3672	0·1410	[illegible]

The nickel glyoxime forms an extremely bulky precipitate, and we found that the concentration of 0·07 grm. of nickel per 250 c.c. was as high as desirable.

The process is applicable to the determination of nickel in the filtrates obtained from the separation of zinc after the removal of the sulphuretted hydrogen, formic acid, etc. The results obtained are shown in Table IV.

One of us is making an examination of the dicyan-diamidine method for the estimation of nickel with special reference to German silver, and will shortly publish his results.

ANALYSIS OF FOOD AND DRUGS.

Estimation of Benzaldehyde in Maraschino Cherries and Liqueur. A. G. Woodman and L. Davis. (*J. Ind. and Eng. Chem.*, 1912, 4, 588-589.)—The following method is recommended for this estimation, which affords a means of determining the genuine nature of these products: 100 c.c. of the liquor from Maraschino cherries, or 50 c.c. of the liqueur, are diluted with water to 140 c.c., and 110 c.c. distilled over. The amount of alcohol in the distillate is estimated approximately from the sp. gr., and sufficient alcohol or water added to 100 c.c. of the liquid to make its content of alcohol approximate to 10 per cent. by volume. One hundred c.c. of the phenylhydrazine reagent (freshly prepared by thoroughly shaking 3 c.c. of glacial acetic acid with 40 c.c. of water and 2 c.c. of pure phenylhydrazine, and filtering till clear) is added as soon as possible after the distillate is obtained, and the mixture vigorously shaken for ten minutes. The liquid is filtered through a tared Gooch crucible, washing the precipitated hydrazone with cold water, and finally with 10 c.c. of dilute alcohol (10 per cent.). A rotary motion of the liquid during filtration prevents loss of hydrazone, which has a tendency to adhere to the sides of the vessel. The precipitate is dried in a vacuum desiccator for twenty-four hours, or at 70° to 80° C. in a vacuum oven for three hours, keeping the precipitate away from strong light. A blank experiment must be made, and the weight of precipitate deducted. The weight of hydrazone corrected, multiplied by 0·5411, gives the weight of benzaldehyde present. The method is applicable to the determination of the benzaldehyde in almond extracts, using 10 c.c. of the extract diluted to 100 c.c. with water, and 15 c.c. of the reagent. Control experiments with pure benzaldehyde showed the method to give results from 95 to about 98 per cent. of the theoretical. Commercial samples of Maraschino cherries were found to contain from 4 to 36 mgrms. of benzaldehyde per 100 c.c., and the liqueurs from 0 to 41 mgrms. per 100 c.c. Genuine Maraschino appears to have a very low benzaldehyde content, and Maraschino cherries showing a relatively large amount of the aldehyde are in all probability artificially flavoured. A. R. T.

Estimation of Crude Fibre. E. Gury. (*Mitt. Lebensmitteluntersuch. u. Hyg.*, 1912, 3, 99-105; through *Chem. Zentralbl.*, 1912, II., 556-557.)—The author has submitted filter-paper, cocoa, cocoa-shell, and sawdust to König's process (*Unters. landw. u. gew. Wichtiger Stoffe*, third edition, p. 249), Parry's modification (*Chemist and Druggist*, 1911, 167) of Henneberg's process, Filsinger's process, and to a modification, now described, of the Zeisel-Stritar process (*Ber.*, 1902, 35, 1252). The modification consists in treating the finely-divided, fat-free substance (1 to 1·5 grm.) with 200 c.c. of water and 10 c.c. of concentrated lactic acid, the whole being boiled under a reflux condenser for thirty minutes. The function of the lactic acid is to render the material more open to the attack of the reagents used subsequently; it also shortens the time required for filtration. The insoluble matter is filtered off on an ordinary filter-paper, washed, and returned to the flask with 180 c.c. of water and 20 c.c. of nitric acid, and, after digesting for thirty minutes, is submitted to the process of Zeisel and Stritar.

König's method, as well as that of Parry, leads to the hydrolysis of from 13 to 16 per cent. of the cellulose in filter-paper, whereas the method of Zeisel and Stritar does not attack cellulose. Yet the methods of König and Parry frequently discover more than 50 per cent. more crude fibre in cocoa or cocoa-shell than is found by the author's modification of Zeisel and Stritar's method. This is due to the fact that, even with very fine division of the sample, the interior portions of the larger particles escape the action of the reagents, unless opened to this action in some such way as that now suggested. Even when using his lactic acid method, the author subjects cocoa and cocoa-shell to special methods to secure fine division of the sample. The paper includes a description of a small winnowing-machine of simple construction. By means of this machine the finer particles of a small sample are driven forward, and the heavier residue is repeatedly ground and returned to the machine until all is fine enough.

In view of the small difference in crude fibre content of cocoa mass (5·5 to 8 per cent.) and cocoa-shell (11 to 18 per cent.), the author thinks that an adverse judgment on cocoa should never be based on the percentage of crude fibre alone. On the other hand, he thinks the Swiss *Lebensmittelbuch* is unduly lenient in fixing 11 per cent. as the permissible limit of crude fibre in cocoa. Though König's method may show nearly 9 per cent. of crude fibre in some genuine samples, the author's process never discovers as much as 8 per cent. Filsinger's method is much too crude to give results of any value in examining cocoa for shell. G. C. J.

Modification of the Sweeney Method for Crude Fibre. C. Kennedy. (*J. Ind. and Eng. Chem.*, 1912, 4, 600-601.)—Sweeney (*U.S. Dept. Agri. Bur. Chem. Bull.*, No. 137, 157) has modified the U.S.A. official method of fibre determination by dispensing with the filtration of the material after boiling with acid. He merely neutralises the whole with 10 per cent. caustic soda and then adds 200 c.c. of boiling 2·65 per cent. caustic soda for the final boil. This neutralisation, the author [illegible] out, throws down a certain amount of the material dissolved by the acid, and thereby introduces an error, since the precipitate will be weighed as fibre. It is recommended that, instead of neutralisation as carried out by Sweeney after boiling with acid, sufficient boiling caustic soda should be added in one operation to leave 1·25 per cent. soda after its addition. Boiling for half an hour follows, and the fibre is filtered on a linen filter and washed free of alkali. The precipitate is then washed on the filter with boiling 1·25 per cent. sulphuric acid, thus dissolving any material precipitated by the addition of alkali, and finally washed free of acid with water. The advantage of the Sweeney method over the official method—namely, the saving of time and trouble due to two filtrations—is thus preserved, and the results as recorded show that the modification proposed yields results in agreement with the official figures within the experimental error, which is not the case with the Sweeney method.

H. F. E. H.

Solubility of Ether in Normal Salt Solution. R. R. Bennett. (*Pharm. J.*, 1912, 89, 146.)—The author has determined, by the cryoscopic method, the solubility of pure and commercial ether in "normal" salt solutions, prepared by dissolving 0·91 grm. pure sodium chloride in 99·09 grms. of distilled water. The freezing-point of this "normal" solution is −0·56° C. When commercial ether is added to the salt solution, the freezing-point of the solution is always a little lower than when the same quantity of pure ethyl ether has been added. This is due to the fact that alcohol has a smaller molecular weight than ether, and therefore produces a greater depression. It is found that there is increased molecular dissociation in the salt solution in the presence of ether.

The solubility results are shown below:

Temperature, °C.	Pure Ethyl Ether.		Purified Ethyl Ether Prepared from Methylated Spirit.	
	Grms. Ether Dissolved by 100 Grms. Normal Salt Solution.	C.c. Ether (15° C.) Dissolved by 100 C.c. Normal Salt Solution.	Grms. Ether Dissolved by 100 Grms. Normal Salt Solution.	C.c. Ether (15° C.) Dissolved by 100 C.c. Normal Salt Solution.
0°	13·08	18·27	13·46	18·80
5°	11·15	15·58	11·55	16·14
10°	9·45	13·20	9·87	13·79
15°	8·10	11·31	8·50	11·87
20°	6·87	9·60	7·38	10·31
25°	5·96	8·33	6·46	9·02
30°	5·30	7·40	5·83	8·14

The amount of ether present in solution at the different temperatures was ascertained by reference to a curve of freezing-points plotted out from actual determinations made on solutions containing known quantities of ether. A. R. T.

Examination of Methods used in the Analysis of Honey. J. Fiehe and Stegmuller. (*Arbeit. Kaiserl. Gesundheitsamte*, 1912, **40**, 305-356.)—The authors give the results of a critical examination and comparison of various methods which have been proposed and which are used for the analysis of honey. The results of their work may be summarised as follows: The total solids of honey may be estimated accurately as follows: The honey, or its solution, is mixed with sand and dried at about 65° C. in a closed vessel from which the air is exhausted, and to which a current of dry air is admitted in such quantity that the pressure in the vessel is maintained at about 30 mm. When the total solids are calculated from the sp. gr. (d) of a 20 per cent. solution of the honey, according to the formula, $\text{T. S.} = \frac{d-1}{0{\cdot}0007714}$, only approximately correct results are obtained. Litmus-paper is the best indicator to use in titrating the acidity of honey, and, as it is doubtful whether the acidity is due entirely to the presence of formic acid, the result should be expressed in c.c. of $\frac{N}{1}$ alkali solution. The estimation of the alkalinity of the ash of honey may be combined with a simple acidimetric titration of the phosphates present; the weighed ash is heated with 20 c.c. of $\frac{N}{10}$ hydrochloric acid in a covered flask on a water-bath for one hour and, after cooling, the solution is titrated with $\frac{N}{10}$ alkali solution using methyl orange as indicator. Two c.c. of a neutral 2 per cent. calcium chloride solution are now added, together with a few drops of phenolphthaleïn solution, and the titration with alkali is continued until a pink coloration is obtained; the quantity of alkali used in this second titration is equivalent to the phosphate present, each c.c. of $\frac{N}{10}$ solution corresponding with 0·0035 grm. of P_2O_5. The sugars, according to the author, should be estimated gravimetrically. As regards the tests which have been proposed for the detection of artificial invert sugar, Fiehe's reaction (ANALYST, 1908, **33**, 397) yields the most trustworthy results, especially in combination with the test for enzymes (ANALYST, 1910, **35**, 165); the presence of starch syrup may be detected by a test also described by Fiehe (ANALYST, 1909, **34**, 440). Ley's test (ANALYST, 1907, **32**, 291) was found to be unsuitable for the detection of added invert sugar, and the results obtained by Lund's test for proteins (precipitation with tannin) did not afford much evidence as to the purity of the samples of honey examined.

W. P. S.

Estimation of Lecithin in Medicinal Tablets. C. Virchow. (*Chem. Zeit.*, 1912, **36**, 906-907.)—A modification of a process described previously by the author (*cf.* ANALYST, 1911, **36**, 510) is recommended for the estimation of lecithin in tablets, in the so-called lecithin-albumin, etc. Two grms. of the substance are boiled with three successive quantities of 25 c.c. of absolute alcohol, the alcoholic extracts are filtered and evaporated together with a quantity of alcohol which is used for washing the extracted mass and the filter. The residue obtained after the evaporation of the alcohol is dried completely, and extracted with 20 c.c. of warm anhydrous ether, the ethereal extract being then evaporated, the residue weighed, and the phosphorus contained in it estimated as described (*loc. cit.*).

W. P. S.

Estimation of Dirt in Milk. W. F. Lowe. (*Chem. News*, 1912, **106**, 61-62.) —The dirt which is present in certain samples of milk usually consists of cow-dung, and several methods for its estimation have been proposed. In experiments carried out by the author it was found that when cow-dung is added to milk, then separated by sedimentation, collected on a filter, washed, and weighed, the dry residue obtained only weighs about one-eighth of the weight of moist cow-dung added. It was, however, ascertained as the result of further experiments that the volume of the sediment (in c.c.) was practically equal to the weight of the added cow-dung (in grms.), and the author, therefore, employs the following method for the estimation: Five hundred c.c. of the milk are thoroughly mixed and placed in a cylinder, the lower end of which is drawn out and attached by means of a piece of rubber tubing to a small glass tube, graduated in 0·01 c.c. The bottom of this tube may be closed with a rubber stopper. After standing for about fifteen hours, the volume of the sediment is noted; the sediment is then removed from the tube and examined microscopically. It will usually be found to consist of undigested vegetable fibre and tissue stained yellowish with bile, and the presence of bile may be proved by moistening the sediment with sugar solution, drying the mixture, and adding a drop of sulphuric acid. A red colour develops round the particles stained with bile. W. P. S.

Preparation of Milk Serums and their Use in the Analysis of Milk. R. Pfyl and R. Turnau. (*Arbeit. Kaiserl. Gesundheitsamte*, 1912, **40**, 245-304.)—A serum which contains the albumin and globulin of the milk may be obtained by shaking 50 c.c. of the milk with 5 c.c. of carbon tetrachloride for ten minutes, then adding 1 c.c. of 20 per cent. acetic acid, again shaking the mixture, and submitting it to centrifugal action. When it is desired to prepare a serum free from coagulable proteins, the milk is heated in a flask on a boiling water-bath for twenty minutes, the flask being provided with a reflux apparatus; 50 c.c. of the heated milk are then treated as described above. The serums may be employed in place of those obtained by the use of calcium chloride, etc. (*cf.* ANALYST, 1907, **32**, 117), over which they possess certain advantages. They are suitable for the determination of various physical and chemical constants in the analysis of milk, and afford a means of distinguishing raw from heated milk. The serum obtained from heated milk does not yield a precipitate when again heated. W. P. S.

Estimation of Sucrose in Condensed Milk. H. Nowak. (*Zeitsch. anal. Chem.*, 1912, **51**, 610-614.)—The method proposed recently by Jolles (*cf.* ANALYST, 1911, **36**, 28) was found to be trustworthy; it depends on the fact that all mono- and disaccharides, with the exception of sucrose, are rendered optically inactive when they are heated with sodium hydroxide solution under certain conditions. The author finds that the most convenient and satisfactory method of carrying out the process is as follows: Five grms. of the condensed milk under examination are dissolved in about 200 c.c. of water in a 250 c.c. flask, 10 c.c. of Fehling's copper sulphate solution are added, the mixture is nearly neutralised with sodium hydroxide solution (it should still have a very faintly acid reaction), then diluted to the mark, and filtered. The lactose may be estimated in a portion of the filtrate in the usual way. Another portion of about 100 c.c. of the filtrate is now treated with about 0·5 grm. (or more, if necessary) of potassium ferrocyanide, in order to precipitate the excess of copper, and again filtered. Fifty c.c. of this filtrate are placed in a Lintner's pressure flask, 1·3 c.c. of a 16 per cent. sodium hydroxide solution are added, the flask is closed, and heated for forty-five minutes in a boiling water-bath. After cooling, 3·7 c.c. of basic lead acetate solution are added, the mixture is shaken, and filtered. The optical rotation of the filtrate is then observed in a 220 mm. tube. The reading multiplied by 0·75 gives grms. of sucrose per 100 c.c. of the filtrate, and the percentage quantity of the sugar is then calculated. The addition of the alkali and basic lead acetate increases the volume of the 50 c.c. of filtrate to 55 c.c., and the reading is consequently observed in a 220 mm. tube. For example, 5 grms. of a sample of condensed milk to which 40 per cent. of sucrose had been added, when treated as described above, gave a reading of +1·06° corresponding with 39·75 per cent. of sucrose.

W. P. S.

Direct Determination of Sucrose in the Presence of Reducing Sugars. W. E. Cross and W. G. Taggart. (*Intern. Sugar J.*, 1912, **14**, 444-448; through *J. Soc. Chem. Ind.*, 1912, **31**, 831.)—As a more rapid means than the Clerget inversion process of determining the sucrose content of sugar-factory products containing reducing sugars, Jolles (ANALYST, 1911, **36**, 28) has recommended destruction of the rotatory power of the dextrose and lœvulose by sodium hydroxide. Using samples of cane sugars and molasses the authors obtained much lower results than the Pellet-Lemeland process with the Clerget-Herzfeld inversion method, the differences varying from 2 to 14 per cent., and determinations made with pure solutions of sucrose, dextrose, and lœvulose, in the proportions obtaining in cane molasses confirmed these figures. Experiments were afterwards made for the purpose of modifying the process to obtain more trustworthy results. As finally elaborated the procedure now recommended is as follows: Fifty c.c. of the "normal" sugar solution are transferred to a 100 c.c. flask, 6·3 c.c. of sodium hydroxide solution (sp. gr. 1·332) and 7·5 c.c. of hydrogen peroxide (100 vol.) added, and the mixture cooled to prevent effervescence. The flask is then immersed in a water-bath at 55° C. for twenty minutes, after which the liquid is cooled, acidified with acetic acid, made up to the mark, clarified with dry basic lead acetate, filtered, and polarised, using preferably the 400 mm. tube. It is stated that the solution thus obtained is almost colourless and quite bright. On applying (*a*) this modification, and comparing the results with (*b*) the Clerget-Herzfeld process, satisfactory results were obtained, some of these being as follows: Syrup (*a*) 32·40, (*b*) 31·87; open-kettle molasses (*a*) 41·12, (*b*) 40·98; molasses (*a*) 28·40, (*b*) 27·93 per cent. As this method has been found so reliable in the authors' hands, they recommend it as a substitute for the Clerget-Herzfeld inversion method in the analysis of syrups and molasses, and especially as a routine method for the determination of the sucrose content of low-grade products in hot-room goods.

Estimation of Essential Oil in Preparations of Mustard. H. Penau. (*J. Pharm. Chim.*, 1912, **6**, 160-164.)—Estimation of essential oil in mustard by the silver sulphide gravimetric method is unreliable, results differing by 16 per cent. being obtained with the same sample of mustard. The following modification of the French Codex method was found to be the most accurate of any: Five grms. of the mustard are digested with 100 c.c. of water in a closed flask for six hours, after which 20 c.c. of alcohol and 20 c.c. of poppy-seed oil are introduced, and the flask thoroughly shaken. The liquid is then very slowly distilled on a glycerol bath, and 90 c.c. of the distillate collected in a flask containing 10 c.c. of 50 per cent. ammonia solution. After the addition of 20 c.c. of $\frac{N}{10}$ silver nitrate solution, the flask containing the distillate is closed, and left in the dark for twenty-four hours, the precipitate being then rapidly filtered off, and washed with water. The filtrate is slightly acidified with nitric acid, the silver precipitated with 1 c.c. of $\frac{N}{10}$ hydrochloric acid, and the precipitate dried on counterpoised filters and weighed. The excess of silver may also be estimated volumetrically by the potassium cyanide method, though the results are not so good as by the gravimetric method (error in five estimations of allyl mustard oil = 2·4 per cent.). Volumetric estimation of the silver with ammonium thiocyanate is inaccurate (error in five estimations = 5·1 per cent.). (*Cf.* ANALYST, 1912, 309.)

C. A. M.

Methods of Estimating Nicotine in Tobacco and Tobacco Extracts. J. Tóth. (*Chem. Zeit.*, 1912, **36**, 937-938.)—The silico-tungstic acid method of Bertrand and Javillier (ANALYST, 1909, **34**, 219) gives results in close agreement with those given by the methods of the author and of Kissling. The following modification of the method was used: Ten grms. of the dried powdered tobacco are digested for fifteen to twenty minutes on the water-bath with 100 c.c. of 0·5 per cent. hydrochloric acid, then centrifuged and decanted, and the residue treated similarly three times. To the solutions thus obtained are added 10 to 20 per cent. of silico-tungstic acid or potassium silico-tungstate, and the precipitated nicotine silico-tungstate separated in the centrifuge. After standing for one or two days the precipitate is taken up in a little dilute hydrochloric acid, mixed with the reagent, and again separated. It is next mixed with ignited magnesia, and heated in a current of steam, and the nicotine in the distillate titrated, using iodeosin as indicator. The method is particularly useful for estimating nicotine in the presence of ammonia or pyridine bases, none of which are precipitated by silico-tungstic acid from a hydrochloric acid solution. (*Cf.* ANALYST, 1911, **36**, 106, 143, 279, 348, 544, 545.)

C. A. M.

Solidified (Hydrogenised) Oils. A. Bomer. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 104-112.)—During recent years many processes for solidifying oils have been patented, and these methods consist essentially in subjecting the oil to the action of hydrogen in the presence of a catalyst. According to the claims of the patentees the catalysts employed may be metals (such as nickel, platinum, palladium, etc.) or metallic oxides in a fine state of division. The solidifying process is carried on to any desired extent according to the consistence desired in the finished product. For instance, earthnut oil may be hydrogenised until it resembles tallow, or, by a shorter period of treatment, it may be converted into a product which cannot be distinguished from lard as regards its appearance, consistence, taste, smell. The process results in the conversion of the unsaturated fatty acids (oleic acid, etc.) of the oil into stearic acid; the iodine value is diminished to a very considerable extent, and the melting and solidifying points raised. For example, solidified earthnut oil may have an iodine value as low as 42·2 and sesame oil 25·4, these being the results obtained by the author on the examination of some of the products. The phytosterol present in vegetable fats is not altered by the treatment, and the phytosterol acetate test described previously by the author enables a solidified vegetable oil to be distinguished from an animal fat yielding similar chemical and physical constants. W. P. S.

Estimation of Succinic and Malic Acids in Wine. C. von der Heide and E. Schwenk. (*Zeitsch. anal. Chem.*, 1912, **51**, 628-638.)—Slight modifications are made in the methods described previously by von der Heide and Steiner (*cf.* ANALYST, 1909, **34**, 278, 279). In the case of succinic acid, the ethereal solution obtained at the end of the process (*loc. cit.*) is evaporated after the addition of water, and the residual aqueous solution is rendered alkaline with barium hydroxide. The mixture is then heated on a water-bath for ten minutes, the excess of barium is removed as carbonate, the mixture is cooled, filtered, and the filtrate titrated with silver nitrate solution. It is recommended that at least two hours should elapse after the addition of the silver nitrate, and before the excess of the latter is titrated. For the estimation of malic and succinic acids together, 100 c.c. of the wine are evaporated to a volume of 20 c.c., and in this residual liquid the tartaric acid is separated and estimated. The filtrate from the potassium hydrogen tartrate precipitate is treated as described (*loc. cit.*), but, after the ether has been evaporated from the ethereal extract, the residue is treated with barium hydroxide, and the solution containing soluble barium salts of the two acids is evaporated, the residue ignited, and titrated. The alkalinity gives the sum of the quantity of succinic and malic acids present. W. P. S.

Estimation of Phosphoric Acid in Wines. C. von der Heide and J. Schwenk. (*Zeitsch. anal. Chem.*, 1912, **51**, 615-627.)—As regards the alleged loss of phosphoric acid during the ignition of the total solids of wine, the authors find that no such loss takes place, and that in the case of ordinary table wines, sweet wines, musts, and yeast, the addition of sodium carbonate and potassium nitrate previous to the ignition is quite unnecessary. In preparing the ash of the wine for the estimation of the phosphoric acid, it is recommended that 50 c.c. of the sample be evaporated, and the residue incinerated; the carbonaceous mass is then extracted with water, and the washed carbon is ignited to a white ash, which is dissolved in nitric acid and the solution added to the aqueous extract. This solution is used for the estimation of the phosphoric acid, for which purpose the method proposed by von Lorenz (*Landw. Versuchsst.*, 1901, **55**, 183; *cf.* ANALYST, 1903, **28**, 229) is recommended. Grete's method (ANALYST, 1909, **34**, 541) is also trustworthy, and may be employed for estimating the total phosphoric acid directly—that is, without previously incinerating the wine residue. The amount of organically combined phosphoric acid in wine is only a small proportion of the total phosphoric acid; it may be estimated by the method described by Philippe and Duperthius (*Mitt. a. d. Geb. der Lebensmittelunters. u. Hyg.*, 1910, 1, 125), which depends on the precipitation of the inorganic phosphoric acid by means of barium hydroxide, the barium salts of the organically combined phosphoric acid being soluble in water.

W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Studies of Amylases. IV. A Further Investigation of the Properties of Pancreatic Amylase. H. C. Sherman and M. D. Schlesinger. (*J. Amer. Chem. Soc.*, 1912, 34, 1104-1111.)—In a previous paper (*J. Amer. Chem. Soc.*, 1911, 33, 1195) the authors describe preparations of purified pancreatic amylase, having an activity of about 5,000 on Lintner's scale for purified diastases. A detailed method of preparing such amylase is described with modifications suggested by recent work, the preparation having a heat of combustion of 5,568 calories per grm., and the following approximate composition, C 51·9, H 6·6, N 15·3, S 1·0, P 0·8, O (and undetermined) 24·4. Coagulation occurs at 70° C. In the determination of diastatic activity it was at first found that the yield of reducing sugar did not amount to more than 85 per cent. of the starch used, but on increasing the amount of enzyme and allowing it to act on relatively small amounts of starch, such as 20 mgrms. of enzyme to 100 c.c. of 1 per cent. soluble starch for seventy-two hours, the resulting sugars were found to be a mixture of maltose and glucose, and confirmed by a special quantitative modification of the osazone method. The method of purification of the pancreatic-amylase had thus resulted in a concentration of a glucase or maltase in addition to the amylase. In the absence of electrolytes, the preparations very rapidly lose their enzymic activity, and even in the presence of salt and phosphate, as used for the determination of diastatic power, the purified amylase deteriorated from 33 to 50 per cent. in twenty-four hours, the commercial pancreatins being much more stable. This was thought to be due to the presence of a protease of a trypsin-like character, which might digest the protein with which the amylase was associated. It was found on measuring the proteolytic activity of both the crude pancreatin and the purified amylase prepared from it, that the increase in activity of both enzymes was about proportional. Other preparations examined showed much higher proteolytic activity with an amylolytic action only one-fifth as great. It is possible that one of the pancreas enzymes is both a protease and amylase, with the potentiality of an increase in the one activity accompanied by a decrease in the other.

H. F. E. H.

Note by Abstracter.—The formation of glucose, if it occurs, of course vitiates the Lintner value for diastatic activity, since this value is an expression of the activity of the enzyme in terms of maltose produced. The fact that in some cases the "R" (= per cent. of maltose) does not exceed 100 does not rule out the possibility of glucose having been formed simultaneously with or at the expense of the maltose.

Chemical Detection of Blood in Blood-Stains. E. Schär. (*Pharm. J.*, 1912, 89, 157-158.)—In cases where the quantity of suspected material is too small for spectroscopic examination, or for the preparation of hæmin crystals, the author employs several of the well-known colour-reactions based on the action of blood upon hydrogen peroxide in presence of oxidisable substances forming coloured oxidation-products. The blood, in solution, is mixed with the solution of oxidisable substance and either hydrogen peroxide, or turpentine oil previously shaken with water in the presence of air. The tests are: (1) tincture of guaiacum, which yields a blue colour; (2) tincture of aloes (isobarbaloin), a raspberry-red colour; (3) Adler's test with an acetic benzidine solution, a greenish-blue; (4) Adler and v. Fürth's leucomalachite green test, giving a dark green; (5) and the author's test with hydrocœrulignone, yielding the scarlet-coloured cœrulignone. Certain inorganic substances (iron and copper salts) and substances containing enzymes of the "peroxydase" class give similar reactions, but these may be ruled out, in the first instance (inorganic substances), by control reactions, and secondly, as regards interfering enzymes, by first heating the material for a short time from 80° to 100° C. In any case, a negative result may be considered as proof of the absence of blood.

According to the author, the best method of preparing the blood solution for the tests, whether from old or recent stains, is by means of chloral hydrate. The spot or stain is first moistened with a drop of acetic acid, and then soaked for one to several hours in chloral hydrate solution of 70 to 80 per cent. strength. The blood solution may then be used for the above tests. Zone reactions may be carried out by dissolving a little of the solutions of one of the oxidisable matters in the chloral hydrate solution of the blood, and carefully adding a quantity of hydrogen peroxide solution (3 per cent.), diluted with twice its volume of alcohol and slightly acidulated with acetic acid, by superposition. A deeply-coloured zone will appear between the two strata in the presence of blood, and will gradually spread into the liquids. When pyridine is used for the extraction of blood from stains, etc., the colour-reaction is accelerated and intensified. A. R. T.

Physico-Chemical Method for Determining the Changes taking place in Meats. O. von Fürth and E. Lenk. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, 24, 189-197.)—When flesh is immersed in a 15 to 25 per cent. sodium chloride solution it gradually diminishes in weight, but this only holds good for flesh one day old, counting from the death of the animal from which it was obtained. In the case of flesh more than one day old, an increase in weight is observed during the first ten to fifteen hours it is immersed in the salt solution, and this increase is always followed by a decrease during the succeeding hours. Chilled beef rapidly increases in weight when placed in sodium chloride solution. The increase in weight is probably due to the formation of lactic acid, as acids, when not above certain concentrations, greatly accelerate the imbibition capacity of muscular tissue, etc.; the subsequent decrease in weight appears to be due to a coagulation of the proteins. It is suggested that when the subject has been further investigated the phenomenon may be of use in testing meats. W. P. S.

Quantitative Estimation of Quinine in Urine and in Blood. A. Baldoni. (*Arch. d. Farmacol. sperim.*, 1912, 13, 324-352; through *Chem. Zentralb.*, 1912, II.

554.)—An experimental examination of the methods of Gordin (*Ber.*, 1899, 32, 2843), Kleine (*Zeitsch. f. Hyg.- u. Infect.- Krankh.*, 1901, 38, 458), Gaglio (*Atti per gli studi del. Malaria*, 1905, 6, 77), and Nishi (*Arch. f. exp. Pathol. u. Pharmak.*, 1909, 60, 312). The method of Nishi was found to give results which were uniformly somewhat low, whilst the method of Kleine showed errors somewhat beyond the permissible limit, and not all in the same direction. The results obtained by the methods of Gordin and Gaglio agreed closely with each other and with the amount of quinine actually present. Making use of these methods, the author was able to show that the resorption of quinine is more rapid when it is administered by the mouth than when administered hypodermically. Quinine disappears from the blood in a very few hours, and in no case could it be detected twenty-four hours after administration, a statement which conflicts with that of De Luca (*Arch. d. Farmacol. sperim.*, 1901, 2, 390). G. C. J.

Iodine Content of Thyroid Glands. N. H. Martin. (*Pharm. J.*, 1912, 89, 144-145.)—The following analyses of sheeps' thyroid glands, normal in size, are given:

Date.	Number of Glands Used.	Weight of Fresh Glands.	Weight of *Thyroideum Siccum* Obtained.	Average Weight of Each Fresh Gland.	Average Yield of *Siccum* per Gland.	Iodine in [illegible]	Iodine on Fresh Weight.	Average Iodine per Gland.
1911.		Grms.	Grms.	Grms.	Grms.	Per Cent.	Per Cent.	Grms.

June ...	830	1,284	426	1·55	0·51	0·38	0·126	0·00195
	6,560	9,299	2,737	1·42	0·38	0·34	0·091	0·00129

The author has examined glands having the enormous weights of 12·0, 14·0, and 32·5 grms., containing 0·22 per cent., 0·20, and 0·08 per cent. of iodine in the *thyroideum siccum*, and 0·00616, 0·00660, and 0·00600 grms. iodine per gland respectively. Thus the larger amount of iodine in these glands was not proportional to their increased weight, and the percentage of iodine in the dry substance was reduced.

The figures, as a whole, lend no support to the statement that the amount of iodine in the dry substance is greater in the winter months. A. R. T.

Measurement of Relative Tryptic Activity. A. R. Smith. (*Pharm. J.*, 1912, 89, 137-139.)—The author has applied the method of Sorensen (*Compt. rend. Trav. du Lab. de Carlsberg*, 1907, 7, 1) to the determination of the relative tryptic activity of certain pharmaceutical preparations. The method is based on the facts that the main products of the hydrolysis by trypsin are amino-acids, and that if the basicity of the amino-groups be neutralised, the carboxyl-groups can be titrated in the usual way. Schiff has shown that these amino-groups can be converted into neutral methylenic groups by adding formaldehyde, and the acids can then be estimated by titration. The reaction with formaldehyde is reversible in presence of water, but an increase of formaldehyde or decrease in the amount of water present tends to make the reaction proceed in the desired direction.

The tests are carried out as follows: A 4 per cent. solution of casein is prepared by dissolving the substance in recently-boiled and cooled water containing 30 c.c. of $\frac{N}{1}$ sodium hydroxide per litre. The solution is made neutral to phenolphthalein with alkali before making up to volume, and a little chloroform is added as an antiseptic. Twenty-five c.c. of this casein solution at 55° C. is mixed with a known volume of the trypsin-containing solution at the same temperature, and water added (55° C.) to make the volume to 50 c.c. One grm. of the enzyme preparation to be tested is triturated in a mortar with a little chloroform-water, and the solution made up to 100 c.c. After standing one hour, 1 c.c. of the well-mixed, unfiltered solution is added to the 25 c.c. of casein solution at 55° C., and the mixture diluted as stated. The mixed solutions are kept at this temperature for twenty minutes, when 20 c.c. of the liquid is removed, and titrated with $\frac{N}{5}$ sodium hydroxide solution after first adding 10 c.c. of neutral formaldehyde solution. (This solution is prepared immediately before use by mixing 1 c.c. of a $\frac{1}{2}$ per cent. solution of phenolphthalein in 50 per cent. alcohol with 50 c.c. of 40 per cent. formaldehyde solution, and adding $\frac{N}{5}$ sodium hydroxide till the colour is just pink.) Sorensen recommends that the titration of the "digest" solution should be carried on till the liquid is the same colour as a control prepared by adding 10 c.c. of the formaldehyde reagent to 20 c.c. of water and 5 c.c. of $\frac{N}{5}$ caustic soda. The solution is titrated back with $\frac{N}{5}$ hydrochloric acid till just pink, when 1 drop of standard alkali makes it distinctly pink, and 2 drops, red. This is the end-point.

A blank experiment must be made by titrating 20 c.c. of the mixed casein and trypsin solutions before digesting, in order to ascertain the volume of alkali required. The difference after digestion is that due to the acids produced in the hydrolysis. The figure multiplied by 100 may be used to express the relative activity of trypsin preparations.

Further experiments with the method showed: (1) That relative measurement of activity can be made so long as not more than 3·5 to 3·7 c.c. of $\frac{N}{5}$ alkali are used in the titration of 20 c.c. of the "digest"; (2) that 55° C. is the optimum temperature for digestion; (3) that under conditions (1) and (2) a period of twenty minutes for digestion is convenient, since then the relative hydrolysis is in direct proportion to the trypsin present. The following figures were obtained by using this method on certain preparations:

Sample.	C.c. NaOH $\frac{N}{5}$.

ORGANIC ANALYSIS.

The Coagulation of Albumin by Heat and its Precipitation by Mercuric-Potassium Iodide. Gravimetric and Volumetric Estimations. L. Vallery. (*Compt. rend.*, 1912, **155**, 417-420.)—In a previous note (*Compt. rend.*, 1911, 153), the author showed that the coagulation of albumin in urine by heat in presence of acetic or trichloracetic acid is incomplete, and he described a new gravimetric method for its estimation, based on the use of Tanret's or Esbach's reagent, giving distinctly higher results. It is now shown that the deficiency in the quantity of albumin coagulated by heat is due to the partial hydrolysis of the albumin by the action of the acid, and the loss when acetic acid is used is always less than when trichloracetic acid is present, owing to the greater degree of dissociation of the latter. It is now found that if a non-dissociated acid—*e.g.*, normal caproïc acid—be employed, perfectly satisfactory results are obtainable without appreciable hydrolysis. A few drops of this acid are to be added to the sample after this has been neutralised with sodium hydroxide in presence of phenolphthaleïn, but without the addition of an electrolyte. This procedure is especially recommended in the analysis of urine. The volumetric estimation of albumin by the use of Tanret's reagent depends on an adsorption reaction with mercury which can be represented by a hyperbolic formula. In the case of serum and egg albumins this law is expressed by the equation $\frac{1}{x}\log.\frac{H}{H-h}=K$; where x = the quantity of albumin, H = the initial quantity of mercury, h = the quantity of mercury adsorbed, and K is a constant. By making H = 0·20 grm. and diluting to 200 c.c. after precipitation, the value of K is 0·54 for serum albumin and 0·52 for egg albumin. The presence of urea and sodium chloride is without influence on the curve, but the presence of phosphates lowers the constant considerably, to an extent depending on their quantity. For this reason the volumetric process is not at present applicable for urine and other organic fluids containing more phosphates than serum and egg albumins.

J. F. B.

Benzoic Acid as an Acidimetric Standard. G. W. Morey. (*J. Amer. Chem. Soc.*, 1912, **34**, 1027.)—A hydrochloric acid solution was standardised by the distillation method of Hulett and Bonner (*J. Amer. Chem. Soc.*, 1909, **31**, 390), by the gravimetric silver chloride method, against sulphuric acid standardised gravimetrically by precipitation as barium sulphate and volumetrically against sodium oxalate, and was finally standardised against benzoic acid. The methods used are described in detail. The benzoic acid was prepared by recrystallising pure samples, twice from alcohol and once from water, subliming in vacuo, fusing at 140° C., and casting into sticks. About 1 grm. was weighed, placed in a 300 c.c. flask, swept free from carbon dioxide, dissolved in 20 c.c. of alcohol, and titrated with $\frac{N}{10}$ alkali, 3 drops of 1 per cent. phenolphthaleïn being used as indicator, and air, free from carbon dioxide, being led through the liquid. A correction for the effect of the alcohol on the end-point was applied. The appended table shows the accuracy of the benzoic acid method:

Method.	$\frac{N}{10}$ factor for HCl.
Direct by Hulett	0·9980
Direct by AgCl	0·9984
H_2SO_4—$BaSO_4$—NaOH—HCl	0·9984
H_2SO_4—$Na_2C_2O_4$—NaOH—HCl	0·9982
$C_6H_5CO_2H$—$Ba(OH)_2$—HCl	0·9984
$C_6H_5CO_2H$—NaOH—HCl	0·9981

Its stability and lack of hygroscopicity make it convenient, and the method involves only a single weighing and a titration. O. E. M.

Estimation of Carbon by Moist Combustion. H. Simonis and F. H. Thies. (*Chem. Zeit.*, 1912, **36**, 917-918.)—The following method is recommended for the estimation of carbon in such substances as phenylacetaldehyde, etc., the oxidation being carried out by means of potassium bichromate and sulphuric acid. A portion of about 0·2 grm. of the substance is weighed into a small platinum boat, which is then filled with powdered potassium bichromate and introduced into a round-bottomed flask of about 200 c.c. capacity. A further quantity of 20 grms. of bichromate are placed in the flask, which is then closed with a stopper through which pass the stem of a tapped funnel and a delivery-tube. The latter connects with a wide tube filled with glass-wool in which most of the moisture leaving the flask is condensed; the other end of the wide tube is in communication with a combustion-tube filled with copper oxide and heated by suitable means. The necessary drying and absorption apparatus are attached to the end of this combustion-tube. It is essential that the gases leaving the oxidation-flask be passed over hot copper oxide, as they contain small quantities of unoxidised carbon compounds. At the commencement of the operation, a soda-lime tube is attached to the combustion-tube in place of the absorption apparatus, and a current of oxygen is passed through the whole apparatus, the supply of oxygen being introduced through a T-piece and narrow tube which extends through the delivery-tube to the bottom of the flask; oxygen is also supplied to the top of the funnel which contains sulphuric acid. When the apparatus has been filled with oxygen the absorption apparatus is connected, and the sulphuric acid is admitted from the funnel, drop by drop, or at such a rate that the evolved gases pass through the absorption vessels at the rate of a few bubbles a second.

The contents of the flask are eventually heated with a burner for thirty minutes, and pure air is passed through the apparatus before the absorption vessels are weighed. Duplicate estimations of carbon in phenylacetaldehyde yielded 79·98 and 79·96 per cent. of carbon, respectively, against 80 per cent. required by theory. W. P. S.

Methods for Determining Neo- and Allo-Chlorophyll in the Presence of one Another. C. A. Jacobson and L. Marchlewski. (*Amer. Chem. J.*, 1912, **48**, 111-124.)—The authors have shown previously (*Amer. Chem. J.*, 1911, **47**, 221) that the ratio of neo-chlorophyll to allo-chlorophyll in plants is not a constant one, varying not only in different species, but in the same when the samples have been grown under different conditions.

Method 1.—Using ultra-violet spectrum.

Neo-chlorophyllan was prepared by two methods in order to obtain a photograph of the ultra-violet spectrum of this material in the pure state. By the shorter method the starting-point is chlorophyllan and the neo-chlorophyllan so obtained is a black, amorphous substance something like oak bark. It gives a deep, olive-green solution, thus distinguishing it from allo-chlorophyllan which has a reddish-brown colour. The ultra-violet spectrum in a concentration of 0·00004 grm. per c.c. of chloroform shows three absorption bands, the wave-lengths in a layer of 6 mm. thickness being (1) λ 365·0 to 382·7, (2) λ 388·8 to 405·0, (3) λ 407·4 to 426·5.

By the second and longer method of preparation, the neo-chlorophyllan is extracted directly from leaves by the use of organic solvents alone and remains in solution in carbon disulphide, while the allo-chlorophyllan is removed by continuous alcoholic extraction. The ultra-violet spectrum is identical with that obtained by the first method. A series of eleven photographs is supplied showing the ultra-violet spectra of artificial mixtures of the neo- and allo- varieties in different proportions equally graded, and the method consists in preparing the chlorophyllan of the plant to be examined in the ordinary way, and then to take a photograph in the ultra-violet of the spectrum yielded by a solution whose concentration is equal to those photographed in the series. A direct comparison with the plates supplied will then reveal the composition of the mixture to within 2 per cent. Care must be taken first to remove all the yellow colouring matters by means of several precipitations with alcohol from the concentrated chloroform solution before photographing the spectrum, except in the case of Acer platinoides, whose yellow colouring matter was found not to interfere.

Method 2 is based on the extinction co-efficients of the chloroform solutions, and has already been employed by one of the authors for determining the total green colouring matter in a plant. A cadmium lamp was employed, giving true monochromatic light in the green part of the spectrum. A table is given of the same eleven artificial mixtures as given above with their extinction co-efficients, for cadmium light λ = 508 μμ and sodium light λ = 589 μμ. The values for both lights are plotted and yield practically straight line curves, and show that the percentage composition of any mixture of neo- and allo-chlorophyllan is a linear function of its extinction co-efficient. The first method is less sensitive to impurities, is more adapted to practical application, and can be used in very small quantities, but where sufficient material is available to allow of very thorough purification, the extinction method allows of greater accuracy. H. F. E. H.

Estimation of Cineol in Volatile Oils. F. D. Dodge. (*J. Ind. and Eng. Chem.*, 1912, **4**, 592-593.)—The author oxidises the terpenes and unsaturated compounds in the cold with potassium permanganate, and measures the remaining insoluble cineol. For the test 10 c.c. of the oil (eucalyptus, cajeput) are treated in a flask of 500 c.c. capacity with potassium permanganate solution (5 to 6 per cent.) added in small quantities, with shaking, till the reagent is no longer reduced. The flask must be kept in ice-cold water throughout the addition of the permanganate, of which from 100 to 400 c.c. are required. When excess has been added, the mixture is kept cold for twelve to eighteen hours with occasional shaking. The precipitated manganic oxide is then dissolved by sulphurous acid and the flask filled with water, the unoxidised oil collecting in the narrow neck. The oil is then transferred by a capillary pipette to a graduated tube, washed with a little alkali and its volume read off. The cineol should have the following characters: Sp. gr. 15° C., 0·929 to 0·930; be optically inactive; soluble in $3\frac{1}{2}$ volumes of 60 per cent. alcohol at 25° C. The isolation of the cineol itself allows of a determination of its purity, or of a detection of other compounds when present with it. Thus camphor, fenchone and bornyl acetate increase the sp. gr. of the residual oil and show optical rotation; inactive camphor increases the sp. gr.; petroleum products lower the sp. gr. and diminish the solubility; borneol and menthol are oxidised to camphor and menthone respectively; and menthone lowers the gravity and shows optical activity. A. R. T.

Detection and Estimation of Halides in the Presence of Cyanides by Means of Formaldehyde. K. Polstorff and H. Meyer. (*Zeitsch. anal. Chem.*, 1912, **51**, 601-609.)—The method is based on the fact that formaldehyde combines with potassium cyanide to form a compound which does not reduce silver nitrate or yield a precipitate with the latter in the presence of nitric acid; Romijn has previously made use of this reaction for the estimation of formaldehyde (ANALYST, 1897, **22**, 221). For the detection of chlorides in mixtures of the same with cyanides, a solution of the salt is rendered alkaline with potassium hydroxide and formaldehyde is added in excess; the solution is then acidified with nitric acid and tested with silver nitrate when the formation of a white, curdy precipitate which is soluble in ammonia indicates the presence of chlorides. For the estimation of chloride, bromide, or iodide in the presence of cyanide, a quantity of about 0·6 grm. of the sample is dissolved in 100 c.c. of water, the solution is rendered alkaline with potassium or sodium hydroxide, and 30 drops of a 35 per cent. formaldehyde solution are added. After the lapse of a few minutes, the mixture is acidified with nitric acid, and the halide is titrated according to Volhard's method. The cyanide may be estimated in a separate portion of the sample by Liebig's method. W. P. S.

Estimation of Halogens in Organic Compounds, including a Device for the Combustion of Volatile Substances. E. E. Reed. (*J. Amer. Chem. Soc.* 1912, **34**, 1033.)—The substance containing halogen is subjected to combustion in a quartz tube, for the arrangement of which the original should be consulted, and the halogen arrested by means of silver powder and silver oxide. The silver is weighed in a silver boat, and the separately weighed silver oxide (0·2 to 0·5 grm.) then added. The silver oxide is prepared from silver nitrate, washed, dried at 100° C., well mixed, and sealed up in 0·5 to 1·0 grm. portions. The loss on reduction is determined by heating a portion in hydrogen from 160° to 170° C. for thirty minutes. It is higher than the theory demands, on account of retention of water by the silver oxide; this is of no consequence if it is uniform. During the combustion the silver and silver oxide is maintained at about 270° C., and when it is finished, reduced by hydrogen at 170° C. In the calculation the loss in weight on reduction of the quantity of oxide used is deducted from the original weight of the boat. In the device for the combustion of volatile liquids (*cf.* original) the substance sealed in a bulb is placed in the larger limb of a U-tube communicating with the heated combustion tube into which its vapour is swept, after the bulb has been broken, by means of a current of air or nitrogen. A table shows that analyses are consistent and sufficiently accurate, and that 0·2 to 0·25 grm. of substance, but not more, may be burnt in twenty minutes. O. E. M.

Analysis of Hydrocarbon Mixtures. O. Routala. (*Ann. Acad. Sci. Fennicæ*, 1912, Ser. A, **2**, 19; through *Chem. Zentralbl.*, 1912, II., 638.)—The iodine value for mineral oils and their derivatives has only a significance when accompanied by an exact description of the conditions under which the estimation was carried out. In the estimation of ethylenic hydrocarbons in mixtures, the results deduced from the iodine value vary according to the method employed, the time of action, the temperature, and the quantity of iodine solution; these should always be specified. The bromine value, estimated according to Frank's method, affords a quantitative measure of the ethylenic hydrocarbons, and is particularly to be recommended when the quantity of the sample is small, for the determination of the degree of refining of colourless or slightly coloured mineral oil products, and for testing the purity of particular fluid ethylenic hydrocarbon preparations. The percentage of ethylenic hydrocarbons can be calculated direct from the bromine value by the formula $A = [K + (n - 5)c].G$, in which A = the percentage of ethylenes; K = a constant; n = the mean number of carbon atoms (not less than 5) in the ethylenes corresponding to the particular limits of boiling-point; and G is the bromine value. $G = \frac{100\,g}{S} = \frac{100\,v.\,0{\cdot}008}{S}$, in which g is the quantity of bromine absorbed in grms., S is the quantity of the substance taken in grms., and v = c.c. of $\frac{N}{10}$ bromine solution. The constants K and c are calculated for each hydrocarbon, so that $\frac{\text{percentage of ethylenes}}{\text{bromine value}}$ = a constant. K is 0·4375 for amylene, 0·5950 for hexylene, 0·6075 for heptylene; for each increment of CH_2 the constant increases on the average by 0·0875 = c. For instance, in a mixture of amylene and isopentane of sp. gr. 15° C. = 0·6424, a quantity of 0·2277 grm. of the sample required 39·5 c.c. of a $\frac{N}{10}$ bromide-bromate solution, corresponding to 0·3160 grm. of bromine; the bromine number is thus 138, and the sample contains 0·4375 × 138 = 60·37 per cent. of amylene. The accuracy of the results obtained by the bromine method is confirmed by those of the sulphuric acid method. J. F. B.

Relationship between the Iodine Value and the Structure of Acids of the Oleic Series. G. Ponzio and C. Gastaldi.

(*Gazz. Chim. Ital.*, 1912, **42**, 92-95.)—While the iodine value of ordinary oleic acid as estimated by the usual methods is in close agreement with the theoretical value, the results obtained with crotonic acid and certain other fatty acids are much too low. Thus in the estimation of the iodine value by the methods of Hübl (4 hours' absorption), Wijs (30 minutes) and Hanus (30 minutes) the following results were obtained:

	Hübl.	Wijs.	Hanus.	Theoretical Value.
Undecylenic acid, $CH_2{:}CH.(CH_2)_8.COOH$, ..	135·1	137·3	—	137·8
Crotonic acid, $CH_3.CH{:}CH.COOH$	17·4	10·3	4·3	295·0
2—3 Hypogæic acid, $CH_3(CH_2)_{12}.CH{:}CH.COOH$	6·6	20·4	1·9	99·8
2—3 Oleic acid, $CH_3(CH_2)_{14}.CH{:}CH.COOH$ ...	8·7	18·0	3·0	89·7

From these and similar results the conclusion is drawn that it is the position of the double bond in unsaturated acids of the series $C_nH_{2n}-2O_2$ that influences the amount of the iodine value. If the double bond is distant from the carboxyl group, as in ordinary oleic and undecylenic acids, the iodine value will be normal, whilst if it adjoins the carboxyl group, as in the case of the other acids in the table above, the iodine value will be lower than the theoretical value. Further experiments showed that it was only the velocity of the reaction that was affected by the position of the bond; for by prolonging the time of absorption to seventy hours, 2—3-oleic acid gave an iodine value of 45·9 by Hanus' method, and of 86·8 by the method of Wijs. The absorption was due to addition and not to substitution. It thus appears that an estimation of the iodine value is a good method of establishing the position of the double bond in an unsaturated acid. C. A. M.

Proximate Analysis of Complex Lipoids by Alcoholysis. Fourneau and Piettre.

(*Bull. Soc. Chim.*, 1912, **11**, 805-810.)—The authors have studied the separation of complex fatty bodies into their proximate constituents by the action of alcoholysis. The material used was lecithin containing 1·76 per cent. of nitrogen and 3·86 per cent. of phosphorus. A solution of 50 grms. of lecithin in 100 grms. of methyl alcohol was saturated at a temperature of 0° C. with gaseous hydrogen chloride. The solution was then heated at about 50° C. for one hour until the excess of hydrochloric acid had disappeared. The liquid then separated into two layers, the upper containing the esters of the fatty acids, and the lower containing the glycerophosphoric acid and choline hydrochloride. The upper layer was carefully decanted off, and washed with a little water, the washings being added to the aqueous acid layer, which latter was then exhausted with ether to remove the last traces of fatty matters. The ethereal extract was added to the fatty esters previously separated.

dried first over sodium sulphate, then over sodium carbonate; the ether was evaporated and the residue distilled under a pressure of 18 mm. Between 200° and 203° C., 18 grms. of a liquid partially crystallising at about 12° C. was distilled over. A second fraction of 13 grms. distilled between 207° and 210° C. Lastly, 3·5 grms. came over between 210° and 230° C. without any definite boiling-point, and the residue amounted to 2·5 grms. The acid solution containing the glycerophosphoric acid and the choline was concentrated at a low temperature *in vacuo* to expel most of the hydrochloric acid; the residue was treated with 500 c.c. of water and 10 grms. of animal charcoal. The solution was neutralised with chalk, made faintly alkaline with milk of lime, and, lastly, very slightly acidified with hydrochloric acid. The filtered solution was evaporated at a temperature not exceeding 55° C. The residue was taken up with absolute alcohol, which dissolves the choline hydrochloride and the calcium chloride, leaving the calcium glycerophosphate undissolved. This latter, after drying, weighed 12 grms. The alcoholic solution was evaporated, the residue dissolved in water, and the solution treated with exactly the quantity of sodium carbonate necessary to precipitate the calcium. The filtrate was evaporated and the choline hydrochloride extracted from the residue by absolute alcohol, the yield on evaporation being 7 grms. The products obtained by the quantitative alcoholysis of the lecithin were thus: 68 per cent. of stearo-oleic methyl esters, 24 per cent. of calcium glycerophosphate, and 14 per cent. of choline hydrochloride, whereas the theoretical values are respectively 76, 26, and 17 per cent. The fatty esters consisted of methyl stearate and oleate, with possibly a little linoleate. The calcium glycerophosphate was optically inactive, and could be split up into two fractions, one of which was crystalline and anhydrous. Alcoholysis is the best method of preparing cholesterin, which body, if present, separates in a remarkably pure crystalline state after the alcoholysis. The method has been applied to the investigation of the complex fats of yolk of eggs, suprarenal capsules, and sheep's skin. J. F. B.

Volumetric Method for the Determination of Phenol-*p*-Sulphonic Acid. C. E. Smith and H. C. Frey. (*J. Amer. Chem. Soc.*, 1912, **34**, 1040.)—A quantity corresponding to 0·18 to 0·2 grm. of phenol-*p*-sulphonic acid, is dissolved in 50 c.c. of water in a 250 c.c. stoppered flask with a long, narrow neck. To this are added 50 c.c. of a water solution containing 2·7833 grms. of potassium bromate and about 40 grms. of potassium bromide per litre, and 5 c.c. of hydrochloric acid of sp. gr. 1·13 to 1·19, the flask quickly stoppered to prevent loss of bromine, and allowed to stand at 20° to 25° C. for not less than ten or more than fifteen minutes. Potassium iodide solution, 1 grm. in 5 c.c. of water, is added, by pouring a small quantity round the stopper, which is then raised while the rest is quickly introduced. The solution is shaken and titrated with $\frac{N}{10}$ sodium thiosulphate. No indicator is needed, but starch can be used. The number of c.c. required is subtracted from 50; each c.c. of the remainder corresponds to 0·00435 grm. of phenol-*p*-sulphonic acid. The limit of error is ± 0·5 per cent. If accurate results are required, a rough preliminary determination is necessary when the approximate quantity of phenolsulphonic acid is unknown. O. H. M.

Parchment Paper. A. Burr, A. Wolff, and F. M. Berberich. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 197-227.)—Analyses of some fifty-eight samples of commercial parchment paper yielded the following results: The moisture varied from 5·49 to 13·10 per cent., but thirty-four of the samples contained less than 8 per cent. The amount of ash present in the papers ranged from 0·23 to 17·10 per cent., but in only twenty-one samples did it exceed 4 per cent.; in a few cases lead was detected in the ash. The papers yielded from 0·05 to 31·10 per cent. of water-soluble matters, thirty-four of the samples giving more than 10 per cent. One sample of paper contained 25·78 per cent. of sugar, and only sixteen were free from this constituent. There was evidence that magnesium chloride and calcium chloride were present in some of the papers. Experiments were also carried out with the object of ascertaining the suitability of parchment paper as a wrapper for butter, etc., particular attention being paid to the behaviour of those papers which contained an undue proportion of foreign substances. Parchment paper containing a large quantity of sugar favours the growth of moulds when wrapped round fresh butter, especially when the latter contains a large amount of water or butter-milk. The presence of salt (1 per cent.) in the butter hinders the growth of the moulds. When butter has to be kept in parchment-paper wrapping for some length of time, it is recommended that the paper before use be washed with hot water and then dipped in a salt solution. Although moulds do not grow well in the presence of glycerol, they are scarcely affected by the quantities of this substance which are present in parchment papers. A satisfactory paper for use as a butter wrapper would probably be one containing not more than 8 per cent. of water-soluble constituents, and yielding not more than 3 per cent. of ash. W. P. S.

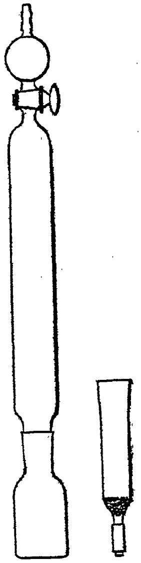
Hübener Bromide Method for the Estimation of Rubber. G. Hübener. (*Gummi-Zeit.*, 1912, **26**, 1284; through *Chem. Zentralbl.*, 1912, II., 762.)—The author replies to criticisms, especially by Hinrichsen and Kindscher (Analyst, 1912, 202), of his bromide method (*ibid.*, 1909, **34**, 365), and mentions a case in which a rubber, stated to consist of 90 per cent. caoutchouc and 10 per cent. sulphur, in reality contained only 65 per cent. caoutchouc, as the bromide method had shown. Sources of error are mentioned. The substance must be sufficiently finely divided, and, in particular, not too much should be taken for bromination. Thus, 0·1 grm. of the rubber mentioned above was completely brominated by a single application of bromine water, while 0·5 grm. required four; there was no over-bromination on six applications. Commercial bromine contains sulphuric acid, so that with repeated brominations a figure may be obtained for the free sulphur in excess of the total sulphur. If the author's conditions are adhered to this is of small importance, since a similar quantity of bromine is used in the estimation of the free sulphur; and it is the difference between the figures, and not the actual figures, which is of importance. After a single bromination of 0·1 grm. substance, the vulcanisation sulphur, from the difference between free and total sulphur, was 2·06 per cent.; after four brominations, 2·61; and after six, 2·11. It is, therefore, not possible to assume that vulcanisation sulphur is oxidised out of rubber by bromine, and this is supported by the higher percentage of vulcanisation sulphur in hard rubber than is found in soft rubber. It is not surprising that Hinrichsen and Kindscher found a higher value for free sulphur from the sulphur in bromine water than from the sulphur dissolved in acetone. Budde (*ibid.*, 1909, **34**, 407) has already shown that acetone does not extract all the free sulphur. There is no material error due to loss of bromine from the bromide.

O. E. M.

Studies on Soil Humus. S. Davitt. (*J. Ind. and Eng. Chem.*, 1912, **4**, 601-604.) —Five samples of soil were experimented with, four being low-grade soils poor in humus from Tennessee, and one rich in humus from Florida. Two methods were employed for the removal of clay—firstly, that of Mooers and Hampton, involving extraction with 1 per cent. hydrochloric acid, followed by successive volumes of 4 per cent. ammonia. The extracts are repeatedly evaporated to dryness and baked. Some months of standing with water follow, to allow the clay to settle out. The second method employed was that of mechanical separation of the clay by long standing without evaporation to dryness. Some preliminary investigations are recorded dealing with the retention of humus from water solution by ferrous iron, ferric iron, and calcium chloride. After such treatment there always remained some organic matter in solution which could be removed more or less completely by a copper salt. A starch-like substance, which gave no iodine coloration, was present to the extent of from 4 to 10 per cent. in humus from Florida; it can be hydrolised by acids and also acted upon by diastase with subsequent acid hydrolysis. Both of these processes gave reducing sugars, one of which was obtained in a crystalline form, but could not be identified. The mother liquor from which this sugar was crystallised was optically inactive and easily fermentable. After fermentation it contained alcohol and acetic acid and still reduced alkaline copper solution.

H. F. E. H.

Study of the Acidity of Soils. A. Gregoire. (*Bull. Soc. Chim. Belg.*, 1912, **26**, 386-409.)—In a previous communication (ANALYST, 1912, 422) a method was described for the estimation of acidity based on the reaction between potassium iodide and iodate by the use of "Kjeldahl's solution." This reagent is capable of estimating the feeblest of organic acids, even those insoluble in water. At the same time it reacts also with inorganic compounds of acid function and shows marked acidity with aluminium compounds and silica. On applying the method to soils it was found that all soils, even those of alkaline reaction to litmus and containing notable proportions of calcium carbonate, showed some acidity with Kjeldahl's reagent, and it is necessary in interpreting the results to establish some limiting standard. Undoubtedly the main acidity of soils is due to the organic matter, and whilst the total acidity has little absolute significance, the ratio of Kjeldahl acidity to organic carbon is capable of giving very valuable information as to the normal or abnormal character of the soil. The results obtained by the author's method as a general rule run parallel with those shown by the litmus method of Larsen and Christensen, and the Kjeldahl reagent possesses the advantage of affording direct numerical expression of the acidity or hydrogen ions. In view of the close correlation between the acidity and the organic matter, the author has worked out a method for the estimation of the organic carbon by combustion of the soil previously treated with acid to decompose the carbonates. The combustion tube is of quartz, 20 to 22 mm. in diameter and 700 to 800 mm. long, connected with the usual supply of oxygen at one end and charged with a layer of about 100 mm. of copper oxide; about 5 grms. of soil are weighed out in one or two quartz boats. The arrangement for absorbing the carbon dioxide produced consists of a Pettenkofer tube, 18 to 20 mm. in diameter and 1·5 to 1·8 metre long. It has an inclination of 120 mm. per metre and is provided with three or four baffle cones of platinum to prevent the direct passage of the bubbles of gas. The absorption liquid is a solution of barium hydroxide. When the combustion is finished the further end of the absorption tube is attached to a filter-tube containing a plug of abestos, similar to, but larger than, those employed for collecting the cuprous oxide in the estimation of reducing sugars. The absorption tube is then detached from the furnace and placed in a vertical position. The filtration of the barium carbonate takes place fairly rapidly and the tube is rinsed down with boiled water. The barium carbonate in the filter tube is estimated gasometrically. Scheibler's apparatus is unsuitable because it has been found that the caoutchouc bag absorbs carbon dioxide. The carbon dioxide must therefore be generated in a glass vessel and measured by displacement of air, air only coming in contact with the rubber connections. The gas evolution vessel employed is shown in the accompanying sketch (see Fig.); it is a cylinder 45 mm. in diameter and 350 mm. long, surmounted by a stopcock and bulb which is charged with acid, whilst the lower end is ground for insertion either into the neck of a flask or into the filter-tube containing the barium carbonate. This vessel is adapted to lie in a large trough of water, whilst the upper end is connected by a rubber tube with the gas-measuring apparatus. Nitric acid of 1·20 sp. gr. is employed, since with hydrochloric acid the barium chloride is only sparingly soluble. A correction must be made for the solubility of the carbon dioxide in the acid liquid. The author points out that a fixed correction, such as is usually recommended, is quite inaccurate, since the solubility of the gas depends on its partial pressure, so that the correction varies with the relative quantity of gas evolved and air present. It is necessary, however, after evolution of the gas is complete, to close the stopcock and effect a thoroughly uniform mixture of the carbon dioxide and air remaining in the cylinder; the cock is then opened again, the levels readjusted and the reading taken. The correction for solubility is then found by means of the formula $\frac{S \times V \times H}{A \times 760}$, where S = the coeficient of solubility of pure carbon dioxide, V = the volume of carbon dioxide read off, H = the atmospheric pressure reduced to 0° C., and A = the volume of the evolution vessel, up to the stopcock minus the volume of the acid. The coefficients of solubility of pure carbon dioxide in 10 c.c. of nitric acid of 1·20 sp. gr. are given as follows, in terms of gas at 0° C. and 760 mm. pressure: At 10° C., 11·48 c.c.; 12° C., 11·28 c.c.; 14° C., 11·02 c.c.; 16° C.,



10·67 c.c.; 18° C., 10·28 c.c.; 20° C., 9·78 c.c.; 22° C., 9·25 c.c.; 24° C., 8·56 c.c. In the case of hydrochloric acid the coefficient of solubility may be taken as the same as in the case of water. J. F. B.

INORGANIC ANALYSIS.

Colour Reaction of Ammonia. P. Thomas. (*Bull. Soc. Chim.*, 1912, **11**, 796-799.)—The blue coloration which is developed when an ammonium compound is treated with a solution of phenol and a hypochlorite is as delicate as the reaction with Nessler's reagent, and, in the author's view, is more specific. It can be used in cases where Nessler's test fails, as, for instance, in the case of liquids containing proteins, more or less cloudy. In carrying out the quantitative test a solution of ammonium chloride containing 1 grm. in 10 litres is employed as a standard; increasing quantities of this are placed in a series of glasses, the volume being made up to 5 c.c. in each case. Then are added 1 c.c. of a 4 per cent. solution of phenol and 1 c.c. of "eau de Javel," the commercial liquor diluted to 10 per cent. The blue coloration develops gradually after mixing and is visible at a dilution of 1 in 500,000. The reaction is applicable to the estimation of ammonia in water, but so far it has not been possible to use it in the case of organic secretions. In testing various nitrogenous substances in order to ascertain how far this reaction is peculiar to ammonium compounds, it is difficult to be quite sure of the absence of ammonia as an impurity. Among the amino-acids glycocoll would appear to be the only one which shows the coloration with any intensity; certain others develop a slight colour, but only at concentrations above 1 per cent. Acetamide shows no colour, but urea gives a pale green. The amines of the fatty series are not readily obtainable perfectly free from ammonia. It would seem that all the primary amines give the same coloration to a greater or less extent, methylamine and ethylamine react with great intensity. The secondary amines react feebly, but their purity is doubtful; the tertiary amines do not give the reaction. J. F. B.

Electro-analytical Estimation of Copper in Pyrites. W. D. Treadwell. (*Chem. Zeit.*, 1912, **36**, 961.)—Copper may be deposited quantitatively by electrolysis of a solution of pyrites in aqua regia without eliminating the aqua regia. If the following directions be adhered to, the deposit will never contain more than 1 mgrm. of iron and lead, but since it invariably includes some iron, it should always be redissolved in nitric acid and redeposited. The solution of 3 to 4 grms. pyrites, which need not be filtered from gangue, is diluted to 100 to 150 c.c., and ammonia is added until a slight permanent turbidity is produced. About 10 grms. of Rochelle salt (about 8 grms. per grm. of iron present) is next added to hold up the iron. Ammonium sulphate (5 grms.) and ammonia (20 c.c.) are added, and the solution is electrolysed in the cold, using a gauze cathode which is rotated at a moderate speed, and preferably a cylindrical anode. The cathode must remain covered by the liquid or copper will redissolve from it under the influence of oxygen and ammonia. With a difference of potential between the terminals of 2 volts, corresponding to a current varying from about 2·7 to 0·7 amp., 0·5 grm. copper may be deposited in sixty to seventy-five minutes from a solution containing 1·5 grms. iron. If speed is no object, the use of a rotating cathode may be avoided, and the terminals of the apparatus connected to those of a single lead accumulator and left overnight. In this case the action is started with the temperature of the electrolyte at about 40° C., and not more pyrites than corresponds to 0·3 grm. copper should be taken for the estimation. In any case, the deposit is washed with a jet of water as the cathode is lifted out of the bath, and is redissolved in 5 c.c. of nitric acid, and the solution is boiled to expel nitrous gases and re-electrolysed, preferably with the use of a rapidly rotating cathode, and the current from two Edison accumulators short circuited through the bath (about 2·6 volts). This second electrolysis occupies only ten to fifteen minutes. The first one may be accelerated by the use of hydrazine sulphate or sodium bisulphite to reduce the iron to the ferrous state, instead of leaving this work to the current, but this is not permissible if the pyrites contains arsenic, for these reagents reduce arsenic to the arsenious condition, with the result that arsenic is deposited on the cathode with the copper. G. C. J.

Reaction of Gold Salts with *m*-Phenylenediamine. J. A. Siemssen. (*Chem. Zeit.*, 1912, **36**, 934.)—A solution of *m*-phenylenediamine (5 : 1,000) is a sensitive reagent for gold salts, and will give an immediate violet coloration with a 0·005 per cent. solution of gold chloride. With stronger solutions of the gold salt (0·5 per cent.) the reagent gives colorations ranging from yellow to dark brown. The *m*-phenylenediamine solution must be decolorised, if necessary, by boiling with freshly ignited animal charcoal. C. A. M.

Separation of Iron from Titanium. F. Bourion. (*Ann. Chim. anal.*, 1912, **17**, 281-284.)—The extreme error of the method, which has been described before (ANALYST, 1912, 323), is ± 2 mgrms. when operating on 0·5 grm. or less of the mixed oxides. G. C. J.

Quantitative Separation of Lanthanum from Yttrium. C. James and T. O. Smith. (*Chem. News*, 1912, **106**, 73-74.)—The following method was found to give a more perfect separation than the potassium sulphate method. It depends on the insolubility of lanthanum magnesium nitrate in concentrated nitric acid saturated with bismuth magnesium nitrate. Yttrium forms no double nitrate with magnesium. The solution containing lanthanum and yttrium as nitrates is evaporated to dryness, and the residue is treated with 25 c.c. of concentrated nitric acid saturated with bismuth magnesium nitrate. Solid bismuth magnesium nitrate (10 grms.) and 1 grm. of magnesium nitrate are added, and the mixture warmed and stirred, and then allowed to stand for twenty-four hours. The crystalline deposit is filtered off on a Gooch crucible, and washed with nitric acid saturated with bismuth magnesium nitrate. The filtrates and washing are evaporated to dryness, the residue is treated with 200 c.c. of cold water, and bismuth is precipitated with hydrogen sulphide. The bismuth sulphide is filtered off and washed with cold water, and the filtrate is boiled to expel hydrogen sulphide, cooled, treated with ammonium chloride, and nearly neutralised with ammonia. Yttrium is then precipitated by means of oxalic acid, and the oxalate ignited to the oxide and weighed. The lanthanum magnesium nitrate and bismuth magnesium nitrate in the Gooch crucible are washed into a beaker, bismuth is precipitated as sulphide, and in the filtrate from the bismuth sulphide lanthanum is precipitated in a manner exactly similar to that followed in the case of yttrium. With 0·2 grm. of lanthana and 0·2 grm. of yttria present, the amount of each earth may be determined with an error which does not exceed ± 4 mgrms. It is pointed out that the error would probably be greater if the method were applied to the separation of lanthanum from holmium and dysprosium, since these elements have a tendency—slight though it may be—to form double nitrates with magnesium. On the other hand, the method might be expected to give a nearly perfect separation of lanthanum from those members of the yttrium group, the nitrates of which are more soluble than that of yttrium itself.

In the author's hands the potassium sulphate method underestimates yttrium by more than 10 per cent., and no satisfactory results were obtained by substituting sodium sulphate for potassium sulphate, nor by methods depending on the different solubilities of the formates and cacodylates of lanthanum and yttrium. G. C. J.

Determination of Lithium. L. R. Milford. (*J. Ind. and Eng. Chem.*, 1912, 4, 595-597.)—Of mineral waters containing much sodium and potassium relatively to lithium, 250 c.c. are evaporated to dryness in a large platinum dish, with occasional addition of a few drops of hydrochloric acid. The residue is heated to 120° C. for half an hour to render silica insoluble, and is then moistened with hydrochloric acid and rubbed up with 25 c.c. of 95 per cent. alcohol. The alcoholic extract is filtered, and the insoluble matter washed with 95 per cent. alcohol so long as lithium can be detected spectroscopically. The alcoholic filtrate and washings are evaporated to dryness, a little hydrochloric acid being added towards the end, and the residue is extracted and the extract filtered as before, but using absolute alcohol in place of weaker spirit. The alcoholic filtrate is evaporated to dryness, and the residue taken up in a little dilute hydrochloric acid. Magnesia is precipitated by addition of an excess of calcium hydroxide, and the solution is filtered, and most of the lime precipitated by addition of ammonia and ammonium oxalate. After standing overnight, the calcium oxalate is filtered off and washed with at least 100 c.c. of water, or until lithium can no longer be detected. The filtrate and washings are evaporated to dryness, ammonium salts expelled at a low temperature, and the residue taken up once more in a little hydrochloric acid. Ammonia and ammonium oxalate are added again, any precipitate which separates at once or on concentrating is filtered off, and the filtrate is evaporated to dryness, and ammonium salts expelled by heating in platinum just short of redness. The residue is taken up in water, filtered and washed, using as little wash-water as possible, and is then evaporated with hydrochloric acid and chlorine-water to decompose any bromide or iodide. The ignited residue is taken up with a little water, and the solution, acidified by a few drops of hydrochloric acid, is transferred to a large platinum dish. About 30 c.c. of amyl alcohol are added and the water boiled off, with constant stirring to prevent bumping. A drop of dilute hydrochloric acid is added to reconvert traces of lithium hydrate to chloride, and the solution is concentrated to about 15 c.c. on the steam-bath, and then filtered into a platinum dish and evaporated to dryness. This treatment with amyl alcohol separates most of the sodium and potassium chloride which escape separation by means of alcohol in the earlier stages of the process. The residue of lithium chloride is treated with water and a few drops of sulphuric acid and evaporated to dryness, the excess of acid is expelled by heating to dull redness, and the residue again taken up in water. Ammonia is added to precipitate the last trace of magnesia, which is filtered off and washed with boiling water. The filtrate and washings are evaporated to dryness, freed from ammonium salts, and the treatment with ammonia repeated until no further precipitate of magnesia is formed. The lithium is finally weighed as sulphate, and a deduction of 1·7 mgrms. is made to correct for the solubility of sodium and potassium chlorides in amyl alcohol.

G. C. J.

Gravimetric Estimation of Magnesium. L. Karaoglanow. (*Jahrbuch d. Univ. Sofia,* 1910-1911, 1-57; through *Chem. Zentralb.*, 1912, II., 548-549.)—Magnesium ammonium phosphate, precipitated from solutions of magnesium chloride or nitrate, should be washed with ammonia containing ammonium salts, but precipitates obtained from the sulphate are best washed with 2·5 per cent. ammonia. The method of Neubauer always gives higher results than the method of Gibbs or that of Schmitz, and the results obtained by the latter methods agree closely with those yielded by the oxide and sulphate methods, which the author has slightly modified with a view to making them sufficiently accurate to serve as control methods in his experiments on the phosphate method. The high results yielded by Neubauer's method are not due to the formation of $(NH_4)_4Mg(PO_4)_2$, as Neubauer, and also Gooch and Austin, have assumed, but are probably due to the power of adsorption possessed by the amorphous or granular magnesium ammonium phosphate. Pellet's method is useless for quantitative purposes, since no definite magnesium sulphopyrophosphate is obtained, but only an equilibrium between magnesium pyrophosphate and sulphuric acid.

G. C. J.

Volumetric Estimation of Manganese. L. Karaoglanow. (*Jahrb. der Univ. Sofia,* 1910-1911, 1-33; through *Chem. Zentralbl.*, 1912, II., 548.)—Some of the disadvantages of Volhard's method disappear when it is applied to solutions of manganous nitrate instead of to solutions of the sulphate. For example, the titration can be carried out in presence of ferric nitrate and aluminium nitrate, whereas the corresponding sulphates hinder the action of permanganate on manganous sulphate. Moreover, manganous nitrate can be titrated in nitric acid solution, whereas in sulphuric acid solution manganion is not oxidised by permanganate. The presence of the nitrates of barium, zinc, potassium, and silver, further the reaction between manganous nitrate and permanganate. Ferric nitrate and aluminium nitrate in high concentration limit it, their action depending on their tendency to hydrolytic dissociation in aqueous solution, the nitric acid thus set free being the agent which interferes with the oxidation. The method always gives results somewhat below the truth, the most accurate results being those obtained in presence of some ferric nitrate. The most convenient form of the method, however, is that in which silver nitrate is added to the solution to be titrated, the results render such circumstances being "sufficiently exact." Silver nitrate reacts with manganous acid to form silver manganite, the amount of the latter formed depending on the relative concentrations of silver nitrate, manganous nitrate, and manganous acid. In practice, the precipitate consists mainly of manganous acid, the greater part of the silver nitrate remaining unchanged in the solution. If other nitrates are present, even less silver manganite is formed, the other metals replacing the silver of silver manganite. These other metallic ions exercise a similar influence on the divalent manganese of manganous manganite. This is the explanation of the favourable influence of metallic salts on the reaction between permanganate and manganous nitrate. Equivalent quantities of different metallic nitrates displace different quantities of silver or manganese from their combination with manganous acid; the order is ferric, silver, zinc, aluminium, barium, and potassium nitrate. The same order applies to the accuracy of the results when manganese nitrate is titrated with permanganate, the most exact results being those obtained in presence of a reasonable amount of ferric nitrate. The variation in the results cannot be ascribed to disturbed equilibrium between manganous manganite and metallic nitrate, but depends on the fact that the formation of manganous manganite cannot wholly be prevented even if the titration be conducted in presence of a great excess of another salt. Once manganous manganite is formed, however, it is with difficulty either oxidised by permanganate or substituted by another metal, since the system is heterogeneous. The author's work proves the untrustworthiness of Rössler's method for the volumetric estimation of manganese, and throws doubt on Rose's method for the preparation of silver manganite, which afforded the basis of Rössler's method. G. C. J.

Absorption of Ultra-violet Rays in Ozone, and its Application to the Estimation of Ozone in Small Concentrations. F. Krueger and M. Moeller. (*Physikal. Zeitsch.*, 1912, **13**, 729; through *Chem. Zentralbl.*, 1912, II., 748.)—The rapid absorption in the region of wave-lengths from 200 to 300 $\mu\mu$ may be used for the estimation of ozone if the coefficients of absorption for the several wave-lengths are accurately known. The authors find that the maximum absorption has the position assigned to it by E. Meyer (*Annalen der Physik.*, 1903, **12**, 849), but that his coefficients of absorption require correction. The light from a quartz mercury vapour lamp was passed through a quartz prism, a slit, the absorption-tube, and a photo-electric potassium cell. The current, measured by means of a quadrant electrometer, is a measure of the intensity of the light. Comparative tests with known concentrations of ozone gave satisfactory results with the new data. The optical method is more sensitive than the chemical, and can be carried out on lower concentrations. O. E. M.

Estimation of Inorganic Phosphorus in Plant Substances. R. C. Collison. (*J. Ind. and Eng. Chem.*, 1912, **4**, 606-609.)—Dilute acid extracts of plant substances contain proteins, carbohydrates, and, in the case of cereals, salts of phytic acid, besides inorganic salts. All these substances, especially the salts of phytic acid, inhibit the formation of ammonium phosphomolybdate. The author previously (*Ohio Agr. Exp.*

Sta. Bull., No. 215) recommended a preliminary extraction with 0·2 per cent. hydrochloric acid, followed by precipitation with magnesia mixture. The dried precipitate was then thoroughly extracted with a measured volume of acid alcohol, the mixture filtered, and phosphorus determined in an aliquot portion of the filtrate, thus avoiding the precipitation of phosphorus in presence of proteins and salts of phytic acid. The author has since found that cold alcohol (94 per cent.) containing hydrochloric or nitric acid (0·2 per cent.) dissolves the common phosphates which are insoluble in neutral or slightly alkaline alcohol. Proteins in general, nucleinic acid from yeast, carbohydrates and salts of phytic acid, are mostly insoluble. He therefore recommends such an acid alcohol extraction of the material followed by filtration, thus leaving behind the undissolved organic phosphorous in the residue. The method was fully investigated on soya beans, rice polish (on account of its high content of phytin), and maize germ meal. Known amounts of inorganic phosphorus were added to these materials and recovered with accuracy. Ten grms. of the finely-ground material is placed in a 400 c.c. flask and covered with 300 c.c. of the acid alcohol solution referred to, the whole being shaken every five minutes for three hours. After filtration an aliquot portion is made just alkaline, with ammonia, and then allowed to stand eight to twelve hours. The precipitate is filtered off, washed with 94 per cent. alcohol made faintly ammoniacal, and then dried, after which it is dissolved in 100 c.c. of 0·5 per cent. nitric acid. The material is again filtered and precipitated with acid molybdate solution. A further advantage of the proposed method is that alcohol extraction tends to prevent enzymic and bacterial decomposition of organic phosphorus compounds, evidence being given that in many cases variations in results have been due to the splitting off of inorganic phosphorus from organic compounds. Analyses of some thirteen substances are recorded by the acid water and acid alcohol methods, with and without the addition of known amounts of inorganic phosphorus, in all cases the results agreeing with the theoretical figures when the latter method is used, and in five cases only when the acid water method was adopted, these five being materials which do not give much organic matter on extraction. H. F. E. H.

New Compensation Method for the Comparison of Quantities of Radium, and some Applications of this Method. E. Rutherford and G. Chadwick.

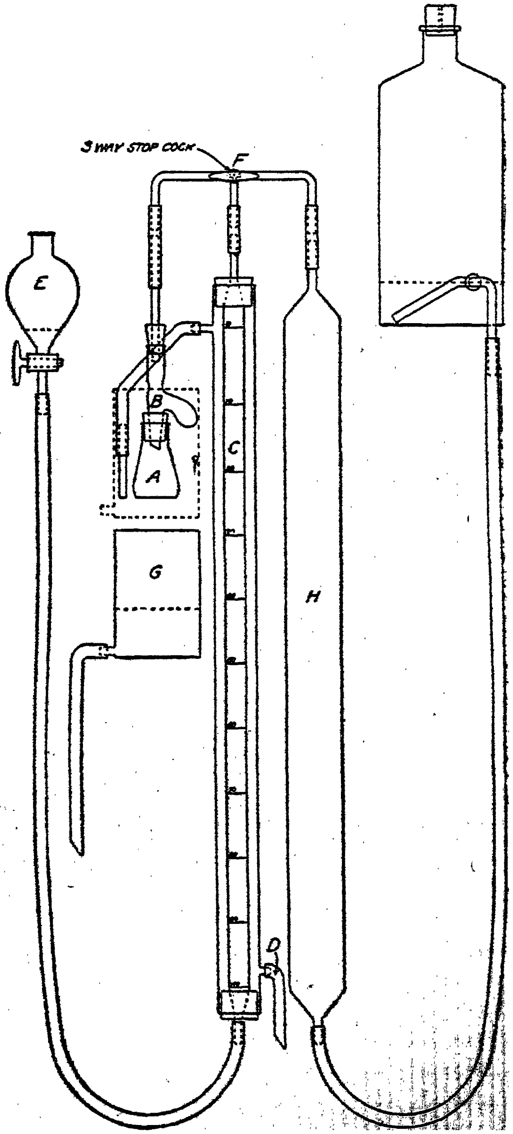
(*Le Radium*, 1912, **9**, 195; through *Chem. Zentralbl.*, 1912, II., 752.)—A preparation of unknown radium content is best compared with a standard by means of the γ-radiation. It is a necessary condition that the preparation shall contain no mesothorium or radiothorium, as both give off γ-rays nearly equal in effect to those of radium. The intensities should not be greatly different, as with ratios of 10 to 1, for example, it is difficult to be certain that there is complete saturation of the ionisation current in the electroscope. To avoid this difficulty, the authors have evolved a compensation method, in which the γ-rays from the radium preparation produce a saturation current, which is compensated in an ionisation vessel by an opposed constant ionisation current from a preparation of uranium oxide. Exact compensation is effected, with the help of a Dolezalek electrometer, by adjusting the distance from the ionisation vessel of the radium preparations, the intensity of which is then proportional to the square of this distance. Corrections for the absorption in air, and, if necessary, in glass, are applied in accurate determinations. Further corrections, for which the original should be consulted, are necessary for the estimation of radium emanations. The γ-activity of a considerable quantity of radium emanation gave by this method an exponential decrease, with a limit of 3,854 days; a tube filled with radium emanation reaches its maximum in 255 minutes. The emission of γ-rays was not affected by bringing the emanation into a powerful magnetic field. O. E. M.

Continuous Fractional Distillation of Water. W. R. Bousfield. (*J. Chem. Soc.*, 1912, **101**, 1443-1453.)—Water having a conductivity represented by $K_{18} = 1 \times 10^{-6}$ is taken as having unit conductivity. In a previous paper (*J. Chem. Soc.*, 1905, **87**, 740) an apparatus yielding water of this order of purity by continuous fractional distillation of tap water was dealt with by the author, and he now describes, with drawings and full details (for which reference must be made to the original), two forms of still more readily managed, and of a simpler type. The first of these—intended for everyday purposes—yields about 30 litres of water per twenty-four hours, two-thirds of which has a conductivity of about 0·8, the rest being of ordinary character. If a strong solution of alkaline potassium permanganate is supplied with the feed-water at the rate of about 10 drops a minute, water of a slightly lower conductivity may be continuously produced. The other apparatus is suited for the continuous redistillation of water under diminished pressure, and by its use water having a conductivity of only 0·5 may be continuously produced by the redistillation of the ordinary product of the first still. Criticising Hartley, Campbell, and Poole (*J. Chem. Soc.*, 1908, **93**, 428), it is shown by several experiments that marked differences characterise the conductivities of the condensation products when waters containing traces of ammonia and acetic acid respectively are distilled and allowed to condense on (1) warm and (2) cold surfaces. In the distillation of ordinary water the "hot-surface" product is the purer when employing the first of the stills figured in the paper; while in the second, as in the still orginally described (*loc. cit.*), the cold-surface product is the purer, and is probably of a higher degree of purity than any hitherto produced on a large scale by any previous arrangement of still. The purest product is obtained from the hot surface, when the rate of distillation is so arranged that the proportions of distillate collected from the hot and cold surfaces are about 2 to 1. Working so as to obtain this ratio, with a total output of 1½ litres per hour, with 3 inches gas pressure, the following conductivities were obtained from the first still:

	K_{18}.	
	Hot-Surface Product.	Cold-Surface Product.
1. From tap water only	0·90	10·0
2. With a large addition of alkaline permanganate	1·20	2·0
3. With 10 drops per minute ...	0·75	2·8

The paper closes with a description and illustration of the second, or "three-bottle," still in series, where an electric heating source is employed in the first bottle, the "hot-surface" product collecting in the second bottle, and the "cold-surface" water going into the third. H. F. E. H.

Calcium Carbide Method for Estimation of Moisture. H. C. McNeil. (*Chem. Eng.*, 1912, **16**, 38-40.)—This method has been made use of for a variety of analyses by different observers (*cf.* P. V. Dupré, ANALYST, 1909, **30**, 266; 1906, **31**, 213; R. A. Cripps and J. A. Brown, 1909, **34**, 519; I. Masson, 1911, **36**, 112). The author's apparatus for measuring the acetylene given off by reaction with the moisture-containing substance, shown in the figure, has been used for the examination of soaps, paints, leather powder, and infants' foods.



The reaction flask, *A*, has a capacity of 25 c.c., and into it a weighed amount of the sample in powder form is introduced. Barium sulphate, silica or similar material is used to mix with the substance, if necessary, so that the carbide will readily mix with it; or the sample may be dissolved or suspended in a liquid, such as toluene, amyl alcohol, or even kerosene and heavy mineral oils. The tube *B* is charged by filling the side projection with carbide ground to a fine powder, a cotton-wool plug pushed down to the constriction, and a little more carbide, covered with wool, placed alternately until the tube is loosely packed, to prevent loss of moisture. The stopcock, *F*, is opened to the air by pulling it partly out, after connecting *A* with *B*, and *B* with *C* by means of tubing, etc., as shown. The flask *A* and tube *B* are surrounded with the vessel *G*, and water is run through *C* and *G* till the apparatus is at the temperature of the water, and when the burette is reading zero by adjustment with *E* the tap *F* is turned so that *B* and *C* are in communication. A little carbide is then tipped into *A* and the rate of reaction carefully controlled. The flask is thoroughly shaken, and the mixture heated for about fifteen minutes, by surrounding the vessel with a bath of boiling water. The apparatus is then reduced to the initial temperature, and the measurements made. The tube *H* is an auxiliary container for use in the case of substances containing much moisture, or of such a nature that a fair sample in small amounts cannot be obtained. In such cases *F* is turned to connect *C*, *H*, and *A*, and the resultant gas is lead from *H* into *C* and cooled, measured, and passed out in portions. Mercury is used in the apparatus, or strong brine saturated with acetylene, and coloured with alkali and phenolphthaleïn.

The apparatus should be standardised, so that the amount of gas given off from carbide by a definite amount of water is known. Practically, 1 grm. of water yields about 582 c.c.

Paints, pastes, and soaps, should be mixed with freshly ignited barium sulphate in sufficient amount to overcome pastiness, and then sand is added to make the mass granular. Alcohol may be used in the case of soaps, instead of the dry method just described, provided that it is first treated with calcium carbide and saturated with acetylene. The infants' foods examined reacted only slowly, the reaction being in some cases incomplete after one hour at 100° C. A. R. T.

Assay of Sodium Peroxide for Bleaching Purposes. W. Herbig. (*Färber Zeit.*, 1912, **23**, 193-196; through *Chem. Zentralbl.*, 1912, II., 636-637.)—In the author's experience the gasometric method for the assay of sodium peroxide often gives too high results, values sometimes equivalent to 114 per cent. of sodium peroxide, which can only be explained by the presence of some higher oxide—*e.g.*, the tri- or tetroxide of sodium. Such higher oxides are of no interest to the bleacher. With the permanganate titration method satisfactory results are obtained by the following procedure: A mixture of 200 c.c. of water and 200 c.c. of dilute sulphuric acid (1 : 5) is cooled to 0° C., by the addition of some clean ice, the permanganate-consumption of which has been previously determined. The height of the liquid in the beaker should be 10 or 12 cm. Then a weighing tube containing 0·2 to 0·3 grm. of sodium peroxide is quickly dropped in a horizontal position to the bottom of the beaker. The air in the weighing tube only allows the acid to come gradually in contact with the peroxide, so that decomposition is slow. If the acid attacks the peroxide all at once the results show considerable variations. The iodometric method may be carried out in a similar manner. The peroxide enclosed in a weighing tube is introduced into a 10 per cent. solution of potassium iodide acidified with hydrochloric acid, and the flask is kept stoppered for forty-five minutes; the liquid is then diluted largely, and the iodine titrated with thiosulphate. The results are concordant if the iodide solution be sufficiently strong during the reaction, but it must be sufficiently diluted before the titration; the acid must be present in excess, and, above all, the thiosulphate solution must only be added drop by drop. Certain samples of sodium peroxide contain greyish black grains consisting apparently of sodium ferrate; such impurities are liable to be very injurious to the cloth in the bleaching process. J. F. B.

Volumetric Determination of Tin. W. W. Patrick and G. C. Wilsnack. (*J. Ind. and Eng. Chem.*, 1912, **4**, 597-599.)—If the alloy does not contain more than 5 per cent. of lead or copper, an amount corresponding to 0·5 grm. or less of tin is taken for analysis, and if the sample contains less than 0·15 grm. of antimony, some powdered antimony is weighed out with it. Solution is effected in a 500 c.c. Erlenmeyer flask by heating with 10 c.c. of sulphuric acid. To the cooled solution 10 c.c. of water is added, and this is followed by 60 c.c. of hydrochloric acid, and a further 40 c.c. of water. The flask is fitted with a four-hole rubber stopper. Through one hole passes a tube for the introduction of carbon dioxide to the bottom of the flask. Another hole carries a short bend which is connected by flexible tubing to a 100 c.c. pipette which dips into water, and serves to prevent air being sucked into the apparatus if the flow of carbon dioxide is not quick enough to prevent the formation of a partial vacuum when the contents of the flask are cooled. A third hole carries a glass rod of such diameter that it can easily be moved up and down. In its lowest position it should nearly touch the bottom of the flask, and at its lower end it has sealed to it a platinum hook to which is attached a spiral of very pure iron made from a 4-inch by ⅛-inch strip of ⅛-inch plate. The fourth hole carries a piece of ½-inch tubing, drawn out to a jet below and with a lateral hole blown on it just above the jet. This tube serves for the introduction of the iodine solution used for titrating the tin, and also for the introduction of water to wash the iron coil when this is raised out of the liquid. With this latter object the jet is bent at a slight angle from the vertical. The lateral hole allows carbon dioxide to escape without impeding the even delivery of iodine solution drop by drop. This stopper being fitted to the flask, and the jet tube being suitably plugged, the air in the flask is displaced by carbon dioxide, and the contents of the flask are maintained in gentle ebullition for twenty-five minutes, and then cooled in running water, the current of carbon dioxide being continued all the time. The iron wire is raised out of the liquid and washed free from tin solution by means of freshly boiled water admitted through the jet tube. The tin is then titrated with iodine and starch, after raising the iron coil to such a position that iodine falling from the jet cannot come in contact with it.

Alloys containing more than 5 per cent. of copper or lead are decomposed by covering with 10 c.c. of concentrated nitric acid, followed by evaporation to dryness. The residue is baked strongly for fifteen minutes, and, when cool again, is rubbed up with 20 c.c. of dilute (1 : 1) nitric acid. The insoluble matter is filtered off, washed with hot water, and then transferred with the filter-paper to a 500 c.c. Erlenmeyer flask, in which it is digested, at first at a gentle heat, with 20 c.c. of sulphuric acid and 2 grm. of potassium sulphate. Before the liquid loses its black colour, it is allowed to cool, and any carbon on the sides of the flask washed down with water, aided, if necessary, by a "policeman." The digestion is then continued until the solution is colourless. To the cooled solution, 50 c.c. of water and 45 c.c. of hydrochloric acid are added, and the reduction and titration of the tin completed in the manner already described.

The iodine solution is standardised on the purest tin obtainable. The maximum error of the method is 1 in 400 if sufficient of the alloy is taken to give a large reading on the iodine burette. G. C. J.

Analysis of the Waters of the Thermal Springs of Bath. I. Masson and W. Ramsay. (*J. Chem. Soc.*, 1912, **101**, 1370-1376.)—The King's spring, the largest of the three main springs, delivers half a million gallons in twenty-four hours at a temperature of 50° C. Potash drinking glasses, after prolonged use, turn yellow owing to the niton or radium emanation contained in the water having liberated potassium in an atomic state of subdivision. Soda glass, similarly exposed, turns pale violet. The water has a density of 1·0175 at 4° C., and a freezing-point of $-0·07°$ C., and gas escapes at the rate of 4,927 litres in twenty-four hours. Oxygen, hydrogen, and methane were absent from this gas, and 168 c.c. of residual inactive gases freed from CO_2 by potash and from nitrogen by passing through red-hot tubes charged with magnesium lime, were fractionally condensed in charcoal cooled with liquid air. Portion 1 measured 96 c.c., and weighed 1·706 grm. per litre. Helium and krypton were absent, and calculation showed the presence of 88·7 c.c. of argon and 7·9 c.c. neon. Portion 2 measured 61 c.c., weighed 1·3509 grm. per litre, and consisted of 31·1 c.c. of argon and 29·9 c.c. neon. Helium lines were absent. Portion 3 was uncondensable by charcoal, the weight of a litre was 0·2681 grm., and the fraction measured 5·6 c.c.; 4·9 c.c. of helium and 0·7 c.c. of neon were calculated to be present. Adding these three portions together, the total gas contained per litre is CO_2, 36 c.c.; nitrogen, 954·1 c.c.; argon, 7·263 c.c.; neon, 2·334 c.c.; and helium, 0·297 c.c. Bath gas, therefore, contains 0·779 times as much argon, 188·1 times as much neon, and 72·8 times as much helium as atmospheric air. In the total of 5,363 litres of gas escaping daily from the three springs, there are 39 litres of argon, 12·5 litres of neon, and 1·6 litres of helium. Niton or radium emanation is also present in too small quantity for chemical estimation, but was measured by comparing the rate of discharge of an electroscope filled with Bath gas, with the effect produced by the niton accumulated during a definite time from a standard solution of radium bromide containing $\frac{1}{10000}$ mgrm. of metallic radium. The niton in a million litres of gas from the King's spring was thus found to be in equilibrium with 33·65 mgrms. of radium. The residue left on evaporating the water had the following composition in mgrms. per litre: Li, 0·16; Na, 181·1; K, 16·7; Mg, 4·1; Ca, 335·7; Sr, 3·2; Fe, 40·2; Al, 9·7; As, trace; Cl, 154·8; Br, 4·4; SO_4, 1054; CO_3, 15·8; SiO_3—. Total, 1811·0. The rare earths were absent. Radium, as metal, amounted to 0·1387 mgrms. in a million litres, the small quantity being due to the high percentage of sulphate. Some deposit on the old Roman lead pipes still at the spring consisted mainly of calcium sulphates. The radium in it was determined, since in 1,760 years half of that originally present would have changed into niton and its products. One part of radium in 10 million parts by weight of the deposit were found. Radium was not detectable in the modern deposit. H. F. E. H.

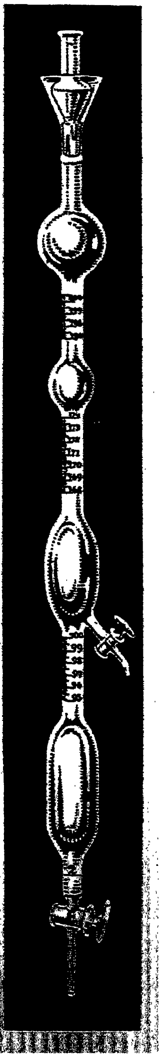
APPARATUS, ETC.

Application of Light Energy to the Study of Certain Problems in Analytical Chemistry. M. Landau. (*Compt. rend.*, 1912, **155**, 403-406.)—The author has studied the action of ultra-violet rays on certain hydrocarbons and carbon monoxide. This action is of two kinds: It causes the polymerisation of unsaturated gaseous hydrocarbons into liquid and solid bodies, whilst in presence of excess of oxygen it brings about photocombustion of hydrocarbon and carbon monoxide gases. The polymerising action is very slow, even when a powerful quartz mercury lamp of 500 volts is used at a distance of 4 cm. In the case of ethylene, the shrinkage of a volume of the gas amounted to 71 per cent. after nineteen hours, whilst a much longer exposure was required to produce complete condensation. In the case of acetylene the action was still slower. The photocombustion was studied in the case of ethane mixed with an excess of oxygen; combustion was complete after sixteen hours' exposure. The combustion of methane was more difficult, and incomplete in the time devoted to its study. That of carbon monoxide amounted to 72 per cent. in fifteen and a half hours, and was complete after longer exposure. In the combustion of hydrocarbons, intermediate products, including carbon monoxide, were formed. The combustions were carried out at a temperature of 80° C. The above reactions were applied to the analysis of a mixture of ethane, ethylene, and hydrogen. Such a mixture cannot be resolved by explosive combustion, because ethylene and hydrogen together are equivalent to ethane; but by a very prolonged exposure to the ultra-violet rays in absence of oxygen the ethylene may be condensed by photo-polymerisation and the contraction measured; oxygen is then added in excess, and the residue submitted to photocombustion. The spectra of the gaseous hydrocarbons show a strong absorption of ultra-violet rays whereas those of carbon monoxide and dioxide do not.

J. F. B.

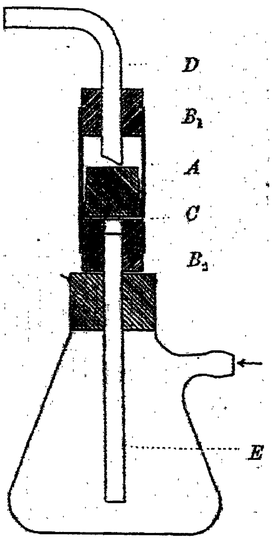
The "Sapometer." C. Huggenberg and H. Stadlinger. (*Chem. Zeit.*, 1912, **36**, 938.)—The special form of burette here illustrated is recommended for use in soap analysis. A weighed quantity (about 10 grms.) of the soap is dissolved in warm water, the solution poured into the "sapometer," which has previously been charged with 30 c.c. of $\frac{N}{1}$ sulphuric acid, and warm water added to bring the total contents to about 97 to 100 on the bottom scale. After the mixture is cold the fatty acids are extracted by shaking with ether or a mixture of ether and petroleum spirit, which is added until the contents reach a mark on the top scale. Any aliquot part of the upper ethereal solution may then be drawn off through the tap at the side and evaporated, while the lower layer is used for other estimations. The apparatus may be obtained from Altmann, Luisenstrasse, 47, Berlin.

C. A. M.



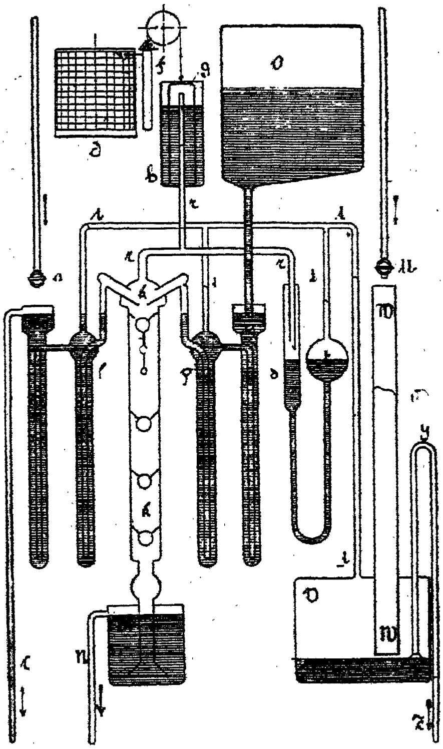
Apparatus for Automatically Decanting and Washing Precipitates. E. Sinkinson. (*Chem. News*, 1912, **106**, 49-50.)—The decanting and washing parts of the apparatus are separate, the former consisting of supports for the funnel and the beaker, containing the precipitate and liquid, and the latter of a rotating jet worked electrically.

The funnel containing the filter-paper is supported in a ring at one end of a balance-arm, and is counterpoised by a sliding weight on the other arm. By moving the weight the amount of liquid run into the filter can be regulated. When sufficient liquid has run into the filter, the funnel drops and is arrested by a fixed support, which carries four mercury cups serving to make and break electrical contact, and so controlling the motors regulating the supply of liquid to the filter. The beaker containing the liquid is supported on a sloping table, the slope being controlled by a motor. Thus, when the funnel drops, the motor is reversed and the liquid ceases to pass into the filter. When decantation is complete, and the precipitate has been transferred to the filter, the washing attachment is brought into use, the jet of wash-water being rotated by means of a worm-gearing electrically actuated. The operations of decantation and washing are carried out automatically, and the apparatus requires no attention except when the washing attachment is to be connected. The original paper is illustrated by four diagrams of the apparatus. A. R. T.

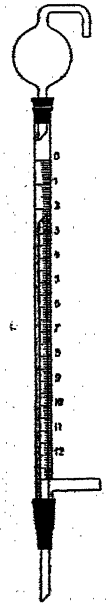


Valve for Filter Pumps. H. B. Hutchinson. (*Chem. News*, 1912, **106**, 99.)—This valve, which is of special use when the water supply is subject to much variation, consists of a stout glass-tube, *A*, $\frac{1}{2}$ inch to $\frac{3}{4}$ inch diameter fitted with two single-bored rubber corks, B_1 and B_2, between which is placed a solid rubber bung, *C*, with its wider end downwards, and fitting loosely into the tube. A glass tube, *D*, with an oblique lower end, is pushed through B_1, until it is about 1 to 2 mm. from the upper surface of the bung, *C*, and a second tube, *E*, is brought sufficiently far through B_2 to enable it to act as a support without bulging the upper surface of the cork. The valve may be used alone or attached to a small filter flask as shown. The latter way keeps the corks moist, which is an advantage, but when the valve is intended only as an air valve, it is best moistened with dilute glycerol. The tube *D* is then attached to the pump, and *E* on the side-tube of the filter-flask is joined to the filtering or vacuum distillation apparatus. Messrs. Gallenkamp supply the valve. H. F. E. H.

Apparatus for Automatic Analysis of Liquids. (*Chem. Zeit.*, 1912, **36**, 962.)—The apparatus figured serves for the automatic and periodical estimation of any constituent of a liquid which yields a gas on admixture with an appropriate liquid reagent—for example, for the estimation of ammonia in aqueous solution by the hypobromite reaction. The reagent is stored in the vessel *o* whilst the liquid to be controlled flows steadily through the cock *a* into *b*, continually overflowing through *c*. The whole apparatus is operated by the syphon tank *v*, and the



periodicity of its operation is controlled by the cock *u*, connected to a water-supply system. As the tank and tube *w* fill, the air-pressure forces the liquid in the bulb *t* into *s*, thus sealing the end of the tube *r*, which is the sole route by which gas can escape from the gas-bell *g*. With increasing head of water in *w* the (ammoniacal) liquid in the measuring tube *l* is forced into the reaction chamber *k*, and at the same time a measured portion of the reagent (hypobromite solution) is forced from *p* into *k*. The reaction chamber *k* is provided with means to ensure intimate mixture of the reacting liquids and with an automatic overflow. The gas generated in *k* passes through *r* to the gas-bell *g*, which rises, and in rising lowers a pencil which traces a continuous line on the clockwork drum *d*. Finally, the syphon *y* operates, the tank empties itself, the level of the liquid in *s* falls sufficiently to allow the gas in the bell to escape through *r*, the reagent measure *p* refills immediately, and the measure *l* fills more slowly with the liquid to be tested. The cycle of operations is then repeated. The point of minimum depression of the pencil are obviously a measure of the amount of ammonia (or other constituent to be estimated) in the liquid, and once the instrument has been calibrated the drum can be supplied with paper ruled to give absolute readings. The makers of the instrument, J. v. Geldern and Co., Düsseldorf, supply with it a self-acting compensator for variations in temperature and barometric pressure. This attachment is not shown in the figure. G. C. J.



Constant Flow Aspirator. J. F. Hoffmann. (*Zeitsch. angew. Chem.*, 1912, **25**, 1723-1724.)—A Mariotte aspirator, when operated at a low speed for long periods, often works irregularly on account of the accumulation of gas bubbles in constricted portions of the apparatus. The apparatus here figured overcomes this difficulty. The horizontal limb of the T-tube, which is conveniently constructed from a broken burette, passes through a rubber stopper in the tubulus of the aspirator (not shown in the illustration). Through a rubber collar, a capillary of suitable dimensions is pushed up into the vertical limb of the T-tube, and the advantage of having the latter constructed from a graduated tube lies in the fact that the speed of flow may be regulated by raising or lowering the capillary, and the graduated tube facilitates the regulation. Before setting the apparatus in operation, the bulb which closes the top of the burette is partly or wholly filled with water by suction, and its limb closed by means of a piece of rubber tube and a glass plug. Any bubbles of gas which may escape from the water accumulate in the bulb, and do not interfere with the regular flow of water.

REVIEWS.

METHODS OF ORGANIC ANALYSIS. By H. C. SHERMAN. Second edition. New York. 1912. The Macmillan Co. Pp. xvi + 407. Price 10s. 6d. net.

The descriptions of the methods in this book were written primarily for the use of third-year students, and, consequently, the technical analyst will find comparatively little that will assist him. In some respects the work is quite up to date. For instance, the methods of glycerin analysis are those of the International Committees, but in others the methods given are nearly obsolete; and as an instance butter may be cited, the Reichert-Meissl method being described in full, while probably the modification of Polenske is now universally employed.

The best feature of the book is the full and clear descriptions of the methods, which are followed by explanatory notes, and the list of references for the student who wishes to follow up the subject. The work appears admirably designed for the purpose for which it was written.

H. DROOP RICHMOND.

WATER ANALYSIS FOR SANITARY AND TECHNICAL PURPOSES. By HERBERT B. STOCKS, F.I.C. 1912. Charles Griffin and Co. Price 4s. 6d. net.

In his preface the author states that he "has endeavoured to give a concise and accurate description of the methods adopted for the analysis of waters for sanitary and technical purposes, with the hope that the information may be of use to Public Analysts, Medical Officers of Health, and students who are interested in this branch of analytical work."

The volume contains 136 pages, of which twenty-eight are devoted to the organic carbon and nitrogen process of Frankland. Neither the arrangement nor treatment of the subject-matter is original, and although most of the ordinary processes are described, the details and hints given are, in several cases, hardly sufficient to enable those unacquainted with water analysis to obtain the most accurate results. The illustrations are but few, and more than half of them poor in quality. The "apparatus for estimating free and saline ammonia," figured on p. 10, probably compares unfavourably with that to be found in most water-analysis laboratories, and the illustration of the combustion apparatus, given on p. 30, is faulty at one point, and the simple gas-measuring tube indicated would be practically useless for the analysis of the products of combustion of many water residues.

Although the work professes to cover analysis for "technical purposes," it contains no reference to the chemistr softening processes. The examination of sewage and effluents is frequently mentioned, but the methods favoured in the laboratory of the Royal Commission on Sewage Disposal,* are not described, and, although a table of standards for effluents is given, the proposed standards of the Commission are ignored.

From a careful perusal of the volume, it appears that Public Analysts and others must still remain contented with some of the works on water analysis already on their bookshelves. WILLIAM T. BURGESS.

TABLES ANNUELLES INTERNATIONALES DE CONSTANTES ET DONNÉES NUMÉRIQUES. Vol. I. Année, 1910. Gauthier, Villars, Paris; Akademische Verlagsgesellschaft, m. b. H., Leipzig; J. and A. Churchill, London; University of Chicago Press, Chicago. 1912. xxxix + 727. Cloth. 24s. net.

The need of collecting physical data has made itself increasingly felt, and probably the chemist has experienced the want of a handy book of reference even more than the physicist. The latter is concerned, generally speaking, more with the methods by which a property is determined, the limits of accuracy attainable, and, above all, the correlation with other properties; the chemist, on the other hand, usually has in view the connection between the constitution of certain chemical compounds and some particular property. The physicist may have considerable trouble in searching scientific literature with regard to some physical property, but it is light when compared with that of the chemist, who, having some particular group of compounds under review, wishes to compare the values of some particular property. He has to find out for which of the compounds in question the value has been determined; secondly, when discrepant values of the constant are given by different observers, to judge which value is the more reliable. In fact, whilst methods for determining some constant will be found described in a comparatively small number of researches, the values of this constant for different substances may be scattered throughout chemical literature.

Organic chemistry has its "Beilstein" and "Richter," physical chemistry its "Landolt and Börnstein"; the latter does not, however, claim anything like the completeness of the organic works, and to remedy this defect the subject was ventilated at the Seventh Congress of Applied Chemistry, an International Committee nominated, and the table of constants for the year 1910 is now published under the patronage of the Association Internationale des Académies.

Values of constants have been accumulated by a large number of abstractors. From the list it will be noticed that the British Empire and Germany have contributed at least two-thirds of the total. The results have been passed on to a relatively small number (thirty-one) of compilers, all men of established reputation. The British members of this shorter list are Messrs. S. L. Archbutt, H. B. Hartley, A. W. Porter, L. J. Spencer, and N. T. M. Wilsmore. Since the foreign compilers are generally of the same status, it will be seen that the work has been placed in reliable hands.

The principles underlying the general classification are not quite obvious. The titles of the chapters given on p. 21, and the table of contents of pp. 22-39, make it easy to search for any particular property; but why diffusion, degree of association, solubility, and similar matters should be dealt with after optical, electrical, and magnetic properties have been given, and be separated completely from coefficients of compressibility, density and viscosity, with which the work opens, passes the comprehension of the reviewer. Again, details relating to crystallography and mineralogy are sandwiched in between adsorption and organic chemistry, whilst mechanical and other properties of metals and alloys come later in the book. No harm is done, for material is found without much difficulty; but the lack of arrangement is to be regretted in a work on which so much pains has been bestowed.

---

* Fourth Report, Vol. IV., Part V., 1904.

The data given are at least as full as one would have expected, and the attempt has been made to record most of the significant figures. Taking a case at random, the densities of solutions of lithium nitrate were determined by Appleby in connection with work on the viscosities of aqueous solutions of this salt, and no less than forty-nine density measurements taken from his work are recorded, in addition to a single value given by Rimbach and Wintgen.

A wise discretion has been exercised in the metallurgical portion; the results of tests (tensile, torsion, etc.) are only recorded for materials of which an analysis has been made. A few matters which had escaped notice in the main part of the work are dealt with in a short supplement.

No index is given; the table of contents renders this scarcely necessary. The care taken in abstracting and compiling is worthy of the highest praise, and the printing and general get-up are excellent. J. T. Hewitt.

NOVEMBER, 1912 Vol. XXXVII., No. 440.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

The ordinary meeting of the Society was held on Wednesday evening, November 6, in the Chemical Society's Room, Burlington House. The President, Mr. L. Archbutt, F.I.C., occupied the chair.

The minutes of the previous ordinary meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. Thomas Rigby Greenough, B.A. (Cantab.), A.I.C., "Beechwood," Leigh, Lancs, Assistant Analyst in the City Laboratory, Liverpool; Harold Lowe, M.Sc. (Manchester), A.I.C., 18, Hough Green, Chester, Assistant to Mr. W. F. Lowe, A.R.S.M., F.I.C.; James P. Ogilvie, "Homedale," Hendon Lane, London, N., analytical and consulting chemist; Stanley Elliott, A.I.C., "Penshurst," Windmill Lane, Enfield, assistant to Mr. C. H. Cribb, B.Sc., F.I.C.; and John Algernon Lacy Sutcliffe, A.I.C., City Analyst's Laboratory, Broad Street, Birmingham, assistant to Mr. J. F. Liverseege, F.I.C., were read for the first time.

Messrs. S. W. Collins, B.Sc., F.I.C., and C. B. Lessner, were elected members of the Society.

The following papers were read: "Note on an Apparatus for Testing Water by Measurement of its Electrical Conductivity," by L. Archbutt, F.I.C.; "The Detection and Estimation of Arachis Oil," by Norman Evers, B.Sc.; "The Examination of Chinese and Japanese Wood Oil," by A. Chaston Chapman, F.I.C.; and "The Estimation of Manganese by the Bismuthate Method," by H. F. V. Little, A.R.C.S., B.Sc.

* * * * *

POISONOUS GASES FROM OILFIELDS.

By HERBERT S. SHREWSBURY, F.I.C.

Recently a negro was killed by breathing the gas at the bottom of a pit under an oil derrick close to the Pitch Lake at La Brea, Trinidad. The pit was some 10 feet deep and surrounded the casing of the tubular oil-well, from which the gas most probably overflowed into the pit. Whilst working in this pit the man became giddy and had to be helped out. Twelve hours afterwards he died.

A sample of gas taken from the top of the well, or oil-tube, was forwarded to this laboratory, and the author found its composition to be as follows:

Sulphuretted hydrogen	0·1
Carbon monoxide	1·1
Saturated hydrocarbons	4·4
Unsaturated hydrocarbons	2·5
Oxygen	8·7
Carbon dioxide	11·9
Hydrogen	18·8
Nitrogen	52·5
	100·0

Assuming all the oxygen and some of the nitrogen to be derived from air, the amount of air present was found to be 43·4 per cent., and the composition of the gas as it issued from the ground was calculated as:

Sulphuretted hydrogen	0·2
Carbon monoxide	1·9
Unsaturated hydrocarbons	4·4
Saturated hydrocarbons	7·8
Carbon dioxide	20·9
Hydrogen	31·4
Nitrogen	33·4
	100·0

A. Wynter Blythe states that 0·05 per cent. of sulphuretted hydrogen in air is the utmost that can be breathed with safety, that 0·08 per cent. is dangerous, and 0·10 to 0·15 fatal to human life. According to Haldane, more than 0·15 per cent. of carbon monoxide is dangerous to human life, and 0·4 per cent. would kill in a moderately short time.

It will be seen that the gas, as it issues from the ground, is extremely poisonous, and that even when mixed with 43 per cent. of air it would kill when breathed for a short time—as, indeed, it did.

The author has visited the Pitch Lake, and the following observations may be of interest. The surface of the lake is covered with little pools and channels of water, through which gas is constantly bubbling. Gas also issues from the pitch itself, which is generally as firm as asphalt, but in places is soft, and in fact liquid. The gas has exactly the same odour as the sample described, the small percentage of sulphuretted hydrogen mixed with the hydrocarbons producing a sweet and tar-like smell. It is an interesting fact, which the author has personally witnessed, that small fishes live in the pools through which the gas bubbles, notwithstanding its poisonous character.

In view of the probability of this evolution of poisonous gas from oilfields being a phenomenon of common occurrence, a widespread publication of the above facts might be the means of averting loss of life.

Government Laboratory,
Trinidad, B.W.I.

THE DETECTION AND ESTIMATION OF ARACHIS OIL.*

By NORMAN EVERS, B.Sc., A.I.C.

(*Read at the Meeting, November* 6, 1912.)

Part I.—Detection.

J. Bellier (*Ann. Chim. anal.*, 1899, **4**, 4) suggested the following qualitative test for arachis oil in olive oil:

One c.c. of the oil is saponified with 5 c.c. of alcoholic potash (85 grms. potash dissolved in a litre of 70 per cent. alcohol), 1·5 c.c. of acetic acid of such a strength as to exactly neutralise the alcoholic potash is added, and the tube cooled in water below 20° C. for not less than thirty minutes. The liquid is then diluted with 50 c.c. of 70 per cent. (by volume) alcohol containing 1 per cent. (by volume) of hydrochloric acid, and placed in water at 17° to 19° C. for an hour. When the oil contains more than 10 per cent. of arachis oil a precipitate is formed, while pure olive oils give a clear solution.

I have used this test on many olive oils and mixtures of olive oil with arachis oil, and have found it to give quite satisfactory indications with as little as 5 per cent. of arachis oil. As noted by Archbutt (*J. Soc. Chem. Ind.*, 1911, **30**, 5-6; Analyst, 1911, **36**, 116), certain neutralised residuum olive oils, known as "saponified" oils, which contain a high percentage of unsaponifiable matter, give a precipitate with this test.

The test was modified by Mansfeld (*Zeitsch. Untersuch. Nahr. u. Genussm.*, 1905, **17**, 57), Adler (*ibid.*, 1912, **24**, 676), and Franz (*Beiträge z. Nachweis und z. Kenntniss d. Erdnussoles Diss. München*, 1910). A more strongly alcoholic potash solution (80 grms. potash dissolved in 80 c.c. of water and diluted to a litre with 90 per cent. alcohol) is used, and the oil saponified in a flask with a condensing-tube for four minutes. This obviates a difficulty which I have frequently found with Bellier's test—viz., the loss of all the alcohol before the saponification is complete. After adding 1·5 c.c. of dilute acetic acid (1 volume glacial acetic acid to 2 volumes water) and 50 c.c. of 70 per cent. alcohol, the liquid is cooled to 15·5° C., and allowed to remain at this temperature for five minutes. In this way the long standing in cold water is dispensed with. I have found this test, for these reasons, to be preferred to that of Bellier. A distinct turbidity is produced by 5 per cent. of arachis oil, and, except in the case of a sample of "saponified" oil, I have never found a pure olive oil which gave a positive result.

---

* This work was carried out under the Analytical Investigation Scheme.

PART II.—ESTIMATION.

Franz and Adler (*loc. cit.*) have shown that the above qualitative test can be made approximately quantitative by determining the temperature at which a turbidity is first produced. The following table is taken from their paper, and shows the various "temperatures of crystallisation" of olive and arachis oils and of mixtures:

Oil.	Temperature of Crystallisation.	Oil.	Temperature of Crystallisation.
	° C.		° C.
Olive oil	11·8–14·3	Arachis oil, 50 per cent.	33·8
Arachis oil, 5 per cent.	15·9–17·0	" 60 "	35·3
" 10 "	19·8	" 70 "	36·6
" 20 "	25·7	" 80 "	38·0
" 30 "	29·2	" 90 "	39·3
" 40 "	31·5	Arachis oils	40·0–40·8

I have been able to verify these temperatures given by Adler with several olive and arachis oils and mixtures, and have found the values obtained remarkably constant, and in all cases within the limits given by him. In the case of the "saponified" olive oil mentioned above, a faint turbidity was observed as high as 45° C., becoming more definite as the liquid was cooled; but no distinct precipitate could be seen until after standing at 15·5° C. for five minutes. This is quite unlike the behaviour of arachis oil, which gives a definite precipitate very shortly after the first opalescence is observed.

Bellier's Process.—This process is carried out as follows:

Five grms. of the oil are weighed out, saponified with 25 c.c. of alcoholic potash (85 grms. potash dissolved in a litre of 70 per cent. alcohol), and the fatty acids liberated with 7·5 c.c. of dilute acetic acid, which exactly neutralises the potash. The liquid is then cooled rapidly and allowed to stand for an hour to precipitate the fatty acids. After filtering, the fatty acids are washed at 15° to 20° C. with 70 per cent. alcohol containing 1 per cent. (by volume) of HCl until the filtrate gives no turbidity with water. The precipitate is then dissolved in 25 to 50 c.c. of boiling alcohol of 92 to 93 per cent. strength, and sufficient water added to reduce the strength to 70 per cent. The fatty acids are allowed to crystallise below 20° C. for an hour, then filtered off, washed with 70 per cent. alcohol until no turbidity is given with water, dissolved in warm ether, and weighed. Using this method, Bellier obtained 4·2 per cent. of fatty acids from two arachis oils, and none or practically none from several olive oils.

Archbutt (Allen's "Commercial Organic Analysis," 4th edition, vol. ii., p. 101) states that he has obtained low results by this method.

The process was tested on various oils in conjunction with Renard's process as modified by Archbutt (*ibid.*, p. 93). The results are given in the following table :

TABLE I.

Oil.	Renard.			Bellier.		
	Arachidic Acid. per Cent.	Melting-point. ° C.	Arachis Oil. per Cent.	Arachidic Acid. per Cent.	Melting-point. ° C.	Arachis Oil. per Cent.
Arachis (A)	4·59	73·5	—	3·56	71	78
Arachis (B)	5·15	72·0	—	3·76	71	83
Olive oil, Nice superfine ...	0	—	—	0	—	—
Olive oil, "Seconds" ...	0	—	—	Trace	—	—
Olive oil, Malaga ...	0	—	—	Trace	—	—
Olive oil, 50 per cent. Arachis (A), 50 per cent.	2·28	73·5	50	1·36	72	30

The factor used in the calculation of the percentage of arachis oil by Bellier's process is 22, as used by Bellier. It is obvious that the results obtained are exceedingly low. This may be due either to the solubility of arachidic and lignoceric acids in 70 per cent. alcohol, or to the incomplete precipitation of the fatty acids on account of their solubility in the strong solution of oleic and other fatty acids.

Solubility of Arachidic and Lignoceric Acids in 70 *per Cent. Alcohol.*—Renard (*Compt. rend.*, **73**, 1330) states that these acids are quite insoluble in 70 per cent. alcohol, but the following determinations show that they possess a quite marked solubility:

The acids employed were obtained from arachis oil by Renard's process. The solubility was determined by dissolving about 0·2 grm. of fatty acid in 100 c.c. of 93 per cent. alcohol, adding sufficient water to reduce the strength to 70 per cent., and keeping at a fixed temperature for several hours. The liquid was then filtered at the same temperature, a measured volume of the filtrate evaporated to dryness, and the residue weighed.

The following are mean values of several results obtained :

TABLE II.

Melting-point.	Solubility, Grms. per 100 c.c.	
	At 13° C.	At 18° C.
71° C.	0·016	0·023
72° C.	0·012	0·017
73° C.	0·009	0·012

The solubility was also determined when the fatty acids were washed on a filter-paper, about 0·2 grm. being used. The results obtained were—

Melting-point, ° C.	Grms. dissolved per 100 c.c.
71	0·008
72	0·006
73	0·005

The presence of 1 per cent. of hydrochloric acid in the alcohol does not affect the solubility.

Saponification, etc.—It is preferable to use the alcoholic potash recommended by Adler, as in the qualitative test, and to saponify in a flask under a reflux condenser.

As a slight excess of acetic acid does not affect the precipitation, 7·5 c.c. of a solution of 1 volume glacial acetic acid in 2 volumes water are added instead of exactly adjusting the strength to that of the potash.

Bellier states that in the absence of 1 per cent. of hydrochloric acid from the 70 per cent. alcohol, the washing is very tedious. The reason does not seem obvious, but this is undoubtedly the case, though the solubility of the arachidic and lignoceric acids themselves is not affected by this amount of hydrochloric acid.

Crystallisation from 90 per Cent. Alcohol.—The final crystallisation was carried out from 90 per cent. instead of 70 per cent. alcohol, where the quantity was sufficient, and the crystals washed, first with 90 per cent., and then with 70 per cent. alcohol as in Renard's process. This procedure gives a purer acid of higher melting-point.

Correction for Solubility in 70 per Cent. Alcohol.—The process was carried out with the above modifications, and corrections added separately for the volume of 70 per cent. alcohol, used for crystallisation and washing, from Table II. above. It was found, however, that when the proportion of arachis oil was less than 50 per cent. the results obtained were too high, because the correction varied with the amount of the precipitate. In order to avoid complication the list of corrections given in Table III. has been drawn up, by means of which a single correction is added for the total volume of 70 per cent. alcohol used, and will be found sufficiently accurate for ordinary purposes.

TABLE III.

Weight of Acids. (Corrected for 90 per Cent. Alcohol.)	Correction per 100 c.c., 70 per Cent. Alcohol.

* In these cases the correction has been added for melting-point 71° C.

† This result was obtained by recrystallising the fatty acids obtained from 70 per cent. alcohol from 10 c.c. of 90 per cent. alcohol.

The Modified Process.—Weigh out 5 grms. of the oil into a saponification flask, add 25 c.c. of alcoholic potash (80 grms. potash dissolved in 80 c.c. water and diluted to a litre with 90 per cent. alcohol), and saponify for about five minutes under a reflux condenser. To the hot soap solution add 7·5 c.c. of acetic acid (1 volume of glacial acetic acid to 2 volumes of water) and 100 c.c. of 70 per cent. alcohol containing

1 per cent. (by volume) of HCl, and cool to 12° to 14° C. for an hour. Filter and wash with 70 per cent. alcohol containing 1 per cent. HCl at 17° to 19° C., the precipitate being broken up occasionally by means of a platinum wire bent into a loop. The washing is continued until the filtrate gives no turbidity with water, the washings being measured. Dissolve the precipitate, according to its bulk, in 25 to 70 c.c. of hot 90 per cent. alcohol, and cool to a fixed temperature between 15° and 20° C. If crystals appear in any quantity, allow to stand at this temperature for one to three hours, filter, wash with a measured volume of 90 per cent. alcohol (about half the volume used for crystallisation), and finally with 50 c.c. of 70 per cent. alcohol. Wash the crystals with warm ether into a weighed flask, distil off the ether, dry at 100° C., and weigh. If the melting-point is lower than 71° C., recrystallise from 90 per cent. alcohol. Add the correction for the solubility in 90 per cent. alcohol as in Renard's process, from the table given by Archbutt (Allen's "Commercial Organic Analysis," 4th edition, vol. ii., p. 94), and also for the total volume of 70 per cent. alcohol used in precipitating and washing (including the 100 c.c. added in the first instance) from Table III.

If there are no crystals from 90 per cent. alcohol, or if they are only in very small amount, add a sufficient quantity of water to reduce the strength of the alcohol to 70 per cent. (31 c.c. water to 100 c.c. 90 per cent. alcohol). Crystallise at 17° to 19° C. for an hour, filter, wash with 70 per cent. alcohol, and weigh as before, adding the correction for the 70 per cent. alcohol from Table III. If the melting-point is below 71° C., recrystallise from a small quantity of 90 per cent. alcohol, or again from 70 per cent. alcohol.

The results obtained by this method are given in Table IV.

The following oils gave no crystals: Olive oils, including "Nice superfine," "Nice seconds," "Malaga," and eight of unknown origin, almond, poppy, and rape oils.

In conclusion, I wish to express my thanks to Mr. L. Archbutt for his valuable advice and assistance throughout the work.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Insoluble Carbohydrates of the Apple. E. C. Schneider. (*Amer. J. Physiol.*, 1912, **30**, 258; through *Chem. Zentralbl.*, 1912, II., 937.)—Marc obtained from pounded Ben Davis apples by extraction with water, alcohol, and ether contained 28 per cent. of reducing sugar, 28 per cent. of pentosan, and 11·5 per cent. of galactan; the pectin prepared from this marc by hydrolysis with 0·4 per cent. hydrochloric acid at a temperature of 38°C. contained 57·5 per cent. reducing sugar, 36 per cent. pentosan, and 46 per cent. galactan. Intestinal bacteria destroyed the hemicellulose and pectin; reducing sugars were not found as end-products of this action. Pentosan and galactan were about equally attacked. Marc and pectin were not hydrolysed by animal enzymes, malt diastase, or taka diastase. Experiments on human beings showed that 79 to 84·5 per cent. of the hemicelluloses of the marc were utilised or destroyed during digestion. O. E. M.

Detection of Cane Sugar. S. Rothenfusser. (*Chem. Zeit.*, 1912, **36**, 1100-1101.)—With the exception of cane sugar and raffinose, all sugars are completely destroyed when treated with hydrogen peroxide in alkaline solution (*Cf.* ANALYST, 1910, **35**, 539; 1911, **36**, 588), and the presence of cane sugar in the resulting solution may be ascertained by means of the diphenylamine reagent described previously by the author (ANALYST, 1910, **35**, 208). The use of calcium or barium hydroxide is preferable to that of an alkali hydroxide, as in the former case a precipitate of barium peroxide is formed on the addition of the hydrogen peroxide, and oxygen is liberated quite slowly, so that the sucrose present is not attacked during the digestion. At the end of the operation the excess of hydrogen peroxide in solution is destroyed by the addition of a catalyst, and the solution is tested with the diphenylamine reagent.

W. P. S.

Estimation of Cane Sugar in Foods, etc. A. Jolles. (*Chem. Zeit.*, 1912, **36**, 1100.)—In the method described originally by the author (ANALYST, 1911, **36**, 28) it was recommended that not more than 2 per cent. of sugars other than cane sugar should be present in the solution in which the latter sugar is to be estimated, as with larger quantities the solution becomes brown in colour and the polarimetric examination is affected. He now states that the brown coloration which develops when concentrated sugar solutions are employed in the process may be removed by means of mercuric acetate and phosphotungstic acid. After the sugar solution has been heated with $\frac{N}{5}$ sodium hydroxide solution for twenty-four hours at 37° C., a measured portion of it is neutralised with dilute acetic acid, and 50 per cent. mercuric acetate solution is added as long as a precipitate is formed, the quantity added being noted. The mixture is then filtered, and an aliquot portion of the filtrate is precipitated with a 25 per cent. phosphotungstic acid solution, the necessary volume of which is also noted. The mixture is again filtered, and then examined with the polarimeter. The rotation observed is due solely to cane sugar, and in calculating the quantity of the sugar present, allowance is made for the dilution caused by the introduction of the precipitants. W. P. S.

Analysis of Commercial Casein. W. Hopfner and H. Burmeister. (*Chem. Zeit.*, 1912, **36**, 1053-1054.)—Good commercial casein should exhibit at the most a slight yellow colour, and should be free from rancid or cheese-like odour and from foreign matters. For the estimation of the moisture, 5 grms. of the sample are dried at a temperature of 100° to 105° C. until constant in weight; this requires about two hours' heating, and the weighing should be made at frequent intervals to avoid oxidation of the casein by prolonged heating. The quantity of fat is best estimated by extraction in a Soxhlet apparatus by a mixture of ether and petroleum spirit, the casein being ground and mixed with sand before being placed in the cartridge. A silica basin should be used for the estimation of the ash, and in cases where the ignition proceeds with difficulty the carbonised mass must be extracted with water in the usual way. The acidity of the sample is estimated under the following conditions: Ten grms. of the casein are shaken with 100 c.c. of water, filtered, and 50 c.c. of the filtrate titrated with $\frac{N}{10}$ potassium hydroxide solution, using phenolphthaleïn as indicator. It is useful to determine the solubility of the casein in ammonia. For this purpose 10 grms. of the sample are mixed with 50 c.c. of water and 2 c.c. of 33 per cent. ammonia. After the lapse of a few hours the mixture is warmed to 60° C. Pure casein swells and yields a thick, opalescent liquid, whilst casein which has been stored for a long time gives a turbid liquid. If sand is present it settles to the bottom of the liquid and may be separated and weighed; foreign substances, such as starch, etc., may be detected by means of the microscope. The total nitrogen is estimated by the Kjeldahl method; as regards the calculation of nitrogen into casein, attention is drawn to the different factors, varying from 6·34 to 6·99, which have been proposed. The author finds that the factor 6·61 probably is most correct, as the quantity of casein calculated by its use generally approximates 100 per cent. The maximum and minimum results obtained on the analysis of thirteen samples of commercial casein were: Water, 7·27, 10·50; fat, 0·28, 2·06; ash, 3·53, 4·95; nitrogen, 12·52, 13·55; nitrogen in the fat and ash-free, dry substance, 14·68, 15·65 per cent. W. P. S.

Edible Beans from Hong-Kong. (*Bull. Imp. Inst.*, 1912, **10**, 235-239.)—The following are analyses of three varieties of beans from Hong-Kong, the figures yielded by the corresponding varieties of Indian origin being given in each case:

	Hong-Kong.	Indian Lablab Beans.	Hong-Kong.	Indian Catiang Beans.	Hong-Kong.	Indian "Mung" Beans.
	Dolichos Lablab, Linn.		*Vigna Catiang*, Walp.		*Phaseolus Mungo*, Linn.	
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Moisture	12·63	12·1 to 14·6	11·65	12·7	11·88	10·1 to 11·4
Total nitrogen as crude proteins ...	19·51	17·1 to 22·4	22·05	23·1	19·98	22·2 to 23·8
True proteins ...	18·46	—	20·38	—	18·04	—
Other nitrogenous substances ...	1·05	—	1·67	—	1·94	—
Fat	1·24	1·4 to 2·3	1·23	1·1	0·75	2·0 to 2·7
Starch, etc.	57·66	54·2 to 57·4	57·99	55·3	58·96	54·1 to 55·8
Fibre	5·89	5·0 to 6·5	3·83	4·2	4·76	4·2 to 5·8
Ash	3·07	3·4 to 3·6	3·25	3·6	3·67	3·8 to 4·4
"Nutrient ratio" ...	1 : 3·10	1 : 2·5 to 1 : 3·7	1 : 2·75	1 : 2·5	1 : 3·03	1 : 2·5 to 1 : 2·7
"Food units" ...	109·5	105·9 to 113·7	116·2	115·8	110·8	116·3 to 119·3

The "nutrient ratio" is the ratio between the percentage of crude proteins and the sum of the percentages of starch and fat, the latter being first converted into its starch equivalent. The "food-units" is the total obtained by adding the percentage of starch to 2·5 times the sum of the percentages of fat and crude proteins.

A. R. T.

Estimation of Fat in Cocoa by Means of Zeiss' Refractometer. O. Richter. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 312-319.)—The cocoa powder is treated with trisodium phosphate solution and a mixture of ether and alcohol, and the amount of fat present is determined from the refraction of the ethereal solution. The trisodium phosphate solution should contain 65 grms. of the salt per litre, and the alcohol-ether mixture is prepared by mixing equal volumes of these solvents. Preliminary experiments must be made to ascertain how much of the ether-alcohol must be added to 100 c.c. of the phosphate solution so that 5 c.c. of ether shall separate after mixing. The proportions of ether and alcohol in the mixture are so adjusted that about 25 c.c. of the mixture must be added to yield 5 c.c. of ethereal layer. Ten grms. of the cocoa powder are then mixed with this quantity of the ether-alcohol mixture, and 100 c.c. of the phosphate solution are added. The whole is then shaken for some ten minutes and allowed to settle; in the case of chocolate or coarsely powdered cocoa the mixture may be warmed slightly, and then cooled to 17·5° C., at which temperature all measurements of the solutions are made. The clear ethereal layer is next examined in the refractometer, and the percentage quantity of fat (F) present is calculated from the formula:

$$F = \left(\frac{n - n_1}{n - n_2} - 1\right) \frac{100\,xy}{z},$$

where n is the refractive index of cocoa butter (1·4653), n_1 that of the solvent (1·3543), n_2 that of the fat solution observed, x the excess volume of the ether (5 c.c.), y the sp. gr. of the fat, and z the weight of substance in grms. (10 grms.). Tables are also given showing the quantity of fat corresponding with refractive indices ranging from 1·3560 to 1·4200.

W. P. S.

Studies on Flour. R. Fanto. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 269-274.)—With regard to the relation between the gluten-content of a flour and its baking quality, the author points out that rye-flour (which does not yield a coherent cake of gluten although it possesses good baking qualities) does not contain any substances which prevent the coagulation of its gluten or of that of wheat-flour. A mixture of rye- and wheat-flours yields the proportionate quantity of gluten. Rye-flour, therefore, does not appear to contain gluten. The grain obtained by crossing wheat and rye gives a satisfactory cake of gluten. The maximum solubility of the proteins of both wheat- and rye-flours in alcohol is reached when the alcohol has a strength of from 50 to 60 per cent. by volume.

W. P. S.

Composition of the Fatty Oils obtained from the Seeds of *Illicium Verum* Hook and *Illicium Religiosum* Sieb. J. Bulir. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 309-312.)—The fruit of *Illicium verum* Hook (Chinese star-anise) is frequently adulterated with the poisonous fruit of *Illicium religiosum Sieb.* (Japanese star-anise); the fruits are very similar in appearance, but may be distinguished from one another by careful examination. The seeds of both fruits contain a fatty oil; the oils were extracted by the author from specimens of the two seeds by means of ether, then freed from ethereal oils by steam, and dried in an atmosphere of coal-gas. Analyses of the oils yielded the following results:

	Illicium Verum.		*Illicium Religiosum.*	
	Oil.	Fatty Acids.	Oil.	Fatty Acids.
Sp. gr. at 15° C.	0·9264	—	0·9295	—
Saponification value ...	193·8	200·2	193·4	200·7
Iodine value (Hübl) ...	93·1	97·4	90·6	93·6
Hehner value	95·2	—	95·0	—
Reichert-Meissl value ...	1·4	—	1·5	—
Mean molecular weight	—	279·7	—	279·0

In the case of *Illicium verum* the fatty acids consisted of—Oleic acid, 45·0; linolic acid, 23·9; palmitic acid, 23·2; stearic acid, 2·6 per cent. The fatty acid from the oil of *Illicium religiosum* consisted of—Oleic acid, 60·2; linolic acid, 9·8; palmitic acid, 22·5; stearic acid, 2·5 per cent. W. P. S.

Shea-Nuts and Shea-Butter. (*Bull. Imp. Inst.*, 1912, **10**, 281-292.)—The shea-nut is the product of *Butyrospermum Parkii*, found in West Africa and Uganda, etc. The figures yielded on analysis by the "butter" prepared by the natives, and by the fat extracted from dried kernels by petroleum ether, are as follow:

	Sp. Gr., $\frac{99^\circ}{15^\circ}$ C.	Saponification Value.	Iodine Value. Per Cent.	Insoluble Fatty Acids. Per Cent.	Unsaponifiable Matter. Per Cent.	Titer Test. ° C.	Percentage of Fat in Kernels.
SHEA-BUTTER from—							
Lagos	0·862	179·0	58·0	96·5	1·7	52·0	—
Gold Coast, 1	—	184·6	56·0	—	—	51·8	—
" " 2	—	183·0	56·7	—	—	—	—
Bahr-el-Ghazal	—	181·7	54·0	—	—	53·2	—
FAT EXTRACTED from kernels from—							
Southern Nigeria, 1 ...	0·869	181·5	62·0	91·2	6·3	—	48·6
" " 2 ...	0·867	182·8	57·7	94·6	7·0	—	52·4
" " 3 ...	—	181·2	59·4	—	—	—	41·4
" " 4 ...	—	180·2	55·8	—	—	—	46·2
Bahr-el-Ghazal	0·859	184·0	62·9	91·9	4·3	—	47·2

The presence of unsaponifiable matter is accounted for by the presence in the nuts of latex containing a gutta-like body. Any appreciable quantity of this unsaponifiable matter will render the fat less suitable for use in the manufacture of butter substitutes or of soap. The fat appears to contain oleic and stearic acids, and possibly arachidic or lauric acid.

The composition of shea-nut oil-cake is shown below in comparison with other oil-seed cakes:

	Moisture. Per Cent	Ash. Per Cent.	Oil. Per Cent.	Proteins. Per Cent.	Carbo-hydrates. Per Cent.	Crude Fibre. Per Cent.
Shea-nut cake	7·85	5·50	20·30	11·13	48·54	6·68
Cotton-seed cake (decorticated	9·00	7·10	11·38	43·78	23·56	5·18
Cotton-seed cake (undecorticated)	13·75	4·60	6·56	24·62	29·28	21·19
Linseed cake	11·16	5·20	9·50	29·50	35·54	9·10
Soya-bean cake	12·70	5·05	11·07	38·82	26·51	5·85

Shea-nut cake possesses a bitter and unpleasant taste, probably due to the presence of saponin, as is the case with other cakes from sapotaceous oil-seeds. The cake is low in proteins, and, although not actively poisonous, animals do not readily become accustomed to eating it, even in small quantities. A. R. T.

Crude Phytosterol of Cocoanut Oil and the Crude Cholesterol of Butter Fat, and the Detection of Cocoanut Oil in Butter Fat. D. D. Kedrovitsch. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 334-335.)—Six different specimens of cocoanut oil yielded from 0·09 to 0·30 per cent. of crude phytosterol, and the melting-point of the phytosterol acetate varied from 122° to 125° C. Butter fat was found to contain about 0·30 per cent. of crude cholesterol, the acetate of which melted at 113° to 113·5° C. From the examination of the phytosterol-cholesterol acetate obtained from mixtures of cocoanut oil and butter fat, it was found that the presence of 10 per cent. of the former could be detected, the melting-point of the acetate, in this case, lying between 114·8° and 117·5° C. W. P. S.

Solanidine from *Solanum Tuberosum.* **A. Colombano.** (*Gazz. Chim. Ital.*, 1912, **42**, 101-116.)—The solanidine obtained in the hydrolysis of the solanine from the germ of the potato differs in chemical composition and physical properties from the solanidine derived from *Solanum sodomæum.* Specimens of potato solanidine prepared by various methods melted at 214° to 215° C., and had the composition $C_{25}H_{39}NO$ when dried at 105° C. Commercial samples of solanidine and specimens prepared from commercial samples of solanine also had the same composition and melting-point. The solanidine from *S. sodomæum* crystallised in nacreous scales, melting at 197° to 198° C., and had the composition $C_{18}H_{[illegible]}NO$ after drying at 105° C. Another difference between the two compounds is that solanidine from

S. sodomæum does not decolorise an aqueous or chloroform solution of bromine, whereas the potato solanidine forms a fairly stable compound with bromine, melting (with decomposition) at 80° to 90° C. C. A. M.

Polarimetric Estimation of Starch in Sausages. P. Lehmann and E. Schowalter. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 319-327.)—The method proposed depends on the optical rotation of starch in hydrochloric acid solution. Lintner and Ewers have already given values for the rotation of starch in acid solution (*cf.* ANALYST, 1906, **31**, 25; 1907, **32**, 179), but the authors find that commercial wheat-starch has a specific rotation of + 181·1° and potato-starch + 183·15°, under the conditions of their experiments. In the process given below the quantity of substance taken for the estimation and the volumes of the solution are such that each degree of rotation exhibited by the final solution is equivalent to 1 per cent. of starch. The sausage is finely divided, and 27·5 grms. are mixed with 80 c.c. of alcoholic potassium hydroxide solution (100 c.c. of potassium hydroxide dissolved in 100 c.c. of water and diluted with 96 per cent. alcohol to 1 litre) and allowed to stand over-night. The mixture is then boiled under a reflux condenser, and the liquid portion is decanted; the residue is washed once with the alcoholic potassium hydroxide solution, and then with 55 per cent. alcohol, until the washings do not yield a turbidity with hydrochloric acid. Decantation usually suffices in this part of the process, and filtration is seldom necessary. The residue is then dissolved by heating it on the water-bath with 2 c.c. of water and 5 c.c. of 8 per cent. sodium hydroxide solution; the mixture is now neutralised with hydrochloric acid, 25 c.c. of $\frac{N}{1}$ hydrochloric acid are added, and the whole is heated for ten minutes on the water-bath. The mixture is then cooled rapidly, neutralised by the addition of 12·5 c.c. of $\frac{N}{2}$ sodium hydroxide solution, and filtered, the filtrate being collected in a 100 c.c. flask. The precipitate obtained by mixing 3 c.c. of basic lead acetate solution with 6 c.c. of 10 per cent. ammonia is added, the whole is diluted to 100 c.c., filtered, and the filtrate is examined in a 220 mm. tube in the polarimeter. If a 200 mm. tube is employed, 25 grms. of the material should be taken for the estimation. W. P. S.

Lintner's Polarimetric Method for the Determination of Starch. C. E. G. Porst and H. A. Crown. (*Eighth Inter. Cong. App. Chem.*, 1912, vol. 13, 213-218.)—The authors have investigated the effect of varying the following conditions: (1) Temperature of digestion with concentrated hydrochloric acid; (2) time of digestion; (3) time of standing after adding the phosphotungstic acid before the reading is taken; (4) volume and concentration of phosphotungstic acid. Results are concordant when the same conditions are observed, and the following method is recommended: Five grms. of starch, or a weight of the finely ground substance equivalent to 5 grms. starch, are mixed with 20 c.c. of water in a mortar cooled down in ice-water. To this is added 40 c.c. of concentrated hydrochloric acid, previously cooled down in a freezing mixture, and the solution is kept at 20° C. for half an hour. The contents of the mortar are transferred to a 200 c.c. flask, 10 c.c. of a 4 per cent. phosphotungstic acid solution added, and made up to volume at 20° C. with acid of 1·125 sp. gr.

The flask is then kept for half an hour in a water-bath at 20° C., filtered, and exactly fifteen minutes after filtering the reading is taken at 20° C. Dry maize starch was thus found to have an $[\alpha]_D$ 199·4. In applying the method to the determination of starch in maize kernels a correction must be applied for the water-soluble matter present. Good agreement was obtained when using the acid method as compared with the diastase and Sachsse methods. In materials such as gluten meal rich in proteins it was found that the readings increased up to a point with the amount of phosphotungstic acid employed to precipitate the protein. The maximum reading was obtained with an amount equivalent to 50 c.c. of the 4 per cent. solution. If more than this were added, the reading fell owing to precipitation of starch. Even with this material, which contained nearly 50 per cent. of protein, the starch value obtained was 44·7 (using the maximum reading), as against 45·2 per cent. by the Sachsse method. The whole operation only takes one hour and a quarter, and if the temperature is kept at 20° C. no inconvenience arises from acid fumes. (*Cf.* ANALYST, 1909, **34**, 332.)

H. F. E. H.

Examination of Storax. C. Ahrens. (*Zeitsch. öffentl. Chem.*, 1912, **18**, 267-272; through *Chem. Zentralbl.*, 1912, II., 873-874.)—A method of examination is based upon the fact that storax is partially soluble in petroleum spirit. From 4 to 5 grms. of the sample are mixed with about 5 grms. of sand and repeatedly triturated with cold petroleum spirit (sp. gr. 0·65; b.-pt., up to 70° C.), the successive extracts being decanted through a filter, until in all about 350 to 400 c.c. of the solution have been obtained. This is distilled in a tared flask and the residue dried in a hot oven until constant in weight. It should be light yellow in colour, strongly refractive, very viscous, and have a pleasant aroma. Pronounced adulteration is indicated by the residue being darker in colour and more solid, and by its odour. This residue is now dissolved in about 30 c.c. of cold neutral alcohol (95 per cent. by vol.) and the solution titrated with $\frac{N}{5}$ alcoholic potassium hydroxide solution, with phenolphthaleïn as indicator, to obtain the acid value; after which an additional 25 c.c. of the alkali solution are added, the flask closed and allowed to stand for twenty-four hours, and the excess of alkali titrated to obtain the saponification value. The moisture is estimated by triturating 4 to 5 grms. of the storax with anhydrous sodium sulphate and ether, and filtering the liquid through a tared paper. The filtrate and washings are made up to 100 c.c., then dried further by means of anhydrous sodium sulphate, and 50 c.c. thereof evaporated in a tared flask. The sodium sulphate is then washed out of the mass on the filter, and the residue dried and weighed. The sum of the two residues deducted from the amount of substance taken gives the amount of water. From the examination of a large number of samples the following limits are provisionally suggested for commercial storax: Petroleum spirit extract, 37·6 to 56·0 per cent. (mean 45·2); acid value of petroleum spirit extract, 33·1 to 62·9 (mean 46·7); and saponification value of petroleum spirit extract, 191·3 to 203·3 (mean 196·1). Products with values outside these limits are to be regarded as inferior or adulterated.

G. A. M.

Tea-Seed Oil and Cake. (*Bull. Imp. Inst.*, 1912, **10**, 234-235.)—The seeds of of *Camellia Sasanqua* (tea-seed) are expressed by the Chinese for their oil, which is used as an illuminant, the residue being employed as a soap-substitute, by virtue of the saponin it contains. Samples from Hong-Kong gave the following results on analysis:

TEA-SEED OIL.

Sp. gr. at 15·5° C.	0·918
Acid value	9·4
Saponification value	193·4
Iodine value per cent.	87·5

TEA-SEED CAKE.

	Per Cent.
Moisture	8·33
Crude proteins	6·49
True proteins	6·13
Other nitrogenous substances	0·36
Fat	1·31
Starch, etc.	43·24
Fibre	37·43
Ash	3·20

The oil sometimes contains saponin, and therefore is unsuitable for edible use. The cake contains 7 to 8 per cent. of saponin, and has an unpleasant and bitter taste, and cannot be used as a feeding-cake. It contains no alkaloids. The amount of saponin is less than is present in quillaia bark, but the cake may be suitable for use in the preparation of vermicides for dressing lawns. A. R. T.

Analyses of Ceylon Tobaccos. (*Bull. Imp. Inst.*, 1912, **10**, 187-205.)—The following are typical examples of analyses of Ceylon-grown tobaccos:

	Samples from Maha-Iluppallama.				Samples from Trincomalee.	
	"Sumatra, No. 1."	"Sumatra, No. 2."	"Java, No. 2."	"Java, No. 3."	December Crop, 1909.	1909-10 Crop.

Nature of ash ...	White; flaky.	White; flaky.	Grey; flaky.	Almost black.	Dark with grey patches.	Black.

A. R. T.

New Colorimetric Method for the Determination of Vanillin in Flavouring Extracts. O. Folin and W. Denis. (*J. Ind. and Eng. Chem.*, 1912, **4**, 670-672.)—The Heis-Prescott method, as modified by Winton (*J. Amer. Chem. Soc.*, 1899, **21**, 256; 1902, **24**, 1,128; 1905, **27**, 719), though accurate, is laborious. By the use of the phosphotungstic-phosphomolybdic reagent (*J. Biol. Chem.*, 1912, **12**, 239) an accurate colorimetric method can be employed, which gives theoretical results with artificial extracts containing known amounts of the substance, and with authentic extracts gives values identical with those obtained by the official method. The solutions required are (1) an aqueous solution of pure vanillin, 10 c.c. of which contains 1 mgrm. of vanillin; (2) phosphotungstic-phosphomolybdic acid prepared as follows: To 100 grms. pure sodium tungstate and 20 grms. phosphomolybdic acid (free from nitrates and ammonium salts) are added 100 grms. of syrupy phosphoric acid (containing 5 per cent. H_3PO_4) and 700 c.c. water: the mixture is boiled over a free flame for one and a half to two hours, cooled, filtered if necessary, and made up to 1 litre. An equivalent amount of pure molybdic acid may be substituted for the phosphomolybdic acid. (3) Saturated sodium carbonate solution. (4) A solution containing 5 per cent. basic and 5 per cent. neutral lead acetate. Vanillin and other mono-, di-, and tri-hydric phenol compounds, when treated with the reagent (2), give on the addition of excess of sodium carbonate solution the deep blue colour which is the basis of the new method. The method cannot be applied to the untreated extract, since tannin also reacts with the reagent, and the following procedure is required: Five c.c. of the extract to be examined are diluted with about 75 c.c. of water in a 100 c.c. flask, 4 c.c. of the lead acetate solution added, and the mixture made up to volume, filtered, and 5 c.c. of the filtrate placed in one 50 c.c. flask, and in another 5 c.c. of the standard vanillin solution. Five c.c. of the phosphotungstic phosphomolybdic reagent are added to each flask, the solution shaken and allowed to stand five minutes, and then each flask is made up to volume with sodium carbonate solution. The solutions are then well mixed and allowed to stand ten minutes, by which time the precipitation of sodium phosphate is complete. The contents of the flasks are filtered rapidly, and the colour of the filtrates, which must be quite bright, are compared in a Dubosc colorimeter. The standard solution is best placed at 20 mm. Thus, if 5 c.c. of the diluted and filtered solution gave a reading of 18 mm., the result would be $0{\cdot}5 \times \frac{20}{18} = 0{\cdot}555$ mgrm., and $55{\cdot}5 \div 250 = 0{\cdot}22$. Hence 0·22 per cent. of vanillin. An advantage of the method is the small amount of solution required, 2·5 c.c. of extract being enough for from two to four duplicate determinations. The official method may be readily checked by using the ether extract after drying and weighing and dissolving it in ethyl alcohol, the estimation then proceeding as already described. Night readings can be taken, the best illumination being an ordinary incandescent electric light, covered with a sheet of white paper. A new portion of the standard solution should be made for each batch of twelve samples examined, as the colour darkens for an hour after the addition of the alkali. A large number of results are recorded determined by the new and the official methods, which show agreements in all cases within 0·01 per cent. Although vanillin, even in dilute solution, may be precipitated with basic lead acetate, in the high dilution above recommended no precipitation occurs. Coumarin, extract of tonka bean, and acetanilide give no colour with the phosphotungstic-phosphomolybdic reagent, and the presence of sugar, caramel, or glycerol does not interfere with or alter the colour formation.

H. F. E. H.

Estimation of Extract in Wort and Beer. W. Fresenius and L. Grünhut. (*Zeitsch. anal. Chem.*, 1912, **51**, 643-658.)—A comparison is instituted between the tables of Balling, Windisch, Schultze, Ostermann, Elion, and Riiber. For the determination of extract in beer, the table of Windisch is shown to give the least inaccurate values. Windisch's table ("Tafel zur Ermittlung des Zuckergehaltes wässriger Zuckerlösungen," 1896) is a cane-sugar table, and, applied to solutions of maltose and dextrin, leads to results much above the truth, as may be calculated from the results of Brown, Morris, and Millar, or those of Ost or Meissl. But in the case of beer extracts the presence of the small amounts of glycerol and non-volatile acid normally present goes far towards compensating the above error, for these substances are under-estimated by 35 to 40 per cent. if the solution factor for cane-sugar be applied to their solution. The nitrogenous constituents of the extract also tend to reduce the *plus* errors attaching to the use of Windisch's table, whilst the ash constituents tend to increase it. The algebraic sum of all the errors is always positive, and appears to lie between 0·4 and 1·2 per cent.

The extract of unfermented malt-worts is over-estimated by as much as 2 per cent. if calculated by means of Windisch's table, since the influence of the maltose and dextrin in unfermented wort quite outweighs the influence of the minor constituents. Of existing tables, that of Riiber ("Videnskabsselskabets Skriften I., Mathematisk-naturv. Klasse," 1897, No. 5) gives the smallest errors when applied to unfermented malt worts. The error is a *minus* one, and its magnitude very close to 1 per cent. Riiber's table being somewhat difficult of access, and occupying several pages in its original form, the present authors have condensed it as follows. The table gives the percentage of extract corresponding to every degree of gravity from 1,000 to 1,085, and the nine columns on the right show the addition to be made for each tenth of a degree.

Extract Table according to C. N. Riiber. (Percentage by Weight.)

G. C. J.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Structural Elements of Cellular Membranes. J. König. (*Chem. Zeit.*, 1912, **36**, 1101.)—In addition to true cellulose, the cellular tissue contains—(A) Fat, wax, resin, tannin, aromatic aldehydes, glucosides, etc.; (B) hemicelluloses; (C) lignins; (D) cutin and suberin. The substances under Group A may be removed by treatment with dilute alcohol or with alcohol, benzene, and ether; the Group B by hydrolysis with dilute acids; the Group C by feeble oxidising agents in alkaline solution; and the Group D by treating the residue from the preceding groups with dilute ammoniacal copper solution or zinc chloride and hydrochloric acid, by which the true cellulose is not attacked. The substance obtained by treating a vegetable substance with dilute acids and alkalis, or with glycerol-sulphuric acid, is not cellulose; it contains large quantities of lignin, together with hemicellulose (pentosan), and is more properly termed "crude fibre" than cellulose. The "cellulose" prepared from wood for paper-making contains considerable quantities of pentosan and lignin. By treating rasped wood with dilute mineral acid, followed by oxidation with the usual agents, a comparatively pure cellulose may be obtained, and also by-products which may be used as fodder.

When beech or pine wood, or hemp fibre, has been treated with benzene, alcohol, and water, and then subjected to hydrolysis with 72 per cent. sulphuric acid, subsequent treatment with water yields a clear solution and a brownish-black sediment; the latter has the structure of the cell-membrane, and may be oxidised by hydrogen peroxide in ammoniacal solution. It consists of lignin, and in this way not only the cellulose, but the lignin, may be estimated in cellular tissues. It is not considered probable that the lignin is combined with cellulose in vegetable tissues, as, if this were so, the two substances would not preserve their original structure when separated. It would appear to be likely that the lignin and the cellulose were mixed in the tissue in much the same way that calcium phosphate and proteins exist in bones.

W. P. S.

Delicate Method for Determining Minute Quantities of Chlorophyll. C. A. Jacobson. (*J. Amer. Chem. Soc.*, 1912, **34**, 1266-1269.)—The author has extended the work of Jacobson and Marchlewski (ANALYST, 1912, 460) in the separation of neo- and allo-chlorophyll, and, modifying the photographic process there described, uses it for the estimation of traces of chlorophyll. The intensity of the chlorophyllan absorption bands in the ultra-violet of the solution to be examined is compared with that of corresponding bands produced by solutions of known concentration. Chloroform, as before, is used as the solvent, and 4 or 5 c.c. of solution was found to be sufficient for the purpose, containing as little as 0·02 mgrm. of chlorophyll. A leaf whose green weight is 0·2 grm. suffices for determining the quantity and character (*i.e.*, ratio of neo- to allo-chlorophyll) of the chlorophyll it contains. Eight photographic plates are given, illustrating the variations in intensity of the spectra obtainable. Leaves are macerated in a mortar with cold 92 per cent. alcohol, filtered, and the residue again ground until the extract is colourless. Two c.c. of 10 per cent. alcohol oxalic acid solution is added to the extract, and the whole allowed to stand two or three hours. Calcium carbonate is then added in slight excess, and the mixture evaporated to dryness on the water-bath. The residue is then extracted with chloroform till colourless, and the chloroform solution is diluted appropriately for photographing the spectrum. H. F. E. H.

Nature of Peroxydase. A. Hesse and W. D. Kooper. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 301-309.)—The results obtained during an investigation as to the nature of the substance which yields the "peroxydase" when milk is treated with Rothenfusser's, Storch's, and Arnold's reagents, in the presence of hydrogen peroxide, lead the authors to the conclusion that inorganic substances also play a part in the reaction, and that these substances are not the alkaline constituents of the milk (*Cf.* ANALYST, 1912, 141). They are of the opinion that the colour reaction is due to the catalytic action of iron compounds such as ferrous lactate. This is borne out by the extreme sensitiveness of the reagents towards ferrous lactate, even in very dilute solutions of the latter, and by the fact that the iron solution loses its property of giving a coloration with the reagents when it has been boiled, either alone or in the presence of milk, or even when it has received the addition of boiled milk. Further, substances such as lactic acid, sodium thiosulphate, ethyl alcohol, methyl alcohol, and amyl alcohol, which prevent the so-called peroxydase reaction, also inhibit the action of ferrous lactate on the reagents, whilst mercuric chloride and chloroform (two substances which destroy enzymes) do not interfere with the reaction, either in the case of milk or of ferrous lactate. W. P. S.

Proteolytic Enzyme of Malt. R. Wahl. (*Eighth Inter. Cong. App. Chem.*, 1912, vol. 14, 216-229.)—The proteolytic activity of malt extracts is much increased by the presence of bacterial acidity due to lactic acid, and the author concludes that the peptic enzyme contained in the malt is combined with some base of an albuminous nature, and becomes active through liberation by bacterial acidity. The optimum temperature for the splitting of albumin in presence of lactic acid is about 30° C., and the reaction is rapidly brought to a standstill at about 50° C. It has hitherto been stated that the optimum temperature for peptic activity was from 40° to 50° C. The substitution of mineral or commercial acid for lactic acid of bacterial origin does not result in any increased activity, and this latter acid, when added to a brewer's mash, increases the total yield obtainable from the malt, owing to an increase in peptic activity. Commercial malts differ greatly as regards their peptic activity, high-dried malts being less active than low-dried. The lactic acid employed for the acidulation of the water used in the malt extractions was prepared by inoculating a mixture of 1 pint crushed malt in 4 pints of water with a culture of lactic acid, and raising to a temperature of 50° or 60° C. for about twenty-four to forty-eight hours, by which time 1 or 2 per cent. of lactic acid is formed. The grains are then separated and the liquid used in suitable dilution for the extraction of the malts under examination. The peptic strength of the extracts was determined by auto-digestion and by a modified "gelatine liquefying strength" method adopted from that of Schidrowitz (*J. Inst. Brewing*, 1904, **10**, 166). The peptic strength of malt extracts was always compared with that of a standard solution of pepsin of known strength.

The gelatine is prepared as follows: 32 grms. of gelatine are dissolved in 318 c.c. of distilled water by gently warming. One-third of a grm. of finely-ground egg albumin dissolved in 50 c.c. of distilled water is then added, and the gelatine solution cooled to 52° C. The temperature is then raised to 85° C. in five minutes, then kept at 100° C. for ten minutes, and filtered into a beaker containing 0·5 grm. of thymol. Tubes are then filled with 6 c.c. of the gelatine solution, and closed with corks to prevent evaporation. When required for use the tube is gently warmed in a water-bath until the contents are liquefied. Five c.c. of the extract to be examined are added, a blank tube being run alongside with 5 c.c. of water. The tubes are incubated for four hours at 37·5° C., and afterwards placed in ice-water at 2° C., the time required for solidification of the gelatine being noted. The time for the blank tube to solidify is subtracted from that of the other tube, as the lactic acid has a slight liquefying action on gelatine. The pepsin standard is prepared by mixing 0·15 grm. of pepsin of 10,000 strength with 10 grms. of powdered sugar, and dissolving the whole in 100 c.c. of distilled water. Five c.c. of this solution are added to a gelatine tube, and, under the conditions already described, should require seven minutes for solidification.

The auto-digestion method consists in measuring the amount of coagulable albumin remaining in the malt extracts after digestion for a suitable time and temperature, and is carried out as follows: The clear filtered extract, after the above-mentioned digestion, is heated to 75° C., and kept at this temperature for thirty minutes, when it is cooled to 25° C. Ten c.c. of the solution are then centrifuged for four minutes at a speed of about 2,500 per minute. The coagulated albumin is then read in $\frac{1}{10}$ths of c.c. A number of values are recorded with varying amounts of lactic acid acidity, and also with mineral acids, none of the latter showing a solidification time beyond five minutes, as against the fifteen to twenty minutes with 1·5 to 2 per cent. lactic acid. Malts containing moisture from 2 to 3·9 per cent. gave gelatine values of sixteen to twenty-one minutes, while from 4 to 6·4 per cent. of water lowered this to about ten minutes. High extract malts also gave a higher gelatine test indicative of greater peptic strength. H. F. E. H.

Sensitive Test for the Detection of Albumin in Urine. A. Jolles. (*Chem. Zeit.*, 1912, **36**, 1108.)—The reagent employed is prepared by dissolving 10 grms. of mercuric chloride, 20 grms. of citric acid, and 20 grms. of sodium chloride in 500 c.c. of water. Five c.c. of the filtered urine are placed in each of three test-tubes; the first tube then receives the addition of 1 c.c. of 30 per cent. acetic acid, and 5 c.c. of the reagent, the second tube 1 c.c. of the acetic acid. Water is then added to the second and third tubes until they are filled to the same height as the first tube, and their contents mixed by shaking. On placing tube No. 3 between Nos. 1 and 2, a difference in the turbidity of the contents of the two latter is readily detected; in the presence of albumin and pus the contents of tube No. 1 will be more turbid than those of tube No. 2. The presence of mucin and nucleo-albumin may be detected by comparison with tube No. 3; an increase in the turbidity of the contents of tube No. 2 when diluted with water indicates the presence of nucleo-albumin. The test will detect 1 part of albumin in 120,000 parts of urine. W. P. S.

Detection of Blood in Urine and other Physiological Fluids. F. Michel. (*Chem. Zeit.*, 1912, **36**, 994-995.)—The guaiacum test for blood is rendered more sensitive if a small quantity of pyridine is added to the urine or other fluid under examination. Five c.c. of urine should be mixed with about 1 c.c. of pyridine before the ozonized turpentine or hydrogen peroxide is added. The extraction of the urine with pyridine, according to the method described by von Furth for the detection of blood on fabrics (ANALYST, 1911, **36**, 549) is in many cases unsatisfactory, as substances are extracted from the urine which interfere with the subsequent test for blood. The following method of carrying out the test is stated to be more trustworthy, and to be capable of detecting the presence of 1 part of blood in 200,000 parts of urine: Twenty-five c.c. of the urine (filtered, if necessary) are treated with 5 c.c. of a 15 per cent. calcium chloride solution, and heated to boiling. To the hot solution are added 5 c.c. of a 10 per cent. sodium phosphate solution, the precipitate (consisting of calcium phosphate together with coagulated blood) is collected on a filter, washed with a small quantity of physiological salt solution, and a portion of it is transferred to a strong stoppered test-tube. Three c.c. of water, 3 c.c. of pyridine, and a few drops of potassium hydroxide solution are added, and the mixture is boiled. It is then shaken, while hot, with an equal volume of 50 per cent. potassium hydroxide solution, the pyridine layer is separated, again shaken with 50 per cent. solution, and separated. This pyridine solution is now treated with an equal volume of glacial acetic acid, 0·5 c.c. of a leuco-malachite green solution (*Cf.* ANALYST, 1911, **36**, 284), and 2 drops of 1 per cent. hydrogen peroxide. An intense green coloration develops if blood is present. Another portion of the calcium phosphate precipitate may be dissolved in a few drops of glacial acetic acid, treated with a small quantity of pyridine, and then tested with the leuco-malachite green solution in the presence of hydrogen peroxide. In both tests the coloration must develop within two minutes, and be of a deep tint; a faint green coloration, which does not indicate the presence of blood, is given by the calcium phosphate precipitate obtained from most normal urines.

W. P. S.

Estimation of Cane-Sugar in Urine in the Presence of Other Sugars. A. Jolles. (*Biochem. Zeitsch.*, 1912, **43**, 56-64.)—The method described previously by the author (*Cf.* ANALYST, 1911, **36**, 28) may be applied to the estimation of cane-sugar in urine under the following conditions: Urine containing less than 5 per cent. of dextrose is diluted with an equal volume of water, but when the dextrose exceeds 5 per cent. it is necessary to dilute 1 volume of urine with 2 volumes of water. Of the diluted urine, 100 c.c. are treated with 2·5 c.c. of a 16 per cent. sodium hydroxide solution, and then maintained at a temperature of 37° C. for twenty-four hours. After cooling, the mixture is rendered slightly acid with acetic acid, and 50 c.c. are mixed with 5 c.c. of 10 per cent. lead acetate solution, filtered, and the filtrate is examined with the polarimeter. A slightly negative reading (about – 3° Ventzke) indicates that cane-sugar is absent, whilst a positive reading shows that this sugar is present in the urine, and its quantity may be calculated from the reading observed, allowance being made for the extent to which the urine has been diluted. As little as 0·2 per cent. of cane-sugar may be detected in urine by means of the method. Trustworthy results cannot, however, be obtained in the case of urines containing a large quantity of ammonium salts, or of β-hydroxybutyric acid or other optically active substance. W. P. S.

Detection of Lævulose in the Presence of Dextrose. A. Jolles. (*Chem. Zeit.*, 1912, **36**, 1108.)—The author's modification of the Ihl-Peckmann reaction will detect the presence of 0·1 per cent. of lævulose in urine which also contains 5 per cent. of dextrose. The test is carried out as follows: 1 c.c. of diluted urine (1 : 10) is treated with 10 drops of a 20 per cent. alcoholic solution of diphenylamine and 1 c.c. of concentrated hydrochloric acid, and the mixture is boiled for fifty seconds. A comparison test should be made at the same time with normal urine, containing a similar quantity of dextrose. The detection of pathological constituents in urine is rendered difficult owing to the increasingly large number of substances which are administered as medicines. For instance, a sample of urine was found to be lævorotatory, yielded positive reaction with phenylhydrazine and Seliwanoff's test, but failed to give the Ihl-Pechmann reaction, and a fermentation test gave a negative result. This urine was from a patient who, for three weeks, had been taking validol (a compound of menthol with valerianic acid). W. P. S.

Detection of Glycuronic Acid in Diabetic Urine. A. Jolles. (*Chem. Zeit.* 1912, **36**, 1108.)—Since dextrose gives a reaction with naphthoresorcinol, it is not possible to detect glycuronic acid directly in diabetic urines by means of this reagent. The test may, however, be carried out as follows: From 200 c.c. to 400 c.c. of the urine are treated with lead acetate until a precipitate no longer forms; after settling, the clear solution is passed through a filter and the precipitate is washed four successive times by decantation with water, using 400 c.c. each time. The filtrate (excluding the washings) is now precipitated with basic lead acetate, and this precipitate is washed in a similar way. The two precipitates are united, mixed with a small quantity of water, heated to 70° C., the lead is removed as sulphide, and the solution is evaporated to 20 c.c.; 5 c.c. of this solution are then tested with naphthoresorcinol. W. P. S.

Method for the Estimation of Hippuric Acid in Urine. T. Hryntschak. (*Biochem. Zeitsch.*, 1912, **43**, 315-322.)—The method is based on the oxidation of hippuric acid by permanganate, the resulting benzoic acid being separated subsequently by extraction with ether. One hundred c.c. of the urine are boiled with 10 grms. of sodium hydroxide in a flask (about 1 litre capacity) under a reflux condenser for one hour. The contents of the flask are then cooled, the condenser is removed, and potassium permanganate is added, in small quantities at a time, until the liquid has a distinct permanganate tint after a further seven minutes' boiling; in the case of human urine, 10 grms. of permanganate is usually a sufficient quantity. The mixture is again cooled, a few pieces of ice are added, together with about 15 grms. of sodium bisulphite. The condenser is attached to the flask, the latter is placed in a vessel of cold water, and 50 per cent. sulphuric acid is added through the condenser until all the manganese dioxide has dissolved. The flask may now be placed aside for a few hours and the contents then extracted five successive times with ether, the condenser and the flask being also rinsed with the solvent. The united ethereal extracts are dried by the addition of fused sodium sulphate and transferred to a round glass basin, the last portion of the ethereal solution being decanted through a small filter in order to remove fragments of sodium sulphate. After the ether has been evaporated the residue is dissolved in a small quantity of chloroform (previously washed with water and dried over anhydrous copper sulphate), the solution is filtered into a weighed flask, and the chloroform is evaporated by placing the flask in a vessel through which a current of dry air is passed. The weight of the benzoic acid found is multiplied by 1·468 to give the amount of hippuric acid present. Results of experiments are recorded which show that, when hippuric acid is added to urine, from 96·1 to 99·9 per cent. of the amount introduced may be recovered by means of the above-described method, provided that an allowance is made for the quantity of benzoic acid yielded naturally by different urines when subjected to the process. In the case of human urine the benzoic acid found amounts to 0·056 grm. per 100 c.c.; with dog's urine it is 0·009 grm., and for horse's urine 1·007 grms. The presence in urine of such substances as hydroxyphenylacetic acid, hydroxyphenylpropionic acid, phenylaceturic acid, and of benzoic acid contained in a glycocoll complex, will influence the results, but, as a rule, these substances occur in such small quantity that their effect may be neglected.

W. P. S.

ORGANIC ANALYSIS.

Elementary Analysis. A. Kurtenacker. (*Zeitsch. anal. Chem.*, 1912, **51**, 639-640.)—The author recommended (ANALYST, 1911, **36**, 516) the use of reduced nickel in the forward part of a combustion-tube to reduce oxides of nitrogen. Doht (*Zeitsch. anal. Chem.*, 1911, **50**, 755) criticised that paper on the ground that its author rejects the use of metallic silver for the same purpose, without adducing any evidence of its failure to reduce oxides of nitrogen and without reference to the work of Epstein and Doht (*Zeitsch. anal. Chem.*, 1907, **46**, 771), who recommended it. The author now points out that in his original paper he gave references to the work of others who had shown the insufficiency of silver, brings forward experimental evidence of his own to the same effect, and shows that the work of Epstein and Doht is inconclusive, since many of the test substances used by them—*e.g.*, *p*-nitraniline and *m*-dinitrobenzene—give accurate results when submitted to combustion in an open tube without the use of any device for the reduction of oxides of nitrogen.

G. C. J.

Estimation of the Acetyl Value. W. Normann. (*Chem. Rev. Fett- u-Harz-Ind.*, 1912, **19**, 205-206.)—The following rapid method obviates errors caused by esterification of acetylated fatty acids when dissolved in hot alcohol: About 2 grms. of the filtered fat are weighed into a saponification flask and boiled with 4 to 6 c.c. of acetic anhydride for thirty minutes to an hour beneath a reflux condenser. The flask is then immersed in a hot-water bath, while a current of carbon dioxide hydrogen (or air in the case of non-oxidisable fats) is blown through it, until the whole of the residual acetic anhydride has evaporated. The contents are next diluted with a little ether, about 5 c.c. of water added, any remaining traces of acetic anhydride and the free fatty acids neutralised with a few drops of aqueous sodium hydroxide solution, and the fat saponified with 50 c.c. of $\frac{N}{2}$ alcoholic potassium hydroxide solution, the excess of which is titrated with $\frac{N}{2}$ hydrochloric acid. The amount of alkali expressed in the usual way gives the value for the saponification of the glycerol ester and of the acetic ester. By deducting from this value the saponification value of the original fat, if neutral, or the ester value if free fatty acids were present, a value is obtained showing the amount of alkali corresponding to the free hydroxyl groups in the original fat. For this the term *hydroxyl value* is suggested in contradistinction to the acetyl value, which only relates to the acetylated fatty acids.

C. A. M.

Hübener Bromide Method for the Estimation of Caoutchouc. R. Becker. (*Gummi-Zeit.*, 1912, **26**, 1503; through *Chem. Zentralbl.*, 1912, II., 966.)—The Hübener bromide is not entirely soluble in chloroform (*cf.* Hinrichsen and Kindscher, ANALYST, 1911, **31**, 224), but is dissolved completely by a mixture of chloroform and carbon disulphide. Caoutchouc brominated by the method of Budde did not show this peculiarity. The proportion insoluble in chloroform increases with the amount of bromine in excess during the bromination. The substance insoluble in chloroform is of a sticky consistency, and may easily be taken for unconverted caoutchouc. The author considers that the error thus introduced into the Hübener method can be avoided by bringing the rubber into less intimate contact with the bromine; this is effected by placing the bromine in a special stoppered porcelain vessel pierced with fine holes at 5 to 10 mm. from the bottom. This is removed from the beaker when the powdered bromide is returned to it. The bromine may also be the cause of the oxidation of vulcanisation sulphur. The presence of sulphur trioxide in the bromine, mentioned by Hübener, is confirmed.

O. E. M.

Hübener Bromide Method for the Estimation of Caoutchouc. G. Hübener. (*Gummi-Zeit.*, 1912, **26**, 1711; through *Chem. Zentralbl.*, 1912, II., 967.)—The sticky substance insoluble in chloroform, observed by Becker (see preceding abstract), may be due, not to over-bromination, but to the presence of compounds of bromine or oxygen with resins, or of the resins themselves, as Becker does not state that these had been removed from the rubber. Pure tetrabromide is not always obtained by the method of Budde (ANALYST, 1909, **34**, 407). Korneck (*ibid.*, 1911, **36**, 158) found that it often contains enclosures of unaltered rubber, and, as Spence and Galetly have shown (*ibid.*, 1911, **36**, 361), the whole of the protein is present. On the other hand, Utz (*ibid.*, 1912, 361) obtained a bromide containing 70·18 per cent. of bromine—a nearly theoretical result. Regenerated rubber, containing more constituents soluble in acetone, yields more substance insoluble in chloroform than does raw rubber, but this comes not wholly from resin and oil, but also from the caoutchouc-sulphur compound which at present cannot be broken up in the process of regeneration. The author's modified method is as follows: The rubber is rasped fine, and 2·5 grms.

are wrapped in filter-paper and extracted in a Soxhlet apparatus with acetone for from four to six hours. If resin insoluble in acetone is present, as in hard rubber mixtures, an extraction with dichlorhydrin follows. The residue is dried at 60° C., and 0·2 grm., or more if necessary, digested with 100 c.c. of water and 5 to 10 c.c. of bromine at a moderate temperature on the sand-bath, until the rubber is completely opened out and most of the bromine driven off. The rest is removed by boiling. The precipitate is washed on a filter with hot water, dried at 50° to 60° C., and fused at a red heat in a platinum crucible with sodium carbonate free from halogen. The melt is dissolved by warming in aqueous nitric acid; overheating must be avoided. The bromine is then titrated (*Chem. Zeit.*, 1909, **33**, 648). An analysis in which extraction with acetone was omitted gave a result exceeding the theoretical by 3·5 per cent.; this is regarded as satisfactory, as the acetone extract was especially high. The author's method is suitable only for vulcanised rubber. O. E. M.

Estimation of Cellulose in Woods and Textile Fibres. C. F. Cross and E. J. Bevan. (*Zeitsch. f. Farbenind.*, 1912, **11**, 197-198; through *Chem. Zentralbl.*, 1912, II., 1066.)—In a paper by König and Hühn (*Zeitsch. f. Farbenind.*, 1911, **10**, 297), it was contended that Cross and Bevan's chlorination process is one of oxidation by which considerable residues of pentosans and other bodies differing from true cellulose are left in the product, whilst the cellulose itself is appreciably modified by oxidation. König and Hühn recommended in preference a process consisting, first, of a hydrolysis with sulphuric acid dissolved in glycerol, whereby pentosans and hemihexosans are hydrolysed and dissolved, and, secondly, of an oxidising treatment (hydrogen peroxide and ammonia) whereby lignin is removed. The present authors condemn such a method on the ground that the products obtained are residues of hydrolysis and degradation, and bear no definitely ascertained quantitative relationship to the original material. The main characteristic of a "normal" cellulose is its quantitative persistence through a cycle of chemical changes—*e.g.*, (*a*) Nitration-denitration, or (*b*) conversion into xanthogenate-reversion to cellulose, with all its colloidal structural properties unchanged. The chlorination of lignin complexes is a specific reaction, and secondary oxidation changes in the cellulose residue may, under proper conditions, be almost entirely suppressed. The authors do not accept the view that the production of furfural from the celluloses isolated by their method indicates the presence of pentosan non-celluloses as residual "impurities." This is supported by the fact that the celluloses isolated from the Gramineæ, by drastic and purely hydrolytic processes (caustic soda), yield 12 to 14 per cent. of furfural, which it is impossible to regard as being derived from adventitious pentosans. Thus, König and Hühn's contention that cellulose, which contains furfural-yielding groups, has not been sufficiently purified by hydrolysis, is untenable. J. F. B.

Estimation of Cellulose in Woods and Textile Fibres. J. König and F. Hühn. (*Zeitsch. f. Farbenind.*, 1912, **11**, 209-211; through *Chem. Zentralbl.*, 1912, II., 1066-1067.)—The authors reply to the specific points raised by Cross and Bevan (see preceding abstract). They state that Cross and Bevan have not proved that chlorination is unaccompanied by oxidation. They rely on the work of Tollens in support of their contention that furfural-yielding groups are synonymous with pentosans, which they contend must be removed by still more drastic hydrolysis before the cellulose can be considered pure. The maximum specific rotation of solutions of cellulose in acid zinc chloride was not put forward as a test for pure cellulose, but the fact was merely recorded that the solutions which showed the maximum rotations were derived from celluloses which, by other characters, were proved to be the purest. König and Hühn found by their proposed method, in a sample of commercial sulphite wood cellulose, only 32·21 per cent. of "true cellulose"; this result is upheld against the criticism of Cross and Bevan on the ground that the sample still contained much lignin. The differences between the authors and Cross and Bevan turn on the question of a definition of chemically pure cellulose, as contrasted with the technically pure article. König and Braun, by the isolation of lignin, free from accompanying cellulose, but still retaining the structural form of the cell membrane, have proved that the lignocellulose of wood is not a chemical combination, but a mixture of two mutually interpenetrating colloids. J. F. B.

Determination of Bleaching Quality of Sulphite Pulp. E. Richter. (*Eighth Inter. Cong. App. Chem.*, 1912, vol. 13, 233-236.)—The author has previously shown that the Hempel-Seidel nitric acid figure of pulp can be employed to determine the percentage of non-cellulose in pulp, jute, or wood, by previously extracting the pulp with ether, alcohol, and water. The nitric acid figure gives values proportional to the bleach test, and an attempt has been made by a colorimetric method to get a value in per cent. of bleach powder. Sulphuric acid which has been employed by Klason (*Papier Zeit.*, **35**, 3781) as the basis of a colorimetric method for this purpose is unsatisfactory, since this acid attacks too much pure cellulose. The author recommends the following procedure: 5 grms. of air-dried pulp are broken up in thin pieces and placed in a wide-mouthed bottle with 100 c.c. of 13 per cent. nitric acid, well shaken, and kept in the dark for an hour. A standard pulp of known bleaching quality is put on alongside. At the end of the hour the mass is filtered through a small piece of pure absorbent cotton on a dry funnel, and 25 c.c. of the filtrate from each transferred into small bottles. From a burette water is added to the darker one until the shade of both solutions is the same. The colours can then be accurately compared in Eggertz carbon tubes. The bleaching quality of the pulp to be tested is calculated by simple proportion from the amount of bleaching powder that is known to be required for the standard. A strongly digested pulp will not always yield much colour to the acid in one hour, but placing the water-bottles in a water-bath at 40° C. and shaking will bring out the colour in about fifteen minutes, and the comparison can then be proceeded with. H. F. E. H.

Detection and Determination of Cyanogen and Hydrogen Cyanide. F. H. Rhodes. (*J. Ind. and Eng. Chem.*, 1912, 4, 652-655.)—The author has examined, from the quantitative point of view, the observation of Wallis (*Ann. Chem.*, 1906, **345**, 353), that while hydrogen cyanide in the presence of cyanogen is quantitatively precipitated when passed through acidified silver nitrate solution, cyanogen may be removed from solution in this reagent by a current of air. He finds that hydrogen cyanide and cyanogen may be determined accurately in the presence of each other, the former being precipitated as silver cyanide in acid silver nitrate solution (10 per cent. with 1 drop of dilute nitric acid), while the cyanogen which passes on may be detected and estimated colorimetrically by collecting it in $\frac{N}{2}$ caustic potash solution, adding ferrous sulphate and 1 drop of ferric chloride, and then, after fifteen minutes, acidifying with dilute sulphuric acid. In this manner as little as 0·3 c.c. of cyanogen can be detected in a mixture of the two gases, and in the presence of large volumes of air. Carbonic acid does not interfere unless present in such quantity as to form potassium carbonate with the whole of the $\frac{N}{2}$ caustic potash employed. If the quantity of hydrogen cyanide is very small, the trace of silver cyanide obtained can be filtered off and sublimed with a trace of iodine in a tube, when as little as 0·1 mgrm. of silver cyanide, equivalent to 0·02 mgrm. of original hydrogen cyanide, can be detected as a sublimate of cyanogen iodide.

H. F. E. H.

Estimation of Dextrose in the Presence of other Optically Active Substances by Bertrand's Method. M. Rosenblatt. (*Biochem. Zeitsch.*, 1912, **43**, 478-480.)—When it is desired to estimate dextrose in a solution containing, in addition, such substances as peptones, amino-acids, etc., by the polarimetric method, it is necessary to remove these substances previously by means of mercuric acetate and phosphotungstic acid (*Cf.* ANALYST, 1912, 145). Such is not the case, however, when the sugar is estimated by Bertrand's method (ANALYST, 1908, **33**, 476), as the results obtained are not affected to any appreciable extent by the presence, in the sugar solution, of glycin, alanin, leucin, tyrosin, asparagin, betaine, glutamin, urea, and peptone. This particularly applies to the estimation of dextrose in urine, for which purpose the polarimetric method is unsuitable, owing to the small quantity of sugar present. Urea and peptone have the most influence on the results obtained by Bertrand's method, the amount of sugar found being too low by from 1·6 to 4·4 per cent. of the quantity actually present. It is pointed out that the ferric sulphate solution used in Bertrand's method should contain 50 grms. of ferric sulphate and 200 grms. (not c.c.) of concentrated sulphuric acid per litre.

W. P. S.

Diphenylamine Test for Gun-Cotton. C. Kullgren. (*Zeitsch. f. Schiess- u. Sprengstoffwesen,* 1912, **7**, 153.)—Guttmann's test consists in maintaining the dried nitrocellulose at 80° C. in a tube in which is suspended a strip of diphenylamine test-paper, and taking as a measure of the stability of the sample the time required for the evolution of oxides of nitrogen sufficient to produce a blue tint on the paper. This investigation is to determine whether the acid substances producing this coloration exist ready-formed in the gun-cotton, or whether they are produced during the heating. The experimental material was a factory gun-cotton containing 12·6 per cent. of nitrogen, and dried at 40° to 45° C. for sixteen hours. Free acid in gun-cotton may be either the remains of nitrating acid not removed in manufacture, or the result of slow decomposition at ordinary temperatures; it was found that washing before the test had no effect if the sample was dried, because the acid is in any case driven off by drying at 45° C. This was supported by the observation that gun-cotton moistened with strong mineral acids recovered its test with sufficient drying; that drying at 45° C. gave rise to a much higher test than drying over phosphorous pentoxide or sulphuric acid at room temperature; and that a gun-cotton, insufficiently stabilised by boiling, gave a much higher test after being dried at 45° C. for two days than it did after standing for fourteen days at ordinary temperature, and drying for three hours at 45° C. The test is thus dependent, not on the free acid present in the gun-cotton, but on that produced during the test (*cf.* Robertson and Smart, *Zeitsch. f. Schiess- u. Sprengstoffwesen*, 1910, **5**, 185, 208). The danger of obtaining fallacious tests due to traces of unstable bodies may be avoided by prolonging the time of drying, and taking tests at intervals.

The decomposition of nitrocellulose is stated to take place in at least two stages, the velocity with which the intermediate body or bodies cause the evolution of oxides of nitrogen being increased more rapidly by rise of temperature than their velocity of formation. The test would then depend, not on the total amount of unstable constituents, but on the amount of intermediate product. Prolonged drying at 45° C. would diminish the amount of intermediate product, with a high test as the result; standing at ordinary temperatures would increase it, and a lower test would be produced. O. E. M.

Gasometric Estimation of Ether and Chloroform Vapours in Air. M. Koehmann and W. Streeker. (*Biochem. Zeitsch.*, 1912, **43**, 410-417.)—The quantity of ether or chloroform vapour in air may be estimated by shaking the gaseous mixture with alcohol and noting the decrease in volume of the former. The most suitable apparatus to use is a Bunte burette, and 96 per cent. alcohol is employed for the absorption. After the vapours have been absorbed, the alcohol vapour remaining in the burette is removed by means of water saturated with air. The necessary allowance is made for the vapour-pressure of water in calculating the decrease of volume due to the absorption of the ether or chloroform vapour, and full details as regards manipulation are given in the original paper. It may be mentioned that, in some preliminary experiments, olive oil and paraffin were used to absorb the ether and chloroform vapours, but the results obtained were unsatisfactory, owing to the formation of numerous small bubbles of air in the oil during the shaking part of the process. W. P. S.

Determination of Humus in Hawaiian Soil. W. P. Kelley and W. McGeorge. (*J. Ind. and Eng. Chem.*, 1912, **4**, 664-667.)—The author defines humus as the organic matter of soils soluble in 4 per cent. ammonia after removing calcium and magnesium with hydrochloric acid, and in the analyses given varies from 2·6 to 18·3 per cent., when estimated by the method described in the paper. A large number of soils were tested for humus content by the following methods, and the results tabulated: Hilgard, Mooers-Hampton, Houston-McBride (official), Cameron-Breazeale, and Rather. In addition the author describes a modification of his own, involving the filtration, under diminished pressure, of the humus solution through a

Pasteur-Chamberland filter, in order to separate the clay, the presence of which in soils containing much of it constitutes the most serious difficulty in the way of accurate determinations (*cf.* ANALYST, 1912, 466). When the first portion of the solution has passed the filter, 4 per cent. ammonia is drawn through as long as any colour is shown, and the filtrate and washings are then evaporated to dryness. The clay is washed out of the inside of the candle with a test-tube brush between each washing. The candle, with a short portion of its neck protruding, is suspended in a bell-jar from which the air is exhausted, the filtrate collecting in a jar beneath, while the solution to be filtered is poured into the candle down its centre from outside the bell-jar. Higher results are obtained by this process than by any of the others, excepting the official and Rather methods, neither of which is to be relied on for Hawaiian soils, as the majority of these are rich in very finely divided clay. The cause of the inaccuracy of these two last-mentioned methods becomes clear when the ash is determined in the humus obtained by evaporating its solutions to dryness, the value rising to as high a figure as 33 and 25 per cent. respectively, as against 0·6, 0·4, and 0·3 per cent. by the other methods. The large amount of clay unremoved from the humus solution accounts for the higher values. H. F. E. H.

Estimation of Methyl Alcohol in Admixture with Alcohol, and Especially in Spirits. W. Koenig. (*Chem. Zeit.*, 1912, **36**, 1025-1028.)—The following modification of the bichromate method of Thorpe and Holmes (ANALYST, 1904, **29**, 113) is recommended as the most generally applicable. The oxidation is effected in a litre flask (previously cleansed with boiling potassium permanganate solution and dilute sulphuric acid), and the carbon dioxide is conducted through drying-tubes, one containing sulphuric acid on pumice-stone, and the other calcium chloride, and is absorbed in two weighed U-tubes containing soda-lime, whilst beyond these are two more guard-tubes containing soda-lime, and calcium chloride. The oxidation flask is closed with a rubber cork with two openings, through one of which passes a dropping funnel, which can be closed at the top by a soda-lime tube, whilst the other opening receives a reflux condenser connected at its other end with the series of absorption tubes. After a current of air (freed from carbon dioxide) has been swept through the apparatus, the mixture of alcohol and methyl alcohol (5 to 10 c.c.) is introduced into the flask, and the dropping-funnel charged with a solution of 30 grms. of potassium bichromate in 500 c.c. of water and 50 c.c. of sulphuric acid (sp. gr. 1·84), this liquid having been first boiled for fifteen minutes and then cooled to 5° C. After this has also been introduced, the oxidation flask is shaken and allowed to stand for four hours, and its contents then slowly heated and boiled for one hour. Air is next drawn through the apparatus for about forty-five minutes, at first slowly, and then more rapidly, and the absorption tubes are then weighed. The weight of carbon dioxide multiplied by the factor 0·728 gives the amount of methyl alcohol. In test experiments with pure ethyl alcohol the amount of carbon dioxide corresponded to an average proportion of 0·50 per cent. of methyl alcohol—a result that agreed well with the observation of Thorpe and Holmes. The alcohol distilled from spirits behaved in the same way as pure alcohol, and in the case of test-mixtures containing from 4 to 15 per cent. of methyl alcohol the amounts found agreed within ±0·19 per cent. of the theoretical quantities. C. A. M.

Rapid Methods for determining Phenol. I. V. Redman and E. O. Rhodes. (*J. Ind. and Eng. Chem.*, 1912, **4**, 655-659.)—The authors compare the bromide-bromate method of Koppeschaar (*Zeitsch. anal. Chem.*, 1876, **15**, 233) with the hypobromite method worked out by Lloyd (*J. Amer. Chem. Soc.*, 1905, **27**, 16). A special shaking machine was employed, and it was found that, using either method, phenol determinations could be made within an error of 0·3 per cent. with one minute of continuous shaking after the solution containing the bromide was added, in place of the usual thirty minutes. It is important that the phenol solution be diluted until approximately $\frac{N}{100}$, and under these conditions the precipitate obtained by either method was white and flocculent, and showed no trace of red tetrabromo-phenoquinone or yellow tribromophenol bromide. The phenol solution employed must be acid after the bromine is added; if alkaline, an error arises, which increases as the concentration of the phenol present diminishes and the reaction period increases. The error introduced by shaking the solution for only one minute after the potassium iodide solution is added before titrating back with thiosulphate is 0·5 per cent. Three minutes shaking eliminates this, and further shaking has no effect. The potassium bromide-bromate solution (3·5 grms. bromate and 55 grms. of bromide to the litre) has the advantages over the $\frac{N}{10}$ hypobromite solution that it is permanent in strength and is free from unpleasant odour and free bromine, and only requires standardising once in three months, whereas the hypobromite solution weakened one-third per cent. every twenty-four hours for the first few days after being made.

H. F. E. H.

"Acid Resins" from Petroleum Residues. F. Schwarz. (*Chem. Rev. Fett- u. Harz.-Ind.*, 1912, **19**, 210-212.)—The acid residues obtained in refining the lighter distillation products of petroleum with sulphuric acid yield when diluted with water resinous substances which are used in the manufacture of varnishes, etc., while the acid is regenerated. In the cases of lubricating oils, however, the mineral acid cannot be separated in this way, and the residues are therefore neutralised with lime and used as asphaltum substitutes. As these products from the so-called "acid resins" are inferior to other asphalt materials, it is desirable to distinguish them from the more valuable distillation residues of petroleum. Samples of the former examined by the author yielded aqueous extracts which were strongly alkaline, owing to the presence of free lime. The presence of sulphonated acids was indicated by extracting the sample with petroleum spirit, evaporating the extract, igniting the residue, and testing the ash for sulphuric acid. In each case a small amount was found. For the separation of the organic acids, 5 grms. of each sample were thoroughly extracted in a basin on the water-bath with a mixture of absolute alcohol and a little hydrochloric acid (sp. gr. 1·19), and the extracts united, cooled to the ordinary temperature, and decanted from the residue. The clear brown liquid was then diluted with an equal volume of water, rendered alkaline with sodium hydroxide, and treated with petroleum spirit to separate unsaponifiable matters, after which the alcohol was evaporated from the alcoholic solution, and the residual aqueous solution shaken with ether and a little hydrochloric acid. On washing the ethereal layer with water, part of the organic acids was taken up by the water—this being an indication of the presence of sulpho-acids. The hydrochloric acid was therefore eliminated by washing the ethereal solution with a concentrated solution of sodium chloride, and the ether then evaporated. The residual acids were brown and resinous. They dissolved in water, forming a clear brown solution, but were only sparingly soluble in petroleum spirit and benzene. When neutralised and ignited they left an ash containing sulphuric acid. The amounts of sulphonated acids thus separated from three commercial samples were 7·5, 0·86, and 3·5 per cent. respectively. A distillation residue from petroleum treated in the same way yielded only an insignificant quantity of a yellow, resin-like mass which was insoluble in water. C. A. M.

General Method for the Estimation of Tartaric Acid. A. Kling and D. Florentin. (*Bull. Soc. Chim.*, 1912, **11**, 886-895.)—The addition of ammonium citrate prevents the interfering action of iron and aluminium salts on the estimation of tartaric acid as calcium racemate (*cf.* ANALYST, 1910, **35**, 323), even when the quantity of iron oxide or alumina present in certain pharmaceutical preparations amounts to 50 per cent. of the amount of tartaric acid. The effect of copper and antimony salts on the estimation is also prevented by the addition of ammonium citrate. The quantity of citrate added should be about ten times the weight of iron oxide or alumina present. When the proportion of alumina is very large, it is better to remove it by precipitation in the form of ammonium-alum. For this purpose the tartaric acid solution is treated with ammonium sulphate, a small quantity of hydrochloric acid, and alcohol; the alum crystals are collected on a filter, washed with alcohol, and the tartaric acid is estimated in the filtrate. Large quantities of iron are removed as sulphide in acetic acid solution. W. P. S.

INORGANIC ANALYSIS.

Titration of Copper Salts with Titanous Chloride. L. Moser. (*Chem. Zeit.*, 1912, **36**, 1126-1127.)—In the titration of copper salts by means of titanous chloride (see Rhead, *J. Chem. Soc.*, 1906, **89**, 1491) the use of thiocyanate and of a ferrous salt as indicator may be dispensed with. The reaction only proceeds quantitatively in strongly acid solutions, and hydrochloric acid is preferred because cupric solutions containing much hydrochloric acid possess a high colour, and the disappearance of this colour marks the end-point of the titration. For the same reason the author makes use of less dilute solutions than Rhead, a $\frac{N}{10}$ solution of titanous chloride being employed, and the copper solution concentrated to approximately $\frac{N}{5}$ strength and mixed with its own bulk of recently boiled hydrochloric acid (1 : 1) before the titration, which must be conducted in a vessel through which a current of carbon dioxide passes. The method is accurate to within 0·05 c.c. of the standard titanous chloride. G. C. J.

Detection and Estimation of Minute Quantities of Fluorine in Waters, Minerals, and Living Tissues. A. Gautier and P. Clausmann. (*Bull. Soc. Chim.*, 1912, 11, 872-884.)—The fluorine is first concentrated by rendering the water slightly alkaline, adding about 0·4 grm. of sodium sulphate together with a slight excess of barium chloride, and evaporating the whole to dryness. The residue is treated with a quantity of water sufficient to dissolve the soluble salts, an equal volume of 96 per cent. alcohol is added, the precipitate is separated by centrifugal action, and washed with alcohol until free from chlorides. In the case of minerals, those which are entirely attacked by sulphuric acid may be tested directly, whilst others are fused with sodium carbonate, dissolved in water, the silica is separated by means of ammonium carbonate, and the solution concentrated. Organic tissues are ignited in the presence of lime, the residue is dissolved in dilute hydrochloric acid, and the solution treated as in the case of water. When a mineral water containing much sulphate is under examination, magnesium chloride, ammonium phosphate, and ammonia may be added, and the precipitate produced employed for the test.

The barium, or other precipitate, obtained as described above, is now heated with concentrated sulphuric acid in a specially constructed gold crucible in such a way that the evolved gases are absorbed by moistened potassium hydroxide contained in a device which covers the crucible. At the end of two hours the potassium hydroxide is dissolved in water, the solution is brought just to boiling, nearly neutralised with hydrochloric acid, and ammonium chloride solution is added until the mixture, while still hot, is neutral to phenolphthaleïn. About 4 grms. of ammonium carbonate are then added, the solution is evaporated to dryness, the residue is dissolved in water, filtered, sodium sulphate is added to the filtrate, which is now heated to boiling, and precipitated with a slight excess of barium nitrate. The mixture is again evaporated to dryness, water is added, together with an equal volume of alcohol, the precipitate is separated by centrifugal action, washed with 65 per cent. alcohol until the last traces of nitrate and chloride are removed, then dried and weighed. A portion of this precipitate may be tested for the presence of fluorine by heating it with sulphuric acid and noting whether the vapours will etch glass. A lead crucible is used in this test, a varnished glass-cover having a small unvarnished portion being employed to cover the crucible. The quantity of fluorine present is estimated in the remaining part of the weighed precipitate by heating the latter with sulphuric acid in a platinum crucible, and absorbing the vapours by powdered lead-glass moistened with water. The lead-glass is then dried, and washed with boiling 85 per cent. alcohol; the lead fluoride is dissolved by washing the lead-glass with a saturated potassium chlorate solution diluted with four times its volume of water, and, after the addition of a small quantity of gelatin solution, the lead is estimated colorimetrically as sulphide, its quantity being a measure of the amount of fluorine present. It is stated that the method will estimate accurately as little as 0·1 mgrm. of fluorine in 1 litre of water, or 100 grms. of vegetable or animal tissue, whilst the qualitative test described will detect as little as 0·001 mgrm. of fluorine.

W. P. S.

Sampling Gold Bullion. F. P. Dewey. (*Eighth Inter. Cong. App. Chem.*, 1912, Vol. I, 155-181.)—In many cases a chip or drill sample may be satisfactory, in others, drillings will give a more representative sample than chips. But with bullion concerning which nothing is known the sample must be remelted, properly mixed, and dipped. In many cases, particularly of cyanide bullion, the composition of the metal interferes with the actual assaying, and the bullion must be refined before the gold can be determined accurately. The paper includes the results of hundreds of assays which support the above conclusions. The degree of divergence between duplicates, when remelting is dispensed with, may be as much as 1 per cent.

G. C. J.

Estimation of Hydrogen and Methane in Gas Mixtures. W. Hempel. (*Zeitsch. angew. Chem.*, 1912, **25**, 1841-1845.)—The temperature obtainable by means of an ordinary Bunsen burner is insufficient to ensure complete combustion of methane in a Drehschmidt platinum capillary. The use of a small blowpipe flame is essential. The Drehschmidt platinum capillary may be replaced by a capillary of transparent quartz, into which is pushed a short length of platinum wire of such diameter that the wire almost fills the tube. Such a capillary has the advantage that there is no risk of propagation of flame from the heated portion of the capillary to an explosive mixture contained in the gas burette to which it is connected.

When using the Winkler-Dennis combustion pipette there is often difficulty in burning the last of the methane, so that the operation extends over a considerable period, during which such an amount of mercury may be oxidised as to give rise to serious error. This source of error may be avoided by enclosing the electrically heated spiral in a quartz glass tube, which becomes the outer limb of the capillary U-tube of a simple mercury pipette. The gas is passed slowly to and fro between the burette and pipette over the heated spiral. The quartz tube is connected at either end by short pieces of rubber tubing to the tubes of soft glass, through which pass the stout platinum wires conveying the current to the spiral. A detailed drawing of a convenient arrangement accompanies the paper.

Fractional combustion of hydrogen by means of palladium asbestos is successful only if the passage of gas through the capillary be slow and the temperature of 400° C. not exceeded. A convenient way of controlling the temperature is to let the capillary containing the palladium asbestos lie horizontally in a groove cut in a massive block of brass, which is heated by a flame. Close to the groove in the block is bored a vertical hole which accommodates a thermometer or a tube of mercury, the boiling of which shows that a suitable temperature has been reached. The author uses a capillary of 1 to 1½ mm. diameter, filled for 10 mm. of its length with palladium asbestos, and it is found that the speed of the gas through such a capillary should not much exceed 10 c.c. per minute.

The use of a palladium sol, together with a soluble picrate as an absorbent for hydrogen, as suggested by Paal and Hartmann (ANALYST, 1910, **35**, 139), gives excellent results, but, as originally described, the method is rendered tedious by the persistent frothing of the liquid. Moreover, the absorptive capacity of the reagent falls off somewhat rapidly on storage, even in the dark. The froth is instantly destroyed by the introduction of 5 drops of alcohol through the capillary, but alcohol makes the reagent useless for further determinations. As the reagent is unaffected by mercury, the most convenient procedure is to use but a small quantity of it confined over mercury. The author treats 0·3 grm. or less of Kalle's colloidal palladium with 5 c.c. of water, and after twenty-four hours the palladium sol is mixed with 10 c.c. of a saturated solution of sodium picrate and charged into a mercury pipette. The quantity named has an absorptive capacity of about 455 c.c. of hydrogen, and can be depended on to absorb a quarter of that amount quantitatively and quickly from a gas mixture. Alcohol is used to destroy foam, and the contents of the pipette are then transferred to the palladium residue bottle, and the pipette is recharged after being washed free from traces of alcohol. G. C. J.

Methods for the Estimation of Iodides. W. Schirmer. (*Arch. Pharm.*, 1912, **250**, 448-451.)—The ferric chloride, nitrite, and iodate methods for the estimation of iodides were found to yield the most trustworthy results under the following conditions:

Ferric Chloride Method.—About 0·4 grm. of the iodide is dissolved in not more than 20 c.c. of water, and the mixture is treated with 5 grms. of ferric chloride solution; after the lapse of one hour the mixture is diluted with 120 c.c. of water, 10 c.c. of phosphoric acid (25 per cent.) are added, the liberated iodine is dissolved by the addition of 0·5 grm. of potassium iodide, and titrated with thiosulphate solution. One c.c. of $\frac{N}{10}$ thiosulphate corresponds with 0·0166 grm. of potassium iodide.

Nitrite Method.—In a stoppered flask 0·5 grm. of the iodide is treated with 50 c.c. of water, 10 c.c. of dilute sulphuric acid, and 10 c.c. of a 1 per cent. sodium nitrite solution. At the end of two minutes, 1 grm. of urea is added, the contents of the flask are shaken for five minutes, and, after the separated iodine has been dissolved by the addition of 0·5 grm. of potassium iodide, the solution is titrated with thiosulphate solution.

Iodate Method.—Twenty c.c. of a 1 per cent. potassium iodate solution, 5 c.c. of dilute sulphuric acid, and 50 c.c. of water are placed in a stoppered flask, and 0·4 grm. of the iodide, dissolved in 10 c.c. of water, are introduced. After the lapse of about two minutes 5 grms. of borax are added, and at the end of a further five minutes the liberated iodine is dissolved by the addition of about 1 grm. of potassium iodide, and titrated with thiosulphate solution. W. P. S.

Applications of the Method of Precipitating Metals as Iodides, etc., from Sulphuric Acid Solution. G. Bressanin. (*Gazz. Chim. Ital.*, 1912, **42**, 97-101.)—

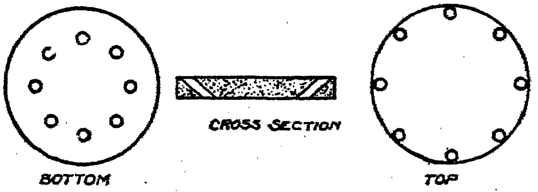
Estimation of Tin.—Solutions of tin in sulphuric acid (sp. gr. 1·52) yield a precipitate on treatment with potassium iodide in an analogous manner to arsenic and antimony (ANALYST, 1912, 206). The reaction, which is given by both stannous and stannic salts, is much more sensitive than the reaction of stannous salts with mercuric chloride. The tin precipitate is bright yellow, and resembles arsenic iodide, but is readily soluble in hydrochloric acid, whereas arsenic iodide is practically insoluble. It differs from antimony iodide in colour, and in being more soluble in hydrochloric acid. In order to obtain quantitative results it is necessary that the tin should be in the higher form of oxidation, since, unlike arsenic and antimony, which are precipitated as iodides, stannic compounds are precipitated as stannic iodate, whilst stannous precipitates are unstable and undergo continuous oxidation. With this precaution of preliminary oxidation of the tin, arsenic and antimony may be estimated in the presence of that metal. The stannic precipitate, when dissolved in dilute tartaric acid solution, gives a solution which, when neutralised with sodium bicarbonates, does not absorb iodine.

Estimation of Arsenic in Commercial Copper.—The proportion of arsenic in commercial copper is so small that a large amount of the copper is required for the estimation; and since the copper salts on treatment with potassium iodide liberate an atom of iodine for each atom of copper, the total quantity of iodine thus set free is so great that it cannot be eliminated by a single washing with a solution of potassium iodide in sulphuric acid. The process must therefore be modified as follows: The finely divided copper (0·5 grm.) is dissolved in 5 c.c. of *aqua regia*, the solution evaporated to dryness, and the residue, after removal of all nitric acid, dissolved in about 250 c.c. of hot sulphuric acid (sp. gr. 1·52). On cooling the solution, and adding 25 c.c. of a 30 per cent. solution of potassium iodide, the copper and arsenic are precipitated together as iodides. The precipitate is allowed to stand for about twenty minutes, after which it is collected on an asbestos filter, and washed with the aid of a filter pump with 30 to 40 c.c. of sulphuric acid containing 5 per cent. of 30 per cent. potassium iodide solution, and the arsenic iodide dissolved off the filter by means of a dilute solution of sulphurous acid, which also reduces the remaining iodine. If the filter bed is sufficiently close none of the copper iodide will pass into the filtrate, which should remain perfectly limpid. The filtrate and washings are treated with sufficient iodine solution to give a distinct blue coloration with starch paste, then rendered alkaline with sodium bicarbonate, and the titration completed with iodine solution. The arsenic is calculated from the amount of iodine used in this second period of the titration. C. A. M.

Colorimetric Determination of Iron in Lead and its Oxides. J. A. Schaeffer. (*J. Ind. and Eng. Chem.*, 1912, 4, 659-660.)—The method is substantially that of Thomson (*J. Chem. Soc.*, 1885, 47, 493), with the difference that greater care is taken to secure similarity in the solutions to be compared. In the analysis of litharge or metallic lead, 1 grm. of the sample is covered with 15 c.c. of water, and enough nitric acid is added to convert all the lead to nitrate. The solution is diluted if basic nitrate separates, is boiled for several minutes to peroxidise iron, and is then neutralised with ammonia, and again rendered faintly acid by addition of a measured amount of dilute nitric acid. It is then transferred to a 100 c.c. Nessler glass, 15 c.c. of thiocyanate (5 per cent.) is added, and the mixture diluted to the mark, and its colour matched by adding a standard solution of ferric ammonium sulphate from a burette to a cylinder containing 15 c.c. of thiocyanate and as much nitric acid as was added to the test solution after neutralisation.

In the analysis of red lead, the initial treatment is the same, but when the solvent action of the nitric acid slackens, 10 c.c. of hydrogen peroxide (2 : 7) is added, and the solution boiled for one minute. The solution is neutralised, acidified again by addition of a measured quantity of dilute nitric acid, and cleared, if necessary, by addition of a few drops of hydrogen peroxide solution. To the comparison cylinder 10 c.c. of hydrogen peroxide solution (2 : 7) as well as a measured quantity of nitric acid and thiocyanate are added. Quantities of iron up to 0·03 per cent. can be estimated with an error not exceeding 0·001 per cent., and the small percentage of copper present in lead and its oxides, such as are used in the manufacture of accumulators and high-grade lead-glass, does not interfere. G. C. J.

Determination of Carbon in Steel by Direct Combustion in the Newest Form of Shimer Crucible, with the Aid of a Perforated Clay Disc. F. O. Kichline. (*J. Ind. and Eng. Chem.*, 1912, 4, 683-684.)—Description of improvements in the platinum crucible with water-cooled brass stopper previously described by P. W. Shimer, and of modifications in the manner of using it for carbon determinations. The crucible is now made of slightly larger diameter, so as to accommodate a No. 00 Berlin crucible instead of a No. 000. This allows the use of 2·727 grms. of drillings (1 mgrm. CO_2 then $=0·01$ per cent. C.), instead of only half this charge. The drillings are placed on a bed of sand, of which enough is taken to half fill the crucible, and are now covered by a perforated disc, like that shown in the illustration, instead of with asbestos as formerly. Allowing for these modifications, the improved apparatus is used in the manner already described. The discs are best made of China clay, which is mixed with water to the proper consistency, moulded into shape, carefully dried, fired and annealed. With a little practice they can be constructed in any ordinary laboratory, and with care in use will last for 100 determinations like the porcelain liners. Compared with asbestos they save time and are cleaner in working. G. C. J.



CLAY DISC.

Technical Analysis of Spelter. E. J. Ericson. (*Eighth Inter. Cong. App. Chem.*, 1912, Vol. I, 183-186.)—The spelter (20 grms.) is covered with 100 c.c. water and 50 c.c. dilute (1 : 3) sulphuric acid, and allowed to stand overnight. The lead, cadmium, and undissolved zinc are then filtered off, washed with hot water, returned to the beaker, and dissolved in 10 c.c. of nitric acid. The solution is boiled until brown fumes cease to be evolved, and is then diluted and filtered from any trace of tin or antimony oxide. If these are absent, as is usually the case, the solution is diluted to at least 100 c.c., and 30 c.c. of ammonia and 5 to 10 grms. ammonium persulphate are added, and the solution boiled for five minutes. After ten minutes, the lead peroxide is filtered off on a double filter (11 cm.) and washed four times with hot 10 per cent. ammonia and five times with hot water. The precipitate is washed back into the beaker and treated with a measured volume of hydrogen peroxide solution of known strength until dissolved. After addition of 15 c.c. of dilute nitric acid (sp. gr. 1·2) and 75 to 100 c.c. water, the excess of hydrogen peroxide is determined by titration with permanganate. If 1 c.c. of the permanganate corresponds to 1 mgrm. of iron, it should theoretically correspond to 1·85 mgrm. of lead; but experience shows that the factor 1·92 should be employed. Using this factor, the results check well with results obtained by the gravimetric chromate method, and the method is recommended for spelter containing 1 per cent. or less lead.

The ammoniacal filtrate from the lead peroxide is boiled until nearly neutral and a white precipitate appears. About 40 c.c. of dilute (1 : 3) sulphuric acid is then added, and boiling continued for ten minutes. After diluting to 200 c.c., the solution is saturated with hydrogen sulphide, with occasional additions of water. The precipitate is collected on a double filter, washed a few times, and then redissolved on the filter with the least possible quantity of hot dilute hydrochloric acid. Any copper which may be present remains on the filter as sulphide, and may be ignited and weighed as oxide. The solution of cadmium (and zinc) chloride is nearly neutralised with ammonia, and about 8 grms. of trichloracetic acid (*cf.* Fox, *J. Chem. Soc.*, 1907, **91**, 964) dissolved in water is added—or more, if more is necessary—to dissolve the cadmium sulphide which separates on neutralisation. The solution is diluted to 200 c.c., and the cadmium reprecipitated by hydrogen sulphide. The cadmium sulphide is filtered off, and finally converted into sulphate or phosphate.

G. C. J.

Determination of Manganese by the Bismuthate Method. W. Blum. (*Eighth Inter. Cong. App. Chem.*, 1912, Vol. I, 61-85.)—As the result of exhaustive research in the U.S. Bureau of Standards, the conclusion is reached that the bismuthate method is more accurate than any other, even for the analysis of high-grade manganese ores. It is shown that the manganese value of permanganate solution is identical, whether calculated from a sodium oxalate titration by means of the theoretical factor 0·1640, or determined by means of pure anhydrous manganese sulphate. Statements to the contrary (*e.g.*, that of Brinton, ANALYST, 1911, **36**, 305; see also Hillebrand and Blum, *ibid.*, 1911, **36**, 430) are probably due to the difficulty of depriving manganese sulphate of traces of free sulphuric acid without at the same time decomposing some of the manganese sulphate. It is shown that prolonged heating to at least 440° C. is necessary to eliminate free sulphuric acid, whilst at temperatures above 525° C. there is risk of decomposition. The sodium oxalate method of standardisation is therefore recommended. $\frac{N}{10}$ permanganate, which should be used in the analysis of high grade manganese ores, is standardised by dissolving as much sodium oxalate as will require nearly 50 c.c. in 250 c.c. of water containing 5 c.c. of sulphuric acid, warming to 80° to 90° C., and titrating slowly. The final temperature should not be below 60° C. $\frac{N}{30}$ permanganate, such as is used for determining manganese in steel, is standardised in a similar manner, but a sharper end-point is obtained by restricting the initial volume to about 75 c.c.

Analyses are conducted as follows: To the cold manganese solution containing 20 to 40 per cent. of nitric acid (free from nitrous acid) in a bulk of 50 to 150 c.c., a slight excess of bismuthate (0·5 to 1 grm.) is added, and the mixture agitated for half a minute. The sides of the flask are washed down with 50 c.c. of 3 per cent. nitric acid, and the solution is filtered at once through asbestos, previously coated with bismuthate. About 100 c.c. of 3 per cent. nitric acid is used to wash the flask and filter. A measured amount of standard ferrous sulphate solution is added, and the excess titrated with permanganate. For quantities of manganese up to 0·05 grm. the method is accurate to 1 in 500. The experience of the Bureau shows that no other known method, gravimetric or volumetric, gives results for which a higher degree of accuracy can be claimed. With quantities of manganese as large as 0·1 grm., the method as described gives rise to errors of several units per cent.

It is shown that permanganate solutions preserve their strength when exposed to diffused light, if protected from reducing substances, and that $\frac{N}{10}$ solutions of ferrous sulphate are as stable as those of ferrous ammonium sulphate, the rate of oxidation under average conditions being about 1 per cent. in five days (see also Baskerville and Stevenson, ANALYST, 1911, **36**, 467). G. C. J.

Rational Analysis of Nitrate of Soda. W. S. Allen. (*Eighth Inter. Cong. App. Chem.*, 1912, Vol. I, 19-31.) — A protest is raised against the custom of estimating the content of sodium nitrate in commercial nitrate of soda by subtracting from 100 per cent. the sum of the water, insoluble matter, and chloride and sulphate expressed as sodium chloride and sulphate. The method invariably overestimates the sodium nitrate, the average error being about 1 per cent.; but it may reach 3 per cent. Not only do all samples contain soluble salts of calcium, magnesium, iron, and aluminium in small amount, but sodium perchlorate is occasionally present up to nearly 1 per cent., and the percentage of potassium nitrate may exceed 8 per cent. Though commercial nitrate of potash is more valuable than the sodium salt, its presence in admixture with the latter is a disadvantage to the nitric acid maker, as its nitrogen content is lower than that of nitrate of soda. It is held that the basis of sales should be the nitrate content as determined by a direct method. A modification of the Devarda method (*Zeitsch. anal. Chem.*, 1894, **33**, 113) is described, and the opinion expressed that it will be found simpler than the use of the nitrometer by those who are not thoroughly familiar with the use of that instrument. The new method consists in reducing the nitrate to ammonia in alkaline solution by means of Devarda metal, and driving the ammonia over into a measured volume of standard acid by means of a current of air, which bubbles through the reduced solution contained in a flask which is heated in a water-bath. Between the flask and the receiver is a spray-tap, consisting of four 1-inch bulbs blown on a tube about 8 inches long. The bulbs are filled with glass-wool, and drain back towards the reduction-flask. To prevent undue condensation in this spray-trap, and to hasten the distillation of the ammonia, the bulbed tube is surrounded with a lead jacket through which steam is passed. The air which is drawn through the apparatus is previously freed from carbon dioxide, and methyl red is preferred as indicator. G. C. J.

Effect of Ignition on the Solubility of Soil Phosphates. C. B. Lipman. (*J. Ind. and Eng. Chem.*, 1912, **4**, 663 664.)—Fraps (ANALYST, 1911, **36**, 371) showed that the ignition of phosphate minerals such as wavellite, dufrenite, etc., for ten minutes at a low red heat increased about ten times the solubility of the phosphoric acid in them in $\frac{N}{5}$ nitric acid, and rendered it almost entirely soluble in 12 per cent.

hydrochloric acid. The author has frequently noticed the reverse effect when soils were ignited, and below are recorded the figures obtainable when the phosphoric acid is estimated in soils of varying composition before and after ignition:

	Percentages of P_2O_5.				
	1.	2.	3.	4.	5.
Ignited ...	0·410	0·150	0·090	0·167	0·151
Not ignited ...	0·460	0·250	0·130	0·191	0·190

Theoretical considerations are discussed as to the possible causes of the loss noticed and the reason for the reverse effect mentioned above. H. F. E. H.

Action of Dimethyl-Glyoxime on Platinum Salts. M. Wunder and V. Thuringer. (*Ann. Chim. anal.*, 1912, **17**, 328-329.)—Platinum salts form an insoluble compound with dimethyl-glyoxime, but with much more difficulty and at a higher temperature than the corresponding palladium compound (ANALYST, 1912, 379). The platinum precipitate is brown, blue, or greenish-blue while moist, but assumes a bronze colour when dry. In experiments to render the reaction quantitative the precipitate, obtained in the same manner as with palladium (*loc. cit.*), was digested for several hours on the water-bath, then separated, dried, and ignited. From 0·0292 grm. of platinum there was obtained 0·0222 grm. Better results (*e.g.*, 0·266 grm.) were obtained by the use of an alcoholic solution of dimethyl-glyoxime, while by adding sodium citrate to augment the reducing action the figures were still better (*e.g.*, 0·0250 grm. from 0·0262 grm.). For each part of platinum one and a half parts of the reagent were used. The presence of ammonium chloride accelerated the formation of the precipitate, but did not lead to better results than those quoted. C. A. M.

Rare Earth Reactions in Non-Aqueous Solvents. O. L. Barnebey. (*J. Amer. Chem. Soc.*, 1912, **34**, 1174-1189.)—A study of the reactions of the common acids and bases with the yttrium group—neodymium, lanthanum, and cerium—using acetone as solvent. The reactions are of the same general order as those in aqueous solution, but the solubilities vary more widely. In some cases compounds which are readily soluble in water have been found to be nearly insoluble in acetone, so that the use of acetone as solvent, in combination with reagents used for the separation of the earths by fractional precipitation, promises to make such separations sharper and less tedious. The basic nitrate scheme of fractionation, using acetone as solvent, is very effective as a means of separating ceria from the other earths, but none of the other separations described are separations in the sense in which the term is usually understood by analysts. A separation of the yttrium group, using tartaric acid as precipitant, has been found very effective for fractional purposes. The serial order established is ytterbium (lutecium and neoytterbium), holmium, erbium, dysprosium, yttrium. Other separations described depend on the use of alkaloids as fractional precipitants in acetone solution. G. C. J.

Exact Determination of Sulphur in Pyrites. W. S. Allen and H. B. Bishop. (*Eighth Inter. Cong. App. Chem.*, 1912, Vol. I, 33-51.)—The method depends on oxidation and solution by means of a solution of bromine in carbon tetrachloride followed by nitric acid, reduction of ferric iron by means of aluminium powder, and precipitation in cold dilute solution by slow addition of barium chloride solution. Large quantities are taken for analysis, so that the barium sulphate to be weighed approximates 5 grms. The results are accurate to within 0·05 per cent. Under the prescribed conditions, the barium sulphate always contains barium chloride, but the amount of this is very nearly constant (0·0137 to 0·0150 grm.), and the results show that the error due to this cause is almost exactly compensated by the solubility of the barium sulphate.

The sample is not ground more finely than 80 mesh (*Cf.* Allen and Johnston, ANALYST, 1910, **35**, 332), and 1·3736 grms. is weighed out into a 300 c.c. beaker and covered with 10 c.c. of a mixture of 2 volumes bromine and 3 volumes carbon tetrachloride. Bromine alone is too violent, and its aqueous solution too weak. The mixture is shaken from time to time, and after fifteen minutes 15 c.c. of nitric acid is added, and the mixture left for a further fifteen minutes at room temperature, with occasional shaking. The beaker is then placed on an asbestos board on the steam-bath until all action has ceased and most of the bromine has volatilised. The clock glass covering the beaker is next raised somewhat by means of glass riders, and the contents of the beaker are evaporated to dryness by immersing it in the steam-bath up to its rim. Hydrochloric acid (10 c.c.) is added, and the solution again evaporated to dryness, and the residue dried for several hours at 100° C. to render silica insoluble. The residue is moistened with 4 c.c. of hydrochloric acid, and after five minutes 100 c.c. of hot water is added, and the mixture boiled for five minutes. It is allowed to cool for about five minutes, and then 0·2 to 0·3 grm. of aluminium powder is added, and the contents of the beaker agitated until the colour of ferric iron disappears. The solution is cooled to arrest the action of acid on aluminium, which might otherwise give rise to mechanical loss on the filter, and is filtered through a 12·5 cm. filter, which is washed nine times. The filtrate is diluted to about 1,600 c.c., and a further 6 c.c. of hydrochloric acid is added to it. About 125 c.c. of 5 per cent. barium chloride solution is added without stirring, and at a rate not exceeding 5 c.c. per minute. The paper includes description of an appliance for effecting this without attention. When all the barium chloride has run in, the contents of the beaker are stirred, and then allowed to stand for not less than two hours. The liquid is decanted through a 35 c.c. Gooch filter with a moderately thick asbestos mat, and the precipitate is transferred to the filter and washed six times with cold water. The crucible is then dried and heated for half an hour with the full flame of a Bunsen burner (or in an electric oven at 870° C.). The weight of the precipitate multiplied by ten gives the percentage of sulphur in the sample. Test analyses show that the method gives results of the accuracy stated, and that it is unaffected by the presence of such amounts of lead, copper, zinc, arsenic, lime, and silica, as may occur in pyrites. G. C. J.

APPARATUS, ETC.

Crystallo-Chemical Analysis: A New Method of Chemical Analysis. G. von Fedorow. (*Zeitsch. f. Krystallogr.*, 1912, **50**, 513-575; through *Nature*, 1912, **89**, 503-505.)—It is shown that there is a correct mode of setting up a crystal for descriptive purposes, and that this setting is arrived at independently of external "habit," being based on calculations of the "reticular density" (closeness of packing of the nodes, or "points," of the space-lattice or point system) along the planes of the principal faces. The setting which corresponds to primary faces of maximum reticular density is the only correct one on which comparisons should be made. A table including 10,000 crystalline substances, which have been goniometrically measured, has been prepared, arranged in regular progressive order, and calculated on the above lines as regards correct setting. If a few measurable crystals of any one of these substances be subjected to a short goniometrical investigation, occupying at most a few hours, and often only a few minutes, the substance of which the crystal is composed can then be identified by reference to the table. In short, provided a chemical substance has once had its crystals measured, it is possible to detect it at any time by merely making a few brief measurements so as to be able to calculate the elements—by a shortened process, partly graphical, which the author has perfected—and then searching the table for the substance therein recorded as possessing such constants. A number of test cases have been sent to the author, and he succeeded in identifying them correctly. The method has the advantage of not injuring the crystals, but fails in its simple form with cubic crystals, in which the angles are always the same; but a determination of refractive index is successful where that of symmetry, elements, and angles fail.

H. F. E. H.

Luminescence Analysis. O. Wolff. (*Chem. Zeit.*, 1912, **36**, 1039.)—Lehmann has devised a fluorescence microscope which is used with ultra-violet light and has a screen for the protection of the eye. By means of this instrument the author has found that the red fluorescent particles in crude potashes consist of potassium sulphide, whilst the particles showing a blue fluorescence consist of organic matter, mainly in combination with the mineral matter. In like manner the orange fluorescence of mercuric chloride is shown to be due to particles of mercurous chloride. The fluorescence of the latter disappears on heating. Chemically pure mercuric chloride shows no fluorescence, but in many of the preparations on the market traces of calomel may thus be detected, although they escape detection by chemical means. Resublimation of pure mercuric chloride in a tube causes the orange fluorescence to appear, owing to the formation of traces of calomel. Another direction in which this microscope has proved useful is in the examination of anthracene, which when pure shows a blue fluorescence, but when impure fluoresces green, owing to the presence of a substance with a yellow fluorescence.

C. A. M.

New Type of Inorganic Filter for Laboratory Purposes. M. A. Williamson and P. A. Boeck. (*J. Ind. and Eng. Chem.*, 1912, **4**, 672-677.)—The material of the new filter is "alundum" (*cf.* Boeck, ANALYST, 1912, 288), a porous ware already in use for the construction of extraction thimbles and filter plates (ANALYST, 1912, 109). When given the form of an ordinary crucible, this ware was not successful in replacing the Gooch crucible with asbestos mat, because the upper portion of the crucible absorbed strong saline solutions, and the time required to wash the salt out from those portions of the crucible above the level where the suction was operative was so great as to outweigh any advantages the crucible might otherwise have possessed. Filtering-cones have now been constructed which overcome this difficulty, and which serve as combined filter and crucible. The use of the cone as filter is shown in Fig. 1. A funnel a little larger than the cone is equipped with a piece of soft rubber tubing about 1½ inches long and 1½ inches in diameter (the cones are 1¾ inches in diameter and 1¼ inches high), and the cone finds a seating on the moistened rubber. The filter and any precipitate it may contain can be washed perfectly in two or three minutes, and, after drying, can be ignited. The material is unaffected by sulphuric, nitric, or hydrochloric acid. It is somewhat hygroscopic, a cone of the dimensions given picking up about 1 mgrm. on exposure to the air of the laboratory for one hour, but there is no further gain in weight in three hours. Among the test numbers given, those for barium sulphate are all low—from 0·1329 to 0·1331 found against 0·1349 required by theory and found by ordinary filtration using a paper. Since parallel experiments in which a paper was placed inside the cones also gave 0·1330, the low results appear to be due not to penetration of the filter by the finely divided precipitate, but to the solubility of the precipitate in the washing water, of which there is a tendency to use large quantities when a filter operates very quickly. Fig. 2 shows how these cones may be freed from any soluble salts suspected to lie within their pores. The illustration actually figures a crucible-shaped filter, of the type which was abandoned owing to its tendency to absorb salts; but a similar arrangement serves to clean a cone, as to the cleanliness of which there may be a doubt. The cones are made by the Norton Company, Worcester, Mass., U.S.A.

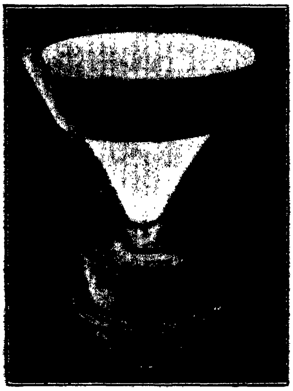


FIG. 1.

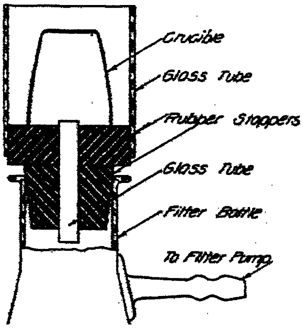

FIG. 2.

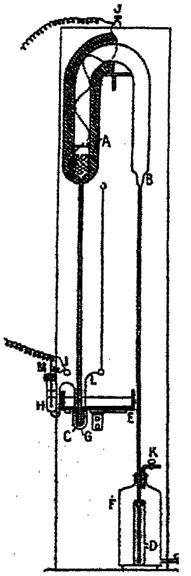
G. C. J.



Apparatus for Rapid Distillation of Mercury in Vacuo. L. Dunoyer. (*Compt. rend.*, 1912, **154**, 1344-1346.)—The apparatus consists of a bent glass barometer tube, *A B*, of 4 to 5 cm. diameter and 35 to 40 cm. high. The limb *A* terminates in a tube about 10 mm. in diameter, which dips into a small beaker, *C*, fixed to the tube. This beaker hangs in a tube, *G*, which is cemented into the bottom of the rectangular glass dish *E*, which can accommodate some 20 kgrms. of mercury. The end *B* of the barometer-tube terminates in a tube about 120 cm. long and not more than 3 mm. in diameter. This narrow tube dips into the vessel *D*, which is provided with a side outlet, and is itself contained within the bottle *F*. The bottle *F* is evacuated by connecting the cock *K* to a water-pump. This causes the mercury to rise to the level shown in *A*, and the circuit is then completed through the electrical heating device, and the distillation commenced. The use of the vessels *C* and *D* make it possible to clean or empty *F* without interrupting the distillation. The heating device consists of a winding of chrome-nickel wire, extending from the constriction of the tube *A* to the highest point of the bend, separated from the glass by insulating material and externally covered with a thick layer of some poor conductor of heat. It is to be noted that only the small portion of mercury in *A* and the vapour above it are heated by the current, the bulk of the mercury in *E* remaining cool until drawn up into *A* to replace mercury which has evaporated.

The apparatus possesses a simple device for breaking the electrical circuit if, and when, the supply of mercury in *E* is exhausted or reduced to some assigned level. From the base of the vessel *H* proceeds a narrow S-tube, the other end of which dips into the mercury in *E*. *H* is closed by a wooden plug through which is screwed an electrode, *M*, of amalgamated copper tube. The height of this electrode is adjusted until its lower end corresponds to the level at which it is wished to arrest the further depletion of the mercury in *E*. Mercury is then poured into *H*, covered with a layer of petroleum, and the plug carrying the electrode is pushed into *H*, whilst closing the upper end of the tubular electrode with the thumb or a stopper. In this way mercury is forced into the S-bend, thus establishing electrical connection between the electrode and the mercury in *E*. The current passes from the terminal *I* through the electrode *M* and the mercury in *H*, the S-bend and *E*, and thence by the nickel wire *L*, which dips into the mercury in *E*, to the heating coil, the other terminal of which is at *J*. When the level of the mercury in *E* has sunk to the level of the lower end of the electrode *M*, the electrical circuit is automatically broken and the distillation is suspended. G. C. J.

Two New Pieces of Laboratory Apparatus. E. Berlin. (*Zentralbl. für Physiol.*, 1912, **26**, 219; through *Chem. Zentralbl.*, 1912, II, 889.)—The first apparatus is for the evolution of hydrochloric acid gas from its aqueous solution by the action of sulphuric acid. It consists of a round-bottomed flask, into the closed top of the neck of which are sealed two tubes, each terminating downward somewhat below the base of the neck inside the flask, and leading upward, through a stopcock, to a bulb carrying a funnel and a tube opening to the air; funnel and tube are simultaneously opened and closed by the plug of a stopcock passing through both. A delivery tube, and an emptying tube reaching the bottom of the main flask, are sealed into the neck halfway up, and are closed with stopcocks. The bulbs are charged with concentrated hydrochloric acid and concentrated sulphuric acid respectively.

The second apparatus is for the continuous extraction of a liquid, such as water, by a heavier liquid, such as chloroform. Into the neck of a round-bottomed flask with reflux condenser is sealed a tube with its mouth, directed downwards, a short distance below the cork. This tube passes down outside the neck to join a second tube, sealed through the base of the neck, and reaching the bottom of the flask. From the junction the tube is widened, and passes diagonally downwards to a smaller flask in which chloroform is boiled. Chloroform is placed in the larger flask until the mouth of the tube reaching to the bottom is well covered, and on this sufficient of the aqueous liquid to be extracted to cause the chloroform to overflow into the smaller flask. Chloroform, as vapour, passes up the side tube, is condensed, sinks in drops through the aqueous liquid, and flows over into the smaller flask. O. E. M.

Apparatus for the Estimation of Adulterants in Vegetable Powders, and Notes on Starch Granules. C. Hartwich and A. Wichmann. (*Arch. Pharm.*, 1912, **250**, 452-471.)—The apparatus consists of a microscope slide on which is engraved a square, the sides of which measure 1·5 cm.; this square is divided into 100 equal squares, and around its edges are placed strips of cover-glass, so that a shallow cell, 0·25 mm. in depth, is formed. The powder under examination is diluted with a known quantity of sugar, say in the proportion of 1 to 100 or 1 to 1,000, and a small quantity of the mixture is weighed out into the cell. For instance, if 0·05 grm. of the mixture (1 to 100) be taken, the cell will contain 0·0005 grm. of the original powder. A drop or so of water is then added to the cell, and, when the sugar has dissolved, a cover-glass is placed over the whole, and the slide is examined under the microscope, the foreign particles being counted. The apparatus is particularly suitable for estimating the amount of clove-stalks in powdered cloves, sandal-wood in saffron powder, starches in powders, etc. The author has also determined the weight of various starch grains by means of the apparatus, the weight of a single grain, after the starch had been dried at 100° C., being: *Oryza sativa*, 0·0000000000163 grm.; *Zea Mais*, 0·000000000729 grm.; *Maranta arundinacea*, 0·0000000063 grm.; *Triticum sativum*, 0·0000000000605 grm.; *Canna edulis*, 0·0000000502 grm.; *Solanum tuberosum*, 0·00000000644 grm. The specific gravities of the dry starches were found to be: *Canna edulis*, 1·5255; *Solanum tuberosum*, 1·5247; *Maranta arundinacea*, 1·5215; *Oryza sativa*, 1·5134; *Zea Mais*, 1·4809; *Triticum sativum*, 1·4696. W. P. S.

REPORT.

Report of the Government Chemist upon the Work of the Government Laboratory for the Year ending March 31, 1912, with Appendices. (*Issued as a Parliamentary Paper*, pp. 1-27.)—The Report commences with a short recapitulation of the principal steps in the history of the Laboratory and its work, from the origin of the Laboratory in 1843 to the year 1911, when the Government Laboratory was separated from the Department of Customs and Excise, and constituted a new Department under the official title of the " Department of the Government Chemist." Changes in the method of staffing the Laboratory have also been made, and, whilst Revenue Officers still attend to that part of the work which pertains to the Revenue, chemists recruited from " the open market " are employed for non-Revenue work. The duties performed by the staff include analyses of samples taken by Revenue officers, of stores supplied to Government Departments, of dairy produce imported into this country, of samples referred by magistrates under the Food and Drugs Act, the Fertilisers and Feeding-Stuffs Acts, etc.

The total number of analyses and examinations made in the two branches of the Laboratory during the year was 195,170, compared with 186,044 for the preceding year. Including samples examined in provincial stations, the total number was 345,181.

For the purpose of checking dilution and adulteration 7,464 samples of beer were taken from retailers, and of this number 452 were found to have been diluted. None of the samples contained saccharine. Of 444 samples of herb beers and temperance beverages examined, 300 contained less than 2 per cent. of proof spirit; 107 contained less than 3 per cent.; 30 between 3 and 5 per cent.; 6 between 5 and 8 per cent.; and 1 sample 10·6 per cent. One thousand and forty-six samples of beer and brewing materials were examined for the presence of arsenic, but only 18 of these contained more than one-hundredth of a grain of arsenious oxide per gallon (or pound, in the case of solids). Of 122 samples of malt 5 exceeded the limit, the highest proportion found being one-fortieth of a grain per pound; 8 samples of wort and beer contained excessive quantities of arsenic—the highest quantity being one-twentieth of a grain per gallon. The highest quantity of arsenic found in 377 samples of other brewing materials was one-fiftieth of a grain per pound. In addition to the samples connected with brewing, 292 samples of mineral acids, chemicals, etc., were tested for arsenic. Attention is drawn to the fact that 19 samples sold as cider were found to be artificially prepared liquids, and to be free from apple-juice. A considerable proportion of the 56 samples of liqueur chocolates analysed was found to contain from 6 to 12 per cent. of proof spirit, and in two cases the quantity reached 25·0 and 28·8 per cent. respectively.

In connection with the Board of Agriculture and Fisheries, and the Department of Agriculture and Technical Instruction for Ireland, 3,228 samples were examined, including 70 samples of milk, 63 of condensed milk, 71 of cream, and 1,309 of butter. Only 11 of the samples of imported butter contained excessive quantities of water; 396 contained boric preservative, and 180 added colouring matter. The samples of imported milk, cream, and butter are always tested for the presence of preservatives

The whole milk imported in churns was usually free from preservatives, but 3 samples contained boric acid and 1 hydrogen peroxide. Boric acid is generally present in imported cream, and its use in past years has been supplemented by the addition of salicylic acid and hydrogen peroxide. During the present year no sample was found to contain salicylic acid, and in only a few cases had hydrogen peroxide been used. The presence of benzoic acid and fluorides was not detected in any of the butters—boric acid being the only preservative present. All the samples of cream and butter from Norway, Sweden, Russia, and Denmark, were free from preservatives. None of the samples of margarine examined contained more butter-fat than is legally permissible, and an excessive quantity of water was found in one case only.

One hundred and forty samples of sheep-dips were received for examination: 20 were deficient in active ingredients, and in 63 other cases the formula required modification.

Linseed sometimes contains small quantities of glucoside, which is capable, under certain conditions, of producing hydrocyanic acid, although it is stated that the hot-press process of preparing linseed cakes destroys the enzyme. Results of an investigation showed that, when allowance is made for the oil removed during the pressing, the cake yields the same amount of hydrocyanic acid as the original seed.

Samples of oysters obtained from the West of England were examined in consequence of a suspicion that copper-poisoning had resulted from eating them. Many of the oysters had a distinct green appearance, and all contained copper and zinc, the largest amount of copper found being 1·22 grains of metallic copper per dozen oysters, and of zinc 2·31 grains. The oysters containing most copper were so distinctly green in colour that no person would have been likely to eat them. The growth of the oysters did not appear to have been affected by the presence of the two metals.

Ninety-three samples referred by magistrates under the Food and Drugs Acts were examined during the year. In 14 cases, including 9 samples of milk, the reports of the public analyst could not be confirmed. Certificates could not be issued with regard to 3 other samples of milk, owing to the high state of decomposition in the case of 2 of the samples, and because the bottle containing the other sample was burst in transit. The following are the particulars of some of the more important cases: *Butter.*—In one case where the charge was excess water, less than the legal amount was found. In 2 out of 3 samples alleged to contain foreign fat, the results obtained confirmed those of the public analyst; in the third case the butter gave results of an abnormal character, but having regard to the fact that similar results were obtained from the analysis of genuine butter from the same locality, it was impossible to say that the fat was not wholly butter-fat. One sample of butter, alleged to contain cocoanut oil and an excess of water, was found to contain excess of water, but no foreign fat. *Milk.*—Except in the case of 9 samples, the results obtained were in agreement wholly or partially with those of the public analyst; the charge in three of these cases was added water and in the other six abstraction of fat. *Malt Vinegar.*—One sample contained a large proportion of vinegar not derived from malt or grain, but in the case of the other sample received the results were not inconsistent with those given by genuine malt vinegar.

Whisky.—In 1 of the 2 samples received the alcoholic strength was found to be 21 degrees under proof, and was not therefore below the legal strength. *Margarine.*—The one sample received contained more than 10 per cent. of butter-fat. *Rice.*—The report of the public analyst, that the sample had been "faced," was confirmed. *Cream of Tartar.*—A sample condemned by the public analyst was found to comply substantially with the requirements of the British Pharmacopœia. The other samples referred consisted of rum, cream, and coffee, and in all these cases the results of the public analyst were confirmed.

The total number of samples submitted by the Board of Agriculture under the Fertilisers and Feeding Stuffs Acts was 47, consisting of 15 fertilisers and 32 feeding stuffs. The particulars relating to some of these samples were as follows: *Plant-Food.*—An article, sold in penny packets, and guaranteed to contain 22 per cent. of phosphates and 0·85 per cent. of potash, consisted mainly of fine earth and ashes with only 1·84 per cent. of phosphate and 0·33 per cent. of potash. *Tomato Manure.*—Contained only 4·7 per cent. of potash available for plant-food, although stated to contain "4·6 per cent. of free potash and 12·4 per cent. of combined potash." *Fish Manure.*—The sample examined consisted of fine ashes mixed with a few fish-bones, and contained only 0·59 per cent. of nitrogen and 2·4 per cent. of phosphates. The other fertilisers examined included superphosphates, wool-waste, bone-meal, and guanos, deficient in phosphates, nitrogen, or potash. *Cottonseed Meal.*—A sample described as "Double Decorticated Cottonseed Meal" consisted of the ground meal of undecorticated cottonseed cake, containing the whole of the cortex proper to the seed. *Milling Products.*—A sample of barley meal was found to contain 5 per cent. of sand. As much as 50 per cent. of ground-oat husks was present in a sample of "sharps." Other samples contained various quantities of tapioca meal and rice husks.

Details regarding the numbers of various articles examined are given in the Appendices to the Report. W. P. S.

STUDY COMMITTEE OF THE INTERNATIONAL DAIRY FEDERATION.*

Lange Voorhout 88, the Hague,
October, 1912.

Dear Sir,—At the final general meeting of the Fifth International Dairy Congress, held at Stockholm, July 1, 1911, the following resolutions were carried:

"The next International Dairy Congress will fix the percentage of butter-fat in the dry matter which may be considered as normal figures for all sorts of cheeses which are found in the markets of the world."

"To secure the exactness of the result of the discussions, the Study Committee of the International Dairy Federation shall do the preparative work necessary specially to arrive at an international agreement on the methods for the analysis of cheese."

At the meeting of the Study Committee, held at Brussels on March 13 and 14, 1912, I was invited to prepare reports for this purpose, and I now beg to submit for your consideration proposals for the unification of the methods for the analysis of cheese.

---

* Readers of the journal interested in this matter are invited to communicate with Dr. Swaving.

These proposals are the consequence of discussions of a special committee composed of delegates of cheese control-stations, of the Government dairy-station at Leiden, of municipal laboratories, of the Government agricultural experimental stations, and of myself as chairman. This committee has agreed to the methods for the analyses of cheese to be followed in the Netherlands.

I should feel obliged if you would kindly give these proposals your careful consideration, and let me know what modifications, if any, you wish to suggest.—

Yours faithfully,

SWAVING,

Secretary of the Study Committee of the International Dairy Federation.

PROPOSALS FOR THE UNIFICATION OF ANALYTICAL METHODS FOR CHEESE.

1. *Determination of Water in Cheese.*—Five grms. of cheese are weighed in a wide dish containing clean sand, and mixed and well ground up by means of a glass bar with flattened end, which has been weighed with the dish. The sample is then dried at the ordinary temperature—if possible *in vacuo*—for at least sixteen hours, and immediately afterwards dried for about one hour in an oven at 105° C., and weighed. Drying is continued, and weighing repeated with short intervals (half an hour).

2. *Determination of Fat in Cheese*—(*a*) *By Gerber's Method, with Modified Cheese Butyrometer* (*Van Gulik*) *for Three Grms. of Cheese.*—Three grms. of cheese are introduced with the aid of a funnel into the widened part of the cheese butyrometer, which has been previously half filled with sulphuric acid (sp. gr. 1·50). The weighing of very soft cheese is made in a small beaker. The butyrometer is then warmed in a water-bath at 65° to 70° C., and the casein dissolved, while shaking and swinging the butyrometer at intervals. When no more small particles of cheese are visible, the butyrometer is left in the water-bath for a short time, while swinging at intervals, and, after 1 c.c. amyl-alcohol has been added, it is filled with sulphuric acid up nearly to the division mark 35. The contents are mixed with care, not swinging the butyrometer oftener than necessary for a complete mixing, then left for about five minutes in

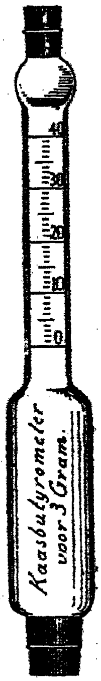

FIG. 1 (½ size).—GERBER-VAN GULIK BUTYROMETER.

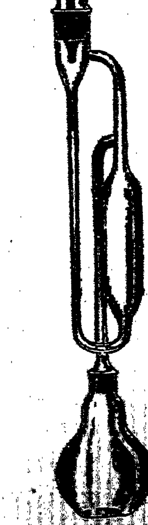

FIG. 2 (½ size).—SMETHAM FLASK.

the water-bath, and centrifuged for four minutes at a speed of 1,000 revolutions per minute. The diameter of the disc-plate of the Gerber centrifugal machine must be at least 47 cms. (the machine should be warmed when the temperature of the room is low). Finally, the butyrometer is placed for five minutes in a water-bath at 65° C., and the height of the fatty layer read at 65° C.

(*b*) *By the Hydrochloric Acid Method.**—One to 5 grms. of rasped cheese are gently boiled with 20 c.c. hydrochloric acid (sp. gr. 1·13) in a small flask, and shaking until all small particles have disappeared; then either Smetham's perforation method or Schmidt-Bondzynski's modified method is applied.

Smetham's Perforation Method.—The hydrochloric acid solution, when cool, is carefully introduced into the flask of Smetham's extractor, as modified for the estimation of fat in milk (Marius, Utrecht), and the flask filled with ether until it flows over. After two hours the ether is evaporated, and the fat dried for half an hour in the oven at 102° C. Drying is continued to constant weight. For control, a second flask can be connected to the extractor and treated as above.

Modified Schmidt-Bondzynski's Method.—The hydrochloric acid solution is carefully introduced into a mixing cylinder of 100 c.c. capacity, and, when cool, ether is added till the total volume is about 50 c.c. The cylinder is closed with a damped cork, then well shaken, and left for at least two hours to separate. The ether-fat solution is then drawn off as completely as possible (to at least 1 c.c.) in a weighed flask. A fresh quantity of 50 c.c. ether is introduced into the cylinder, and the contents swung several times. After one hour's rest the ether is again drawn off as completely as possible and added to the first ether-fat solution in the weighed flask. The ether is then distilled off, and the fat dried for half an hour in the oven at 102° C. Drying is continued to constant weight.

REVIEWS.

THEORIE UND PRAXIS DER MASSANALYSE. Von ALEXANDER CLASSEN. Unter Mitwirkung von H. Cloeren. Leipzig. 1912. Akademische Verlagsgesellschaft, m.b.H. Pp. i-ix + 1-772. Price 32 marks.

The author of this work, it will be remembered, edited and revised two editions of Mohr's classical treatise "Titrimethoden." Recognising, however, that modern developments in chemical science have to a great extent modified our conceptions of the way in which chemical reactions occur, he decided that, instead of revising the seventh edition of Mohr's treatise, he would write an entirely new book, remodelled in accordance with modern theories. Professor Classen's reputation is at once a guarantee that the task which he set himself has been executed in a satisfactory manner; and of the work under review it may be said that, as a student's handbook, for which it is primarily intended, it is in most respects excellent, whilst it will also be found of use to the practising chemist.

---

* In applying this method it is advisable to use within these limits a smaller quantity of fat cheese and a larger one of skimmed cheese.

Volumetric methods are, with very few exceptions, based on scientific principles so that they only became possible after stoichiometrical relations had been established. The pioneer in the elaboration of these methods was undoubtedly Gay Lussac. He it was who first devised methods of alkalimetry and acidimetry, as well as those of estimating chlorine, whilst the degree of accuracy of which these methods are capable first became evident after the classical work of Stas on the determination of the atomic weight of silver. A treatise such as the one under review should therefore be something more than an empirical guide book, and it will be conceded that Professor Classen has dealt liberally with the theoretical side of the subject. Indeed, in some cases the writer ventures to think that the text might have been shortened considerably with advantage to the reader. This applies particularly in the sections in which the methods are described, where many well-known and even self-obvious equations are given, including ordinary double decompositions. The sections dealing with the history and principles of volumetric methods and on the theory of indicators, although very lengthy, deserve special mention for their clearness and lucidity. Under indicators, however, something should, in the writer's opinion, have been mentioned of the tautomerism which some of these substances exhibit (*cf.* J. T. Hewitt, ANALYST, 1908, **33**, 85). The author is, however, throughout immersed in the ionic hypothesis, to the exclusion of any other.

The inorganic methods described form a useful collection, and many of them have been devised or checked in the author's laboratory at the Technical High School, Aachen, but it is surprising to find so few references to British work. There is an important point to which attention may be called—namely, that in no instance is the limit of accuracy of a method stated; nor are any of the methods of estimating one and the same substance compared as to their relative accuracy.

As regards empirical methods, the book is decidedly disappointing. Thus, twelve pages are devoted to a description of various modifications of the soap test for estimating the hardness of water, and about two and a half pages to alkalimetric and acidimetric methods for this purpose. After all this the author very properly remarks that the only reliable method of estimating hardness in a water is by a gravimetric analysis of the mineral matter. The estimation of reducing sugars by Fehling's solution is carried no further than the work of Soxhlet in 1880; and, indeed, the author seems unaware that anything has been done in volumetric analysis since that time, for he gives a reference to Wein's gravimetric tables, making no mention of the fact, however, that one of them—that referring to maltose—is inaccurate.

ARTHUR R. LING.

BLEACHING AND DYEING OF VEGETABLE FIBROUS MATERIALS. By JULIUS HÜBNER. London: Constable and Co., Ltd. 1912. Pp. xiii+434, including Index. Parts 18, with 96 illustrations. Price 14s. net.

It is necessary on occasion for the analyst to have some knowledge of the practical methods of procedure involved in certain industries. The work in question is one which will supply the necessary information in the case of cotton, so far as this can be imparted in such a manner. It opens with a section dealing with the vegetable fibres, including those manufactured artificially from cellulose. The following section deals with the analysis of water and its purification, and the analyst need not expect to gain special information from this or from the following one dealing with chemicals and mordants. The chapter on bleaching is, as might be expected, quite up to date, and gives in outline a satisfactory account of modern practice.

The important operation of mercerising is next considered, and it is pointed out that Persoz, in 1846, preceded Mercer in a description of the contraction, or shrinkage, of a cotton fabric under the action of caustic soda solution. It was not until 1895 that Thomas and Provost obtained a permanent lustre on cotton by mercerising under tension, although Lowe in this country had previously patented a similar process without apparently realising its importance.

A short chapter deals with the production of mineral colours on vegetable fibres, including, of course, the well-known khaki. The natural (vegetable) colouring matters are then considered, and also the artificial or synthetic colouring matters which have played such a leading part in modern dyeing. This section includes many practical details in actual manipulation, and a full account of those dyes which are applied to mordanting fibres and the so-called "oxidation" colours.

An account of the actual machinery used in dyeing operations then follows, and, finally, the testing of dyes and fibres is dealt with. This section, which is probably the one to which the general analyst will turn, occupies only thirteen pages, and therefore cannot deal in any detail with the subject under review, the actual tables concerned with the identification of dyestuffs only taking up about four pages in all. The question of the identification of fibres is also compressed into about one page. The section dealing with actual analysis can therefore only present in outline the methods which might be adopted in practice.

The work is primarily intended, as Professor Meldola points out in an interesting preface, as a practical textbook; and, so far as it is possible to compress detail into the space available, serves its purpose.

The illustrations are above the average, and indicate in a satisfactory manner the nature of the plant used.

W. P. Dreaper.

DECEMBER, 1912. Vol. XXXVII., No. 441.

THE ANALYST.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS.

THE DETECTION AND ESTIMATION OF ARACHIS OIL.

By NORMAN EVERS, B.Sc., A.I.C.

(*Read at the Meeting, November* 6, 1912.)

DISCUSSION.

THE PRESIDENT said that this process would be found to be a great advance upon Renard's process in point of rapidity. In order, however, to ensure accuracy, it was essential that all the modifications mentioned by Mr. Evers should be adhered to.

Mr. R. Ross asked if it would be of any use to ascertain the refractive index of the residues obtained after cooling. He (Mr. Ross) had found this to be useful to a certain extent with butter containing coconut oil, though in that case its utility was limited owing to the variations in composition to which butter was liable. In the case of olive oil, which appeared to be more constant in composition, the refractive index might be more helpful.

Mr. P. A. E. RICHARDS asked how this process compared with Renard's, more particularly with regard to the time required for a determination.

Mr. L. M. NASH asked for a definition of "saponified" olive oil.

Mr. RICHMOND asked whether the factors for calculating the quantity of arachis oil were arrived at from the samples of arachis oil referred to in the paper or from a more extended series of observations. It seemed to him that in order to obtain accurate results the melting-points would have to be very carefully determined, and fully corrected, because, while the variation of the factor from 17 to 22 was appreciable, the difference of 2 degrees between the corresponding melting-points was only just outside the limits of experimental error.

Mr. W. B. SAVILLE said that he had used Bellier's process, and had found it to work very well, though when the proportion of arachis oil was considerable the results were liable to be low. He had usually found the melting-point of the fatty acids to be 73° C. He had tested almond, apricot, cotton-seed, maize, peach-kernel, castor, and sesame oils by Bellier's qualitative method, and in each case found a perfectly clear solution on standing for one to two hours at 17° to 19° C. Rape-seed oil invariably gave a turbidity due no doubt to the small percentage of arachidic acid present in the oil. Arachis oil could be determined with reasonable accuracy by the author's process when in admixture with these oils.

Mr. EVERS, in reply, said that he had not determined the refractive index of the crystals, but should think it quite probable that it would afford valuable information. The time required for a determination of arachis oil by this process was merely a few hours, and little attention was required, whereas the Renard process took considerably longer. "Saponified" olive oil consisted of the oil extracted from the marc after the larger proportion of the oil had been expressed. It contained a good deal of free fatty acid, and in order to remove this it was washed with alkali, which operation gave rise to the term "saponified." The factors were arrived at from the results yielded by the samples of arachis oil referred to in the paper. The melting-points had not been corrected for barometric pressure or the height of the column of mercury above the liquid, and this possibly might account for the difference between his figures and Mr. Saville's. In Bellier's process he had never found the melting-point (uncorrected) to be higher than 71° C. In his experience the melting-point could be determined accurately within half a degree. There was a good deal of difference in the proportion of fatty acids obtained when the melting-point was 71° C. and when it was 72° C., and this accounted for the difference in the factor.

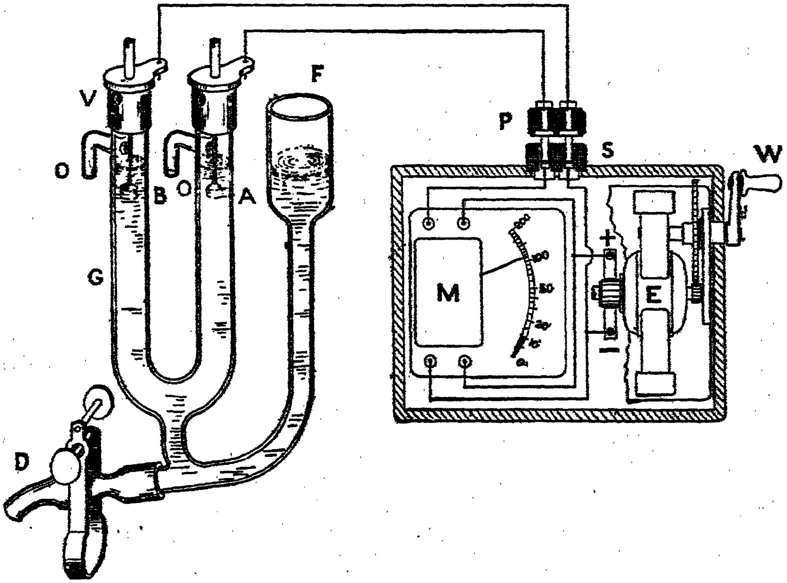
AN APPARATUS FOR TESTING WATER BY MEASUREMENT OF ITS ELECTRICAL CONDUCTIVITY.

BY L. ARCHBUTT, F.I.C.

(*Read at the Meeting, November* 6, 1912.)

AN apparatus known as the Digby and Biggs "Dionic" Water-Tester, designed primarily for detecting leakage in surface condensers, was recently brought to my notice; and having proved of some interest, I thought it might also interest some members of the Society. The usefulness of the apparatus depends upon the well-known fact that the conductivity of pure water is extremely small, and that the presence of any salt, acid, or base, in solution at once increases the conductivity. In very dilute solutions Kohlrausch found that the conductivity due to a given substance increases in proportion to the amount dissolved. For stronger solutions, however, this is not correct. Different salts also have different conductivities. The value of the apparatus depends upon its extreme sensitiveness in detecting mere traces of dissolved electrolytes, and in the rapidity with which a test can be made.

Referring to the diagram, the water to be tested is poured into the funnel *F*, and rises into the two arms of the U tube to the level fixed by the overflows *OO*. The electrodes *A* and *B* are short tubes of platinum-foil, and the current is supplied by the hand-driven dynamo *E*, fitted with a constant-speed friction clutch, which maintains a constant E.M.F. of 100 volts, within ¼ volt, when the handle *W* is turned at a rate faster than that at which the clutch is designed to slip. The current passing through the water is measured by the direct-reading conductivity meter *M*. Temperature is measured by a thermometer immersed in the water in the funnel. To make a test, all one has to do is to empty the U tube and funnel by opening the clip *D*, flush the apparatus with the water to be tested, then close *D* and continue pouring water into the funnel until it overflows at *OO*. Then turn the handle of the dynamo until the clutch is slipping, and at once read off the maximum deflection indicated by the needle.



The current generated is very small, not exceeding 0·004 ampère under normal conditions. The back E.M.F. due to polarisation of the electrodes is allowed for in the calibration of the meter, the scale units of which, ranging from zero to 2,000, represent approximately in value the reciprocals of megohms. The standard temperature for testing is 20° C., and a scale of corrections supplied with the instrument saves the trouble of adjusting the temperature of the water so long as it is between 10° and 40° C. It is therefore necessary only to take the temperature of the water and correct the meter readings by the corresponding factor.

The usefulness of the apparatus in a laboratory or works, and also its limits, will be apparent by the results of the following tests made in my laboratory:—

Distilled Water.	Conductivity (corrected to 20° C.).
Unboiled distilled water	2·7
Another sample	6·0
Another sample, after boiling to expel dissolved gases and cooling in air	1·5
Several samples thoroughly boiled in a silvered flask and cooled *in vacuo*	1·0 to 1·5
Unboiled water after passing CO_2-free air through for about one hour	1·0
Saturated with CO_2, and excess of gas shaken out at 20° C.	44·0

The above figures show that the ordinary distilled water of the laboratory, if boiled to expel CO_2, has a conductivity in this apparatus of 1·0 to 1·5. Derby Town water, with a soap hardness of 18·4°, total solids about 25 grains per gallon, chlorine about 1·15 grains, and SO_3 about 4 to 5 grains per gallon, had a conductivity of 552. 3 c.c. of this hard water diluted to 500 c.c. with boiled distilled water, and containing about 0·15 grain of total solids per gallon, had a conductivity of 4·2. This water gave a faint opalescence with silver nitrate in the cold, which disappeared on heating, and no perceptible precipitate with barium chloride, from which it is evident that a slight leakage of the hard water into the distilled water through a crack in the tin condensing worm, as sometimes occurs, would be detected by the conductivity meter rather more readily than by the silver nitrate test, and the test would be quantitative.

In the next table I give the conductivity of a few public water supplies.

	Conductivity (20° C.).
Glasgow, from Loch Katrine	34
Manchester, from Thirlmere	48
Blackburn	65
Birmingham, from Rhayader	80
Dewsbury	109
East Surrey water, from wells in the chalk, softened by Clark's process	135
West Middlesex water (Metropolitan Water Board)	390
Derby: mixture of spring water and Derwent Valley water (hardness, 11·9 degrees)	380
Derby: spring water only (hardness, 18·4 degrees)	552

The above, except the Derby samples, are from a pamphlet published by Messrs. Evershed and Vignoles, Ltd., the makers of the apparatus.

As there is a tendency for an apparatus of this kind to be offered as a substitute for chemical analysis, I have prepared a few solutions and tested their conductivity.

The saline solutions (except the $MgSO_4$) were made with the salts usually met with in concentrated boiler waters. Being made of equal strength, they show how the conductivity varies with the different salts, also that with solutions of the strengths stated the conductivity is not proportional to the amount dissolved (compare Na_2SO_4).

The acids and bases show enormous variations; the first three, also the caustic soda solution, were made up so as to have about the same conductivity as a solution of common salt containing 50 grains per gallon; the acetic acid and ammonia were random mixtures. I have stated all the strengths in "normal" terms as well as in grains per gallon for convenience of comparison. The figures show how greatly the conductivity of the water tested may be influenced by a slight acidity or alkalinity.

Some Saline Solutions.	Grains of Anhydrous Salt per Gallon.	Conductivity (20° C.).
$NaCl$	50·0	1,287
Na_2CO_3	50·0	1,236
Na_2SO_4	50·0	1,020
Na_2SO_4	100·0	1,751
$NaNO_3$	50·0	900
$MgSO_4$	50·0	954
Acids.		
HCl } 1·6 c.c. normal acid diluted to 500 c.c.	8·16	1,260
H_2SO_4 } 1·6 c.c. normal acid diluted to 500 c.c.	10·98	1,127
HNO_3 } 1·6 c.c. normal acid diluted to 500 c.c.	14·37	1,255
CH_3COOH, 26·5 c.c. N. acid diluted to 500 c.c.	222·60	400
Bases.		
$NaOH$, 3·2 c.c. N. soda diluted to 500 c.c.	17·9	1,214
NH_3, 35·45 c.c. N. ammonia diluted to 500 c.c.	84·7 (174·5 NH_4OH)	325

Lastly, non-electrolytes, such as cane-sugar, might be present in water in large quantity, and would entirely escape detection. Within limits, however, and applied to specific purposes, the apparatus is extremely useful, as is shown by the following tests:

CONCENTRATED WATER FROM STIRLING BOILER.

Total Solids, 130° C.	Non-Volatile Solids.	Chlorine as Chloride.	Conductivity (20° C.).
Grains per Gallon.	Grains per Gallon.	Grains per Gallon.	
19·8	19·0	3·6	445
51·9	47·9	14·3	1,113
53·7	52·1	16·7	1,166
60·1	54·2	17·5	1,261
69·1	64·0	11·7	1,272
73·3	67·2	16·0	1,431
75·6	72·2	18·8	1,579
112·4	108·8	24·2	[illegible]

The above samples were taken on various dates, and do not represent any particular series. They are arranged in order of conductivity. The water used in the boiler was partly condensed water and partly a hard water used as "make-up." The conductivity, though not strictly proportional to the non-volatile solids, is fairly proportional, whilst the chlorine is not. Suppose it were desired, for example, to keep the concentration of the water in this particular boiler below 100 grains per gallon in order to prevent "priming," it is evident from the above figures that the conductivity test is a better, simpler, and more rapid indicator of the amount of saline matter in solution than is the chlorine, which is about the simplest analytical test that could be made.

It is obvious that this apparatus may be extremely useful for detecting leakage of surface condensers. Condensed water from the hot wells of condensing engines will have a quite low conductivity, if there is no leakage, say 3 to 5. Cooling water will generally be hard, and will have a much higher conductivity. This applies especially to sea-water, the conductivity of which is about 50,000 on the scale of this instrument. Having ascertained, therefore, the conductivity of the cooling water used, and of mixtures of this with distilled water, a curve can be constructed from which the percentage of leakage water corresponding to any observed conductivity can be read off.

DISCUSSION.

Mr. F. EVERSHED asked whether the President had found this apparatus to be useful for controlling the addition of chemicals in softening water—one of the purposes for which the makers claimed that it might be used with advantage in place of the soap test. He (Mr. Evershed) should think that in simple cases, where the addition of lime only was required, the apparatus could be so used; but in more complicated cases, when soda, with or without lime, was used, the conductivity would not necessarily be diminished in the final result, though even here such a method of testing might be found useful, if applied with discrimination. In sugar-analysis a conductivity test would often measure inorganic impurities with sufficient accuracy and far more quickly than an ash determination. This last idea was not new, a paper on the subject having been read by Mr. Hugh Main at the International Congress of Applied Chemistry in 1909, but Mr. Main used the Kohlrausch apparatus, which required a supply of electricity from an outside source, while the apparatus now described had the advantage of being self-contained, the current being produced within the box by merely turning a handle. Various other applications of this instrument would no doubt suggest themselves.

Mr. RAYMOND ROSS said that in Lancashire there were many streams which, in addition to their ordinary main flow, received colliery pumpings, and also varying amounts of peaty water from the surrounding hills. Such water often had to be used for boiler purposes, and the variations in its composition presented a problem in regard to which the apparatus referred to might perhaps be useful.

Mr. G. N. HUNTLY said that the principle on which this apparatus was based had already been applied in practice for some time. There is a well-known oil-removing plant, in which the removal of oil from condensed water is effected by passing a continuous current between iron plates, the oil being carried down by the oxide of iron that was thus formed. It is found, incidentally, that if a fuse is placed in the circuit, any leakage of cooling water into the condenser is infallibly indicated by the blowing out of the fuse. The difference in conductivity was so great that a heavy fuse is readily blown out.

Mr. W. T. Burgess said that the conductivity measurements were, of course, mainly influenced by the mineral constituents, and gave no indication of the organic purity, or otherwise, of the samples tested.

Mr. J. H. B. Jenkins said that the apparatus used by Mr. Main answered very well for the estimation of ash in sugar, the determinations being made very quickly. It was quite easy to experiment in this direction without any special apparatus beyond that which was ordinarily at hand in the laboratory. If the terminals of an induction-coil were connected with a Wheatstone bridge—the galvanometer being replaced by a telephone receiver—and if into the resistance space of the bridge were introduced a platinum dish with a small electrode kept about ⅛ inch away from the bottom of the dish, samples of water could be introduced into the dish one after the other and tested by noting when the sound in the telephone receiver disappeared. In this case, of course, it was the resistance and not the conductivity of the water that was measured.

The President, in reply, said that he could quite understand that there might be circumstances in which this apparatus would be useful in connection with water-softening, but, on the other hand, conditions could easily be imagined in which it would be practically useless. Probably in a case such as that mentioned by Mr. Ross, if the conductivities of the different sources of water were known, it would be possible to determine approximately the extent to which the various kinds of water were present, but here again there would be limitations.

* * * * *

THE EXAMINATION OF CHINESE AND JAPANESE WOOD OIL.

By A. CHASTON CHAPMAN, F.I.C.

(*Read at the Meeting, November* 6, 1912.)

Chinese Wood Oil.

During recent years the trade in Chinese wood oil has assumed considerable proportions, and its chemical examination has consequently become a matter of importance both to buyers and sellers. This fact, coupled with the very interesting nature of the oil itself, has induced a number of chemists to devote themselves to its investigation, and a number of papers dealing with the general chemistry and analytical examination of the oil have been published in English, American, and Continental journals. Notwithstanding this, it cannot be said that chemists are in complete agreement as to the properties which should characterise the genuine oil, and for some time past trade disputes culminating in arbitration cases have been of somewhat frequent occurrence. Having for several years been much interested in the examination of this oil, I have thought that it might not be without interest if I were to place some of my results and conclusions before this Society.

This oil is obtained, as is well known, from the seeds of the *Aleurites cordata*—a tree which grows extensively in China and other parts of the East. Other species of Aleurites—as, for example, *Aleurites Fordii*—also occur, and it is probable that the commercial oil often represents a product obtained from more than one species. I shall revert to this later.

According to a recently-published United States Consular Report, it would appear that Szechuan oil is preferred in Hankow on account of its lighter colour, and that the province of Szechuan accounts for 30 per cent. of the total production, Hunan and Kweichow producing 50 per cent., and Hupei (chiefly in the region of Ichang) 20 per cent. Lewkowitsch ("Chemical Technology and Analysis of Oils, Fats, and Waxes," fourth edition, vol. ii., p. 60) states that, in the preparation of the oil, the seeds are roasted in a flat dish over a naked fire, are then crushed between stones, and the oil expressed from the crushed mass in primitive wooden presses. This account of the preparation of the oil is confirmed by several independent statements made to me by persons who have resided for a considerable time in China, and who are familiar with the method of expression adopted by the natives. This crude method of obtaining the oil, considered in conjunction with the fact that the production is in the hands of a large number of very small producers, and that the oil in question is a powerful drying oil, is of considerable importance, since it affords a partial explanation of the somewhat widely varying analytical results which have been obtained by chemists in the examination of this oil, and which have been recorded in the literature of the subject. The small quantities of oil produced by the various individuals are collected by Chinese middlemen, and sold to merchants in Hankow, who clarify the oil in tanks, and then pack it for shipment. In colour the oil varies very considerably, the dark oils having as a very general rule a more markedly unpleasant taste and smell than the paler ones.

The analytical determinations which are of the greatest importance are the specific gravity, the iodine value, the refractive index, the viscosity, and the manner in which the oil polymerises when heated. I propose to refer in the first place to these estimations, and to deal later in the paper with several supplementary methods of examination.

Specific Gravity.—Since the specific gravity of Chinese wood oil is higher than that of any other fatty oil, with the exception of castor oil and possibly of tallow-seed oil, the determination of that number is clearly of great importance. The numbers recorded in literature vary somewhat considerably, but many of the earlier ones are of less value than they might otherwise have been owing to some apparent confusion between the Chinese and the Japanese oil, and also to the fact that in some cases the nature of the ratio oil : water is not clearly stated. Among later and more reliable numbers may be mentioned those of Lewkowitsch ("Chemical Technology and Analysis of Oils, Fats, and Waxes," fourth edition, vol. ii., p. 63) 0·9412 to 0·9418; Kreikenbaum (*J. Ind. and Eng. Chem.*, 1910, **2**, 205), 0·9401 to

0·9454; and F. Browne (*Chem. News*, 1912, **106**, 15), 0·9402 to 0·9431. Jenkins (ANALYST, 1898, **23**, 113), in a paper communicated to this Society, gives 0·9343 and 0·9385 for two samples; but as he uses the terms "Japanese wood oil," "Chinese wood oil," and "tung oil," as synonymous, the value of these numbers is considerably diminished. Rowland Williams (*J. Soc. Chem. Ind.*, 1898, **17**, 304), in a paper entitled "Japanese Wood Oil," gives numbers ranging from 0·9413 to 0·9432, and it is tolerably clear from these and the other results he gives that these were samples of the Chinese oil. Boughton (*Seventh Int. Cong. App. Chem.*, 1909, Section **1**, 89) records numbers for five samples of China wood oil which he had received directly from the United States Consul at Hankow, and for two further samples which had been pressed for him from the nuts. Six of these gave numbers ranging from 0·9408 to 0·9428 at 15·6° C., but one of the five samples from Hankow had at the same temperature a specific gravity of 0·9346, which is far below any number recorded by other observers for the Chinese oil, and which must tend to throw considerable doubt on the purity of the specimen.

Iodine Value.—Since this number depends so largely on the precise method adopted and upon the conditions under which the test is carried out, and as this information is not given in many of the earlier papers, it would serve no useful purpose to refer in detail to the numbers recorded, but it may be said that numbers varying from 150 to 170 have been given. In some cases, however, it is probable that the Japanese oil had been used. Boughton (*loc. cit.*) has made a special study of the extent to which the iodine value varies with different experimental conditions, and finds that variations in temperature have much less effect on the Hubl than on the Hanŭs method. For several reasons I prefer the Wijs method, and the iodine values recorded in the table given below have been determined in the following manner:—About 0·1 grm. of the oil was taken, dissolved in 20 c.c. of purified carbon tetrachloride, 30 c.c. of the ordinary Wijs solution were added, and the reaction allowed to proceed for three hours in the dark.

Refractive Index.—Since the refractive index of wood oil is considerably higher than that of any other fatty oil, the determination of that value is of the greatest importance from the analytical point of view. Comparatively few numbers are recorded in the literature of the subject, but it may be mentioned that Boughton gives 1·5238 at 15·6° C., which is approximately equal to 1·521 at 20° C., the temperature at which my own observations have been made.

Viscosity (Time of Efflux).—As the viscosity of tung oil is considerably higher than that of any other fatty oil which would be likely to be used as an adulterant, a determination of that number is very useful, although, as will be seen from the results recorded below, there are wide variations even in the case of oils of undoubted genuineness. It must not be overlooked, moreover, that the viscosity of wood oil may be very considerably increased by heating it to a temperature short of that required for its solidification. The viscosities given in the following table have been determined in a standard Redwood viscosimeter at 15·5° C. From a circular recently issued by the New York Produce Exchange, it would appear that C. V. Bacon has made a large number of viscosity determinations, using a Tagliabue instrument, and that he attaches considerable importance to the results.

Heat Polymerisation Test.—One of the most interesting and characteristic properties of wood oil is that of solidifying to a jelly when heated to a sufficiently high temperature, a change which appears to be due to the polymerisation of the glyceride of elæomargaric acid, of which the oil largely consists. Since the hardness of the resulting jelly is considerably diminished by the addition of other fatty oils, it will be seen that a test based upon this property is capable of yielding very important indications. Several attempts have been made to make such a test quantitative. Thus, in a circular issued by the New York Produce Exchange, to which I have referred already, a method devised by C. V. Bacon is tentatively put forward as a method to be adopted in the United States. Since this test has not, so far as I am aware, been published in any scientific journal, it may be well to give the following description of it:

"Into a test-tube of ¾ inch diameter and 4 inches in length there are transferred about 10 c.c. of pure China wood oil; into another test-tube there is transferred a similar volume of pure China wood oil adulterated to the extent of 10 per cent. A sample of the oil to be tested is treated in a like manner, and these are placed in a proper support and immersed in an oil bath which has a temperature of about 288° C., so that when the tubes are in it a temperature of 280° or 285° C. (maximum) can be maintained. The oil bath containing the tubes is maintained at this temperature for exactly nine minutes, the tubes are then withdrawn and the test sample is compared with the pure oil, and the same oil adulterated with 5 and 10 per cent. of foreign oil. After the tubes are withdrawn from the oil bath, each tube should be stabbed from the top to the bottom with a small bright spatula. Pure oil will give a hard, clean cut, and when the knife is withdrawn the incision will look like a straight line, while an oil having as low as 5 per cent. adulteration will invariably be softer, and the incision will have a peculiar feathered effect; an adulteration of 10 per cent. will be soft and pushy, while an adulteration exceeding 12 per cent. in many instances will remain entirely liquid."

In the same circular a further test is described as being one at present used by New York importers and varnish-makers. This is described in the following words:

"For Hankow and Shanghai wood oil, 100 grms. should be heated in an open basin (6 inches in diameter) as soon as possible to a temperature between 540° and 560° F., and if it solidifies in about six to six and a half minutes, cuts dry, and is firm in body, without discoloration and without being sticky, it should be passed as a good delivery. For Canton and Hong-Kong wood oil deliveries, the time should be from four and a half to five and a half minutes in an open basin as above. Should a longer time be taken by presumably pure wood oil, other tests confirming purity shall be positive."

This latter test is, in my opinion, an unsatisfactory one, since it is impossible to control the high temperatures necessary or to keep them at all constant, owing to the shallowness of the containing vessel and the large cooling surface. As soon, moreover, as solidification commences, it is impossible to continue the stirring, with the result that, if the application of heat be continued, the bottom portions of the oil will char, whilst the top portions are still in a soft and sticky condition. The main objection to Bacon's method lies in the fact that it involves comparison with a standard sample, which in turn implies that wood oil is practically constant in its polymerising properties. If all genuine wood oils were known to polymerise in precisely the same manner, there would be some justification for drawing definite conclusions from the indications furnished by such a method, although even then they could not, from their very nature, be more than roughly quantitative. There can be no doubt, however, that such is not the case, and consequently it is not wise to attempt to draw too definite conclusions from the results of the heat test, valuable as its indications are. It may be mentioned in this connection that F. Browne (*loc. cit.*) has described a method of applying the heat test which is, in my opinion, superior to that of Bacon, and less open to criticism, inasmuch as he recognises that genuine oils may vary somewhat in their setting properties; but the temperature to which the oil is heated is so high that the differences between the setting period of a genuine oil and one adulterated with, say, 10 per cent. of some other fatty oil is only two or three minutes. As the result of a considerable amount of experience, I have been led to attach more importance to the hardness of the jelly obtained under standard conditions than to the time required for bringing about polymerisation, and I have devised the following method of carrying out the test, which is capable of yielding definite and concordant results:

About 5 c.c. of the oil to be examined are introduced into each of two test-tubes 6 inches long by $\frac{5}{8}$ inch diameter. These are then immersed in a bath containing melted paraffin wax at a temperature of approximately 100° C. The temperature of the bath is then raised to 250° C., taking about fifteen minutes for the operation. As soon as that temperature is reached the time is noted, and the source of heat adjusted so that the temperature of the bath is maintained constant at 250° C. At the end of half an hour one of the tubes is withdrawn, allowed to cool, and, when cold, is broken, and the jelly examined. The other tube is kept in the bath at 250° C. for a further period of half an hour, at the end of which time it also is withdrawn and allowed to cool; it is then broken, and the hardness of the jelly observed. Chinese wood oil of good quality should give at the end of half an hour a fairly firm jelly, which, at the end of one hour, should become quite hard. It is advisable in all cases to carry out comparison tests alongside of the oil under examination, using for the purpose a sample of oil known to be of good quality.

I have not found it possible to express the hardness of the solidified cylinders by means of numbers, but with a little experience it is very easy to distinguish between a sample of genuine oil and the same oil containing a small percentage of some fatty oil, such as soya bean or sesame. In referring to the polymerisation experiments, I have used the words "very hard," "hard," and "fairly hard," to denote the consistency of the polymerised oil, since such expressions are quite sufficient for the purpose. In addition to the degree of hardness of the solid cylinders of oil, some attention should be given to their physical characters. When cut with a knife or broken across, the cut or fractured surface should be smooth and free from stickiness, and small portions when rubbed in the hand should break down completely into a soft crumbly mass, which should not adhere to the fingers.

In the following table I give the results of the examination of seventeen samples of Chinese wood oil from Hankow:

Sample.	Iodine Value.	Sp. Gr. 15°/15° C.	Saponification Value.	Refractive Index at 20° C.	Time of Efflux at 15·5° C. Seconds.	Polymerisation One Hour at 250° C.
No. 1	169·9	0·9419	196·6	1·5207	2178	Very hard.
,, 2	168·4	0·9406	193·8	1·5181	1636	Hard.
,, 3	166·5	0·9426	194·3	1·5190	1946	Fairly hard.
,, 4	166·4	0·9417	193·0	1·5170	1880	,,
,, 5	168·8	0·9430	195·6	1·5195	2017	Very hard.
,, 6	170·0	0·9440	194·5	1·5180	1849	Hard.
,, 7	168·6	0·9416	193·0	1·5150	—	Fairly hard.
,, 8	171·0	0·9414	192·0	1·5170	—	Hard.
,, 9	169·7	0·9437	194·1	1·5176	1997	,,
,, 10	173·0	0·9420	192·5	1·5165	1722	,,
,, 11	176·2	0·9417	192·0	1·5168	1605	,,
,, 12	172·6	0·9429	196·0	1·5180	1740	,,
,, 13	174·2	0·9427	194·6	1·5182	1690	,,
,, 14	173·7	0·9430	195·0	1·5194	1820	,,
,, 15	172·8	0·9440	194·6	1·5193	2047	,,
,, 16	169·5	0·9420	195·2	1·5160	1804	,,
,, 17	169·6	0·9433	195·2	1·5187	1820	Very hard.
Average ...	170·6	0·9425	194·2	1·5179	1850	

On reference to the above table it will be seen that the specific gravities of the seventeen oils in question range from 0·9406 to 0·9440, and these results, which are confirmed by a very much larger number, may be regarded as approximately the limits of variation for the genuine oil. I am not prepared to say that no pure Chinese wood oil has a specific gravity below the lower limit mentioned above, but a result appreciably below 0·940 is in itself sufficient to cause a sample of oil to be regarded with suspicion.

With regard to the iodine value, it will be seen that the average of the results is 170·6, and it may be taken that a genuine oil should not give numbers differing from that by more than a few units, using the Wijs method, and adopting the conditions I have specified.

The saponification value is not, in the majority of cases, of very much importance; but as it may sometimes be useful, it should always be determined. It is interesting to note that my limits agree fairly closely with those recorded by Rowland Williams (190·7 to 196·1), in the paper to which reference has already been made.

The refractive index rarely falls below 1·517, and an oil giving a result below 1·515 at 20° C. should be regarded with suspicion.

As I have already pointed out, the viscosity of this oil appears to vary within somewhat wide limits, but the numbers I have given will suffice to indicate the kind of result which may be expected in the case of genuine oils.

A paper dealing with the oil derived from the seeds of *Aleurites Fordii* having appeared in the Bulletin of the Imperial Institute (1907, 5, 134), I wrote to Professor

W. R. Dunstan asking him if he could let me have some of this oil. Although he had none of the oil left, he kindly supplied me with a quantity of the nuts of *Aleurites Fordii*, as well as with some of the *Aleurites cordata*, and I desire to take this opportunity of expressing to him my thanks for this courtesy. From each of these I prepared a quantity of oil by petroleum extraction, and found that the former had a specific gravity of 0·9427, and the latter of 0·940. Both these oils, however, were abnormal in respect of their polymerising properties, and for that reason I have not included the other analytical results. Whether this abnormality is due to the method of extraction adopted or to the fact that the nuts were several years old, I am not prepared to say, but it is certain that both oils were markedly inferior in their polymerising power to any genuine sample of the commercial oil that I have examined. This result gives point to the remark I made in criticising Bacon's method, that all samples of genuine wood oil cannot be expected to polymerise in exactly the same manner. There is no doubt that Chinese wood oil, like all other oils, varies within certain limits, both in respect of its chemical and physical properties. As a matter of fact, botanical and geographical origin, climatic variations, differences in treatment during the manufacture of the oil, and the duration and conditions of storage, unquestionably affect its properties, and I am, therefore, very strongly of opinion that it is not advisable in determining its purity to adopt any single method which involves a comparison with an oil possessing certain properties in a maximum degree. Of course, if any purchaser desires to buy wood oil on the results of the polymerising test alone, I see no reason why he should not do so. It must not be overlooked, however, that it may quite well happen that oil which does not reach a certain high polymerisation standard may nevertheless be free from adulteration.

Supplementary Tests.

Drying Test.—About 0·3 to 0·4 grm. of the oil is spread in a thin film on a glass plate and heated in an air-bath for one hour at a temperature of 105° C. The genuine oil dries completely to a crinkly, rubber-like substance, which can be removed without difficulty from the glass surface, and which is free from softness or oiliness. Under these conditions the oil gains from 2 to 3 per cent. in weight.

Iodine Test.—As is well known, if a solution of iodine in chloroform or some other suitable solvent be added to the oil, almost immediate solidification takes place. This is a very useful qualitative test, and McIlhiney (*J. Ind. and Eng. Chem.*, 1912, 4, 497; ANALYST, 1912, 410) has recently been carrying out experiments with the object of ascertaining whether it might not be made quantitative. In the method he has put forward tentatively, an excess of a solution of iodine in glacial acetic acid is added to a weighed quantity of the oil dissolved in the same solvent. The products of the reaction are then extracted with petroleum ether, and the amount of oil which has not undergone solidification, and which is soluble in the petroleum, is weighed. I have made a few experiments with this process, and have obtained results which appear to indicate that when this test is fully worked out it will be found to be a very useful one.

Optical Activity.—A number of samples of oil which I have examined have been practically inactive, although in one case a slight dextro-rotation (+ 1° for a

100 mm. tube and sodium light) was observed. Tallow-seed oil, on the other hand, is known to be appreciably lævo-rotatory.

Bromine Thermal Value.—This number was determined by the method recommended by Hehner and Mitchell—viz., by adding 1 c.c. of bromine to a solution of 1 grm. of the oil in 10 c.c. of chloroform, the mixture being kept in a vacuum jacketed test-tube. The following results were obtained in the case of six samples of the oil:

	Rise in Temperature. °C.	Iodine Value. / Rise in Temperature.
Sample A	24·10	7·00
Sample B	24·76	6·80
Sample C	25·57	6·51
Sample D	24·98	6·92
Sample E	24·72	7·00
Sample F	24·56	7·17

For purposes of comparison I give below the values obtained in the case of three samples of the Japanese oil:

	Rise in Temperature. °C.	Iodine Value. / Rise in Temperature.
Sample A	24·70	6·40
Sample B	23·10	6·45
Sample C (prepared in laboratory)	24·50	6·27

It will be seen that the average value (6·9) obtained by dividing the iodine value by the rise in temperature is substantially the same as that given by Jenkins (*loc. cit.*) in his paper on wood oil. There appears, however, to be no reasonable doubt that the two samples of oil with which Jenkins worked were Japanese oil, and for this it will be seen that my average value is somewhat lower—viz., 6·37. In both cases, however, the value is appreciably higher than with the great majority of fatty oils.

Hexabromide Test.—It has been shown independently by Hehner and Mitchell, and by Jenkins, that when wood oil is treated with bromine under the conditions laid down by the former authors (ANALYST, 1898, **23**, 310), no ether-insoluble bromide is formed. I have confirmed the correctness of these observations, working with the seventeen samples of Chinese wood oil referred to above, and with four samples of the Japanese oil. In no case was there the slightest formation of precipitate, even when the flask containing the mixture was kept in iced water and allowed to stand for twenty-four hours. On the other hand, perilla, candle nut, and tallow-seed oils all yield more or less hexabromide; and as these oils are possessed of high drying properties, and are produced in large quantities in China and the East, the test may be one of considerable importance, and is, in any case, one which should always be applied. In addition to the above-mentioned oils, it would, of course, aid in the detection of linseed oil. Tea-seed oil, as might be expected, does not yield any insoluble bromide. I have been able to detect with considerable ease the presence of 10 per cent. of perilla oil, but it should be mentioned that this oil yields a much larger proportion of the hexabromide than any of the oils mentioned above, with the possible exception of linseed.

The oil should, of course, be tested in all cases for those fatty oils such as cottonseed and sesame, which give characteristic reactions. I may mention, in this connection, that although I have only in one instance detected cotton-seed oil in Chinese wood oil, I have obtained the Baudouin reaction for sesame oil in a considerable number of cases. Genuine China wood oil does not give this reaction, nor does tea-seed oil. In a few instances in which the reaction was very faint it is possible that it may have been due to the fact that the wood oil had been tanked in a vessel which had previously contained sesame; but in the other cases there can be no doubt that sesame oil had been used as an adulterant, particularly as the majority of these samples were met with at a time when wood oil was commanding an unusually high price.

JAPANESE WOOD OIL.

As I have already indicated, many observers have regarded this oil as being practically identical with Chinese wood oil, and have referred to the two indiscriminately under the common designation "tung oil." Whilst resembling Chinese wood oil somewhat closely in its general characters, it appears to be chiefly obtained from the nuts of a different tree—viz., the *Paulownia imperialis* (Japanese *Kirinoki*), although it is not improbable that other seeds may occasionally be employed. The chief producing centres appear to be Wakasa and Echizen. Very little of this oil is exported from Japan, almost the whole being required for home consumption; and its chief interest to the analyst lies in the fact that the two oils are not equally suitable for certain manufacturing purposes, and that accidental or intentional substitution of one for the other may occasionally occur. I give below the results of the examination of three samples, all of which were obtained through the courtesy of the British Consul-General in Kobe:

Sample.	Iodine Value.	Sp. Gr., 15°/15° C.	Saponification Value.	Refractive Index at 20° C.	Time of Efflux at 15·5° C. Seconds.	Polymerisation Two Hours at 250° C.
No. 1 ...	158·0	0·9377	195·2	1·5083	1230	Soft.
No. 2 ...	149·0	0·9400	193·4	1·5052	1620	Soft.
No. 3 ...	151·8	0·9349	196·3	1·5034	—	Very soft.

"No. 1" was produced in Wakasa, whilst "No. 2" came from Idzumo. As to the district from which "No. 3" was derived, I am not quite sure.

In consequence of a letter which I wrote to the British Consul at Kobe, I received through the kindness of Messrs. Jardine, Matheson, and Co., Ltd., a quantity of the nuts of the *Paulownia imperialis*, from which the Japanese oil is made. A quantity of the oil was prepared from these nuts by extraction with light petroleum, and gave on analysis the following results:

Specific gravity (15°/15° C.)	0·9351
Iodine value	153·5
Saponification value	193·5
Refractive index at 20° C.	1·5050
Bromine thermal value (rise in degrees Centigrade) ...	24·5

When heated for two hours at a temperature of 250° C., this sample had not solidified, but was still a viscous oil. On reference to the above numbers it will be seen that with the possible exception of "No. 2" the specific gravities are very appreciably below those of the Chinese oil, which confirms the statements of Lewkowitsch and other observers. The same applies to the iodine values and refractive indices. Even greater than these differences, however, are the differences in polymerising properties, the Japanese oil remaining quite liquid under conditions such as suffice to convert the Chinese oil into a very hard jelly, which crumbles when rubbed between the fingers and becomes a dry powder.

My best thanks are due to my assistant, Mr. Frederick T. Harry, for his valuable help in connection with this work.

DISCUSSION.

Mr. HEHNER remarked that when the fatty acids from this oil were dissolved in acetone and cooled, magnificent crystals resulted. This property was possessed by no other fluid oil. The crystals retained their form as long as the vessel was kept closed: when it was opened they generally collapsed immediately into a jelly-like mass. Another remarkable feature of wood oil was that it was not capable of forming a hexabromide like other oils having a high iodine absorption—for example, linseed oil and fish oils—which might be used as adulterants. Probably the differences in the extent to which polymerisation took place were due to small quantities of botanical impurities which exercised a catalytic action.

Mr. J. H. B. JENKINS said that when he examined these oils fifteen years ago the quantity of them on the market was very small, and consequently his investigation had been much more limited than that of Mr. Chapman. He should like to emphasise what Mr. Hehner had said as to the bromine addition value: the absence of any insoluble brominated compound markedly distinguished these oils from other drying oils. It was the indirect result of Mr. Hehner's and Mr. Mitchell's valuable work on the bromine reactions that had called his attention to the peculiarities of these oils. Following those authors' method, he had compared the iodine values and heat of bromination of a wide range of fatty oils. The usual factor for converting the one into the other was found, except in the case of a strange oil which was put into his hands by a friend as "Japanese Wood Oil." In that case, however, the factor was distinctly abnormal, and led him to think that iodine must have some exceptional action on the oil. He consequently tried the effect of adding a saturated solution of iodine to the oil dissolved in chloroform, and, whilst stirring, he found the whole was converted into a jelly. The other abnormal feature disclosed in his early examination of those oils was the very high refractive index. Both samples he had dealt with (ANALYST, 1898, 23, 113) were supplied as "Japanese Wood Oil"; but at that time, in common with many others, he had looked upon Japanese Wood Oil and Chinese Wood Oil as the same.

Mr. E. R. BOLTON asked what was the lowest iodine value that Mr. Chapman had found in what might be accepted as genuine wood oil. In making some experiments with a sample of Chinese wood oil which he believed to be genuine, but of which the iodine value was very low, he had found that with this oil the time required for complete absorption was very short, about a quarter of an hour's contact with Wijs' solution being sufficient, so that some of the low figures that had been published could hardly be attributed to insufficient time being allowed for absorption.

Mr. R. Ross remarked that the specific refraction $\frac{(\mu-1)}{D}$ of the various oils referred to in the first table worked out at 542 to 550, and of those in the last table at 537 to 538, the figure for the oil expressed by Mr. Chapman himself being 534. He had found the McKinley process of bromine absorption to be very useful, since it showed both the addition products and the substitution products, and very often enabled one to account satisfactorily for certain differences that were observed.

Mr. L. M. Nash said that at the present moment the iodine value by itself was of no assistance in judging wood oil, since linseed oil was about £4 per ton cheaper than wood oil. Mr. Chapman's figures confirmed his own views as to the refractive index, specific gravity and viscosity, all of which should be as high as possible. As to heating tests, he agreed with Mr. Chapman's criticism of the American method of heating to a very high temperature in a shallow dish, but he had found it useful to make a test by heating about 5 ounces of the oil in a dish of standard size at a temperature about 100° F. lower than in the American test, and noting the time that it took to reach the condition in which the oil was used in the factory.

The President asked whether Chinese and Japanese wood oils were ever mixed together. If this were done it would probably render the detection of adulterants more difficult.

Mr. Chapman, in reply, said that the difficulty of detecting adulterants would certainly be increased if the two kinds of oil were mixed, but he did not think this was done to any extent. He quite agreed with Mr. Hehner's remarks as to the value of the hexabromide test, and also with the suggestion as to the influence of small quantities of impurities on polymerisation. The oil extracted with petroleum ether polymerised much less readily than oil prepared by expression in the ordinary way. The Chinese oils, however, did vary appreciably in their polymerising power, so that heat tests based upon comparison with a single standard oil must be quite useless for indicating such small amounts of adulteration as were sometimes reported. The iodine test discovered by Mr. Jenkins was an excellent supplementary test. With regard to Mr. Bolton's question, he should not like to say positively that no genuine sample yielded a lower value than those he had given, but he thought that the figures he had recorded might be regarded as representing the limits which in the present state of knowledge it would be safe to adopt. He had met with lower iodine values, but was not sufficiently certain of the origin of the samples to include them.

THE ESTIMATION OF MANGANESE BY THE BISMUTHATE METHOD.

By H. F. V. LITTLE, A.R.C.S., B.Sc.

(*Read at the Meeting, November* 6, 1912.)

THE bismuthate method for the estimation of manganese was originated by Schneider (*Dingl. poly. J.*, 1888, **269**, 224), and improved by Reddrop and Ramage (*J. Chem. Soc.*, 1895, **67**, 268); later it was modified by Ibbotson and Brearley (*Chem. News*, 1900, **82**, 269; 1901, **84**, 247, 302; 1902, **85**, 59), and by Blair (*J. Amer. Chem. Soc.*, 1904, **26**, 793). The method consists in oxidising the manganese—present as manganous salt—in a cold solution free from chloride, and containing 25 per cent. by volume of nitric acid of sp. gr. 1·42, to the state of permanganate by agitation with an excess of sodium bismuthate. The solution is filtered through asbestos and titrated. Reddrop and Ramage added a slight excess of $\frac{N}{10}$ hydrogen peroxide, and titrated back with $\frac{N}{10}$ permanganate; but since in the presence of any appreciable quantity of ferric salt the use of peroxide is attended by an error proportional to the excess of reagent used, Ibbotson and Brearley employ ferrous sulphate. Blair does the same, and only differs from the others in the strengths of the standard solutions he employs.

According to the writer's experience, there is no advantage gained by using reagents of other than decinormal concentration, and he prefers to carry out the method as recommended by Ibbotson and Brearley, and described in Arnold and Ibbotson's "Steel Works Analysis," diluting the oxidised solution, however, before filtration with an equal volume of 3 per cent. nitric acid. The object of the present note is to record a number of observations on the degree of accuracy of the method, which has been adversely commented upon by Brinton (*J. Ind. and Eng. Chem.*, 1911, **3**, 237, 376). According to this author, if the values of the standard solutions employed are deduced in the usual manner and calculated to manganese, the results are appreciably low, and the only way to obtain correct results is to determine an empirical factor by standardisation against a known amount of manganese.

So far as the estimation of small amounts of manganese is concerned, Brinton's statement has been refuted by Hillebrand and Blum (*J. Ind. and Eng. Chem.*, 1911, **3**, 374), and a number of experiments have convinced the writer that the method gives admirable results when large percentages of manganese are concerned and the theoretical factor is employed. Firstly, evidence is supplied by the results obtained by E. Cahen and the writer (ANALYST, 1911, **36**, 52) in determining the manganese in a number of ferros and pyrolusites by four different methods, for the theoretical factor was employed in working out the bismuthate results. Secondly, the test analyses given in Table I. lead to the same conclusion.

The results given in Tables I. and II. were obtained as follows: An approximately $\frac{N}{10}$ permanganate solution was prepared from twice recrystallised potassium permanganate and distilled water, measured portions were reduced in nitric acid solution by a slight excess of concentrated hydrogen peroxide, and the oxidation of the solution with bismuthate effected as usual. A measured excess of approximately

$\frac{N}{10}$ ferrous sulphate or hydrogen peroxide was added, and the excess titrated with the original permanganate solution, against which the ferrous salt and peroxide were checked. In each experiment marked with an asterisk the oxidised solution was filtered into an empty flask, and the titration subsequently performed. Low results are thus obtained. In the other experiments the oxidised solution was filtered directly into the ferrous salt or peroxide. The results are excellent.

TABLE I.

Manganese used in each experiment = 25 c.c. $KMnO_4$ solution.
25 c.c. $FeSO_4$ solution = 30·78 c.c. $KMnO_4$ solution.

$FeSO_4$. c.c. used.	$KMnO_4$. c.c. used.	Manganese found (in c.c. Original Solution).	Error.
25	5·83	24·95	−0·05
25	5·83	24·95	−0·05
25	5·77	25·01	+0·01
*25	5·88	24·90	−0·10
*25	5·92	24·86	−0·14
35	18·06	25·03	+0·03

TABLE II.

Manganese used in each experiment = 25 c.c. $KMnO_4$ solution.
25 c.c. H_2O_2 solution = 27·97 c.c. $KMnO_4$ solution.

H_2O_2. c.c. used.	$KMnO_4$. c.c. used.	Manganese found (in c.c. Original Solution).	Error.
25	2·95	25·02	+0·02
25	3·00	24·97	−0·03
25	3·00	24·97	−0·03
35	14·17	24·99	−0·01
35	14·18	24·98	−0·02
*25	3·08	24·89	−0·11
*25	3·10	24·87	−0·13

TABLE III.

$KMnO_4$ used in titrations = 0·10174Mn.
1 c.c. = 0·001119 grm. Mn.

Excess of $FeSO_4$ over $KMnO_4$.		manganese.		Error.
		Found.	Taken.	
		Iron absent.		
10·05 c.c. $KMnO_4$	...	0·01125	0·01128	−0·03 mgrm.
10·00 " "	...	0·01119	0·01128	−0·09 "
10·05 " "	...	0·01125	0·01128	−0·03 "
		Iron present.		
10·33 c.c. $KMnO_4$	...	0·01125	0·01128	−0·03 mgrm.
10·30 " "	...	0·01122	0·01128	−0·06 "
3·25 " "	...	0·00445	0·00450	−0·05 "
3·27 " "	...	0·00447	0·00450	−0·03 "

In the experiments on smaller amounts of manganese, recorded in Table III., the use of hydrogen peroxide was discontinued. Known quantities of manganese were obtained by reducing a weighed amount of pure potassium permanganate, diluting to a known volume, and taking measured amounts of this solution. The approximately $\frac{N}{10}$ permanganate used in the titrations was standardised against pure sodium oxalate, and the ferrous sulphate against the permanganate. In those experiments indicated as having been performed with iron present, sufficient ferric nitrate was added to contain 1 grm. of iron, and in each case under "manganese found" a correction has been introduced (0·00031) for the manganese present in the ferric nitrate and determined by a blank experiment.

The results are a trifle low—on an average 0·00005 grm.—which corresponds to only 1 drop of $\frac{N}{10}$ permanganate.* With small quantities of manganese, it is a matter of indifference whether the ferrous sulphate is added after filtration or the solution filtered into an empty flask.

The error in these latter experiments only represents 0·005 per cent. Mn, taking 1 grm. of alloy, and duplicate experiments in ordinary working do not agree any closer than this. For example, three estimations carried out at the same time on the same manganese steel gave the writer 0·764, 0·756, 0·757 per cent. Mn respectively, and other alloys gave 0·259, 0·260, 0·271 per cent. Mn, 0·245, 0·236, 0·243 per cent. Mn, and 0·210, 0·203, 0·206 per cent. Mn.

It should be mentioned that the writer has on several occasions encountered the curious experience which led Ramage (*Chem. News*, 1901, **84**, 269) to reject the use of ferrous sulphate, and is at a loss to account for it. Neither Ibbotson and Brearley nor Blair refer to this matter.

In the opinion of the writer, the bismuthate method is the neatest and most accurate of the volumetric methods that have been proposed for the estimation of manganese.

ROYAL COLLEGE OF SCIENCE,
SOUTH KENSINGTON, S.W.

The President writes as follows: The bismuthate method of estimating manganese has been in use in my laboratory for seventeen years, chiefly in connection with the analysis of steel and iron. It is certainly the neatest method I am acquainted with, one of the most rapid, and, when carefully carried out, is very accurate. We use Ibbotson and Brearley's modification. The following results, in which the same steels were analysed by the bismuthate process and by Ford's volumetric method, show how closely the two methods agree:

		Manganese	
	Carbon.	Ford's Method.	Bismuthate Method.
Steel casting	0·28	1·508	1·500 1·503
Tyre	0·41	1·185	1·191 1·183

---

* This is probably due to the presence of a little water (about 0·4 per cent.) in the recrystallised permanganate employed (Blum, *J. Amer. Chem. Soc.*, 1912, **34**, 1379). Blum's study of the bismuthate method appeared some time after this paper was written.

		Manganese.	
	Carbon.	Ford's Method.	Bismuthate Method.
Forging	0·27	1·165	1·171
			1·170
Rail	0·38	0·993	0·992
		0·996	0·993
		1·005 1·003 *	0·995*
Crank axle	0·20	0·485	0·490
		0·484	
		0·488*	0·480*
" "	0·27	0·834	0·844
			0·841

The results marked with an asterisk (*) were obtained by Mr. J. H. B. Jenkins, who analysed the samples in duplicate with me.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOOD AND DRUGS ANALYSIS.

Detection of Adulteration by Colloidal Chemical Methods. E. Marriage. (*Zeitsch. Chem. Ind. Kolloide*, 1912, **11**, 1-5; through *Chem. Zentralbl.*, 1912, II., 1401.)—For the detection of cheap fruit-jelly, such as apple and gooseberry, and also of agar-agar in more expensive jams, a little of the sample is mixed with potassium iodide, and after cooling is covered with lead nitrate solution. From the appearance of the layers of lead iodide in the test-tube it is possible to draw conclusions as to the purity of the jam. Or a drop of the jam, to which 5 per cent. of potassium iodide has been added, is placed in a cell of 18 mm. diameter on a warmed object glass, and covered with a cover-glass of 16 mm. diameter. After cooling, the cell is filled up with 20 per cent. lead nitrate solution, and sealed with a large cover-glass, and the forms assumed by its contents examined under the microscope after the lapse of twelve to twenty-four hours. C. A. M.

Detection of Aniline Dyes and Turmeric in Mustard. E. Sievers. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 393-394.)—Although the method described by Bohrisch for the detection of turmeric (ANALYST, 1904, **29**, 372) is reliable, the twelve hours' extraction with alcohol renders it tedious, and the author, therefore, recommends the following method of procedure: A few grms. of the mustard are moistened with a drop or two of alcohol in a test-tube, and about 10 c.c. of ether are then added. The mixture is shaken, allowed to settle, and the ethereal layer is poured on a strip of filter-paper, and tested in the usual way for boric acid with turmeric. Bohrisch's process for the detection of aniline dyes (*loc. cit.*) is simple and trustworthy. W. P. S.

Detection of Minute Traces of Boric Acid by Means of Tincture of Mimosa Flowers. L. Robin. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1., 429-432.)—Tincture of mimosa flowers is a more sensitive reagent than turmeric for the detection of boric acid. The reagent is prepared by digesting the flowers with 20 parts of 95 per cent. alcohol for ten minutes at the temperature of the boiling water bath, allowing to cool, and filtering. Since organic acids interfere, it is first necessary to incinerate such materials as milk, wines, etc. The liquid to be tested is evaporated in a 2-inch porcelain, flat-bottomed dish, and the residue is burnt and moistened with a few drops of water. A few (2 to 4) drops of the reagent are added, and then 5 per cent. hydrochloric acid drop by drop until the liquid loses its yellow colour. On evaporation to dryness, the residue is citron yellow if boric acid is absent, and its colour is unchanged on treatment with ammonia. In presence of boric acid the residue has a yellowish-brown colour, which changes to red on moistening with dilute (1 : 3) ammonia. A distinct pink is shown by less than 0·0005 mgrm. of boric acid. This test shows that boric acid is not merely an occasional, but a normal constituent of wines, and that it is present in minute traces in many samples of genuine milk. G. C. J.

Detection and Estimation of Formic Acid in Syrups. H. Kreis. (*Mitt. Lebensmitteluntere. u. Hyg.*, 1912, 3, 205-210; through *Chem. Zentralbl.*, 1912, II., 1312-1313.)—The author criticises the official Swiss method, according to which 100 grms. of the substance are acidified with sulphuric acid and distilled until at least 100 c.c. of distillate are collected. According to him, it is not possible to ascertain qualitatively whether, in the case of an acid saccharine liquid, formic acid has been added or not; this can only be determined by a quantitative estimation of the formic acid, bearing in mind that formic acid may be produced in the course of the operation. The quantity of this latter depends on the manner of heating, the concentration of the liquid under distillation, and its acidity. The prescribed addition of dilute sulphuric acid should be omitted. If from 100 grms. of syrup, without the addition of acid, about 1 litre of distillate be driven over with a current of steam in the water-bath, it may safely be concluded that a quantity of formic acid exceeding 5 mgrms. cannot be due to the decomposition of the sugar, and that formic acid was originally present. The distillate obtained should be neutralised with calcium carbonate, being boiled under a reflux condenser with 1 to 2 grms. of finest precipitated chalk for ten minutes before it is evaporated down. J. F. B.

Fractional Saponification of Fats. A. J. J. Vandevelde. (*Ann. Falsif.*, 1912, 5, 417-421.)—Results of an investigation regarding the effect of partial saponification of fats are recorded, statements having been made that such treatment alters considerably the character of certain fats which are employed as adulterants of butter. Coconut oil, lard, and butter fat were saponified with one-half the quantities of sodium hydroxide required for their complete saponification; the unsaponified fats were then separated, an examination being also made of the insoluble non-volatile acids obtained from the soaps. The chief differences were noted in the mean molecular weights of the insoluble non-volatile fatty acids, particularly in the case of lard and butter fat. The molecular weights found were as follows:

	Fatty Acids from Original Fat.	Fatty Acids from the Non-saponified Portion.	Fatty Acids from the Saponified Portion.
Coconut oil ...	208	211	214
Lard	274	273	240
Butter fat ...	259	260	235

In the case of coconut oil, the saponification value was diminished from 271 in the original oil to 254 in the unsaponified portion, and from 236 to 219 in the case of butter fat, whilst the values for lard remained practically constant. The refractive indices and critical temperatures of solution were also lowered. W. P. S.

Experiments on the Value of Ordinary and Treated Sawdust for Animal Nutrition. F. Honcamp, B. Gschwender, H. Müllner, and M. Reich. (*Landwirths. Vers.-Stat.*, 1912, **78**, 87-114.)—An account is given of previous experiments by various authors, all of which tend to show that the fodder value of brushwood, sawdust, and wood-meal, whether raw or treated in various ways—*e.g.*, by fermentation, etc.—is extremely small. It is true that Lehmann had found that the fine subdivision of the wood, as in the case of wood-meal, slightly increased the digestibility of its components, but for practical purposes this effect was negligible. Pfeiffer, moreover, had shown that sawdust, besides affording no nutrition itself, also lowered the degree of utilisation of other fodder stuffs administered simultaneously. The subject has recently been reopened by the use of a product derived from sawdust by hydrolysis with sulphurous acid under pressure, with the formation of 20 to 25 per cent. of sugar. This product, obtained mainly from coniferous wood, occurs in the form of a brown meal, which is readily reduced to a fine dust by rubbing. It is utilised in admixture with molasses, for which it forms a solid vehicle, possessing certain physical advantages. The authors' experiments were carried out upon sheep with the raw sawdust and with the treated product derived from it. These were administered in admixture with a standard ration composed of hay, cottonseed cake, and brewers' grains molasses.

Proximate analyses of the two wood materials, calculated on the dry substance, gave the following results:

	Crude Protein.	Non-nitrogenous Extract.	Fat.	Crude Fibre.	Ash.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Raw sawdust ...	0·88	28·63	1·25	68·64	0·60
Treated sawdust	0·67	40·30	1·00	57·33	0·70

So far as the raw sawdust was concerned, the results of the present trials confirmed the observations of Pfeiffer. Not only was it without appreciable nutrient value in itself, but in certain directions it unfavourably affected the assimilation of the other components of the ration. The results obtained with the treated sawdust were slightly better in so far as the non-nitrogenous extract and the fat were concerned. The meal showed, on the dry substance, 26·20 and 0·73 per cent. respectively of these constituents assimilated. The quantity of fat introduced by the wood-meal is so small that its value is negligible. In the case of the non-nitrogenous extract, the improvement may be attributed to the saccharification of the wood fibre by the chemical treatment. Against this positive nutritive value must be set the fact that not only are the protein and fibre of the modified wood-meal totally unassimilable themselves, but the inclusion of this meal in the diet decreases the assimilation of the protein and fibre of the other constituents of the fodder. A further series of trials was made with a commercial fodder composed of the treated wood-meal and molasses. After correcting the results for the value of the molasses contained in the preparation, the conclusions arrived at in the case of the wood-meal itself were again confirmed. Thus the treated sawdust cannot be regarded as a satisfactory adjunct to molasses fodder, and more suitable vehicles must be sought for.

J. F. B.

Determination of Water in Molasses. C. C. Roberts. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 8, 53-37.)—Various methods of drying molasses for the estimation of moisture have been tested by the author. The direct drying of undiluted molasses in the air-oven at 98° to 99° C. gives low results owing to occlusion of moisture, and after a time the sample begins to gain in weight. The same remark applies when the sample is dried in a current of hydrogen. Drying the undiluted sample in air at 98° C. can only be performed when particular care is taken to place the sample drop by drop on the dish. Drying the diluted molasses on pumice is tedious, and yields low results. The author prefers to dry the diluted sample on a filter-paper coil, such as is used for the estimation of fat in milk by Adams' process. The water can be determined practically as exactly as in hydrogen and in a shorter time than by other methods. The sample is diluted to a uniform strength corresponding to about 30 per cent. of molasses. About 7 grms. of the solution, weighed by difference, are distributed as evenly as possible upon a dried coil of filter-paper, specially prepared for Adams' method, of dimensions 65 × 565 mm. The coil is dried for three hours in a water-oven, cooled and weighed. The loss is calculated as total water, including water of hydration of the sugars. If only the actual moisture is required, the sample must be dried at 70° C. to constant weight.

J. F. B.

Polarimetric Estimation of Banana Starch. G. Baumert. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 449-452.)—The methods described by Lintner (Analyst, 1897, **32**, 179) and Ewers (Analyst, 1908, **33**, 101, 481) may be employed for the estimation of this starch. Under the conditions of the former method banana starch has a specific rotation of +209·8°, whilst in Ewers' method this value is +196·4°. The finely divided banana substance should be extracted successively with cold water, alcohol, and ether before the starch is estimated. (See also Analyst, 1911, **36**, 588.)

W. P. S.

BACTERIOLOGICAL, PHYSIOLOGICAL, ETC.

Substitute for the Petri Dish for Cultivating Fungi and for Biological Analysis. P. Lindner. (*Wochenschr. f. Brau.*, 1912, 29, 589-590.)—The ordinary Petri dish presents certain difficulties in manipulation, particularly as regards infection from the air at the time of inoculation or when opening the dish to take off sub-cultures or specimens for examination. The vessels known as Lindner's fungus-culture glasses are far more suitable for general purposes than Petri dishes. These glasses resemble in shape the inverted specimen jars, consisting of a round-ended cylinder with constricted neck, terminating in an enlarged foot. They are constructed of thin glass and are without stoppers, the opening in the foot being closed by a plug of cotton-wool. They are practically incapable of becoming infected from the air if properly manipulated, and the author has taken as many as sixty sub-sowings from one culture without infection. The walls are coated with an extremely thin layer of solid culture medium by rolling them round whilst the medium is fluid. The layer of medium and the glass both being extremely thin, the colonies are easily inspected. Contrary to the Petri dish, it is the underside of the colony which is seen in these glasses, and the peculiar ring structure of the growth is visible unimpeded by surface vegetation. Further, by binding a sheet of gaslight photographic paper around the cylinder, and exposing it to the light, a direct photographic record of the culture at any stage is easily obtained. J. F. B.

Estimation of Fat and Lipoids in Blood, and Notes on the So-called Lipolysis. L. Berczeller. (*Biochem. Zeitsch.*, 1912, 44, 193-200.)—Results of experiments carried out by the author confirm the statement made by Shimidzu (*cf.* ANALYST, 1910, 35, 527), that more fat is obtained by extracting the blood with alcohol, and saponifying this extract, than is found by saponifying the blood directly according to the Kumagawa-Suto method. It is recommended that 50 c.c. of blood be added drop by drop to 400 c.c. of alcohol; the mixture is then boiled for five hours, filtered while hot, and the precipitate washed with alcohol and ether. The filtrate and washings are evaporated to about 100 c.c., and then saponified as described by Kumagawa and Suto (ANALYST, 1908, 33, 362). Horse's blood yielded from 0·3 to 0·4 per cent., and dog's blood from 0·5 to 0·6 per cent., of fat by this method, results which were about 0·1 per cent. higher than those obtained by the direct saponification method. The loss of fat (lipolysis) which has been observed when blood is aerated is probably due to the formation of compounds of the fat with other constituents of the blood; these compounds are soluble in alcohol, but not in ether. Alterations in the structure of the lipoids may also take place. It does not seem probable that the loss is due to the action of bacteria. W. P. S.

Polarimetric Estimation of Glucosamine in Ovomucoid and Pseudomucin. C. Neuberg and O. Schewket. (*Biochem. Zeitsch.*, 1912, 44, 491-494.)—A method which has been described by Neuberg and Ishida (ANALYST, 1912, 145) for the estimation of sugars in the presence of amino acids, peptones, etc., may also be employed for the estimation of glucosamine. It depends on the fact that amino acids, peptones, and albumoses, are precipitated by mercuric acetate and phosphotungstic acid, whilst sugars and glucosamine in neutral solution are not precipitated by these reagents. One grm. of ovomucoid is hydrolysed by boiling for three hours with 50 c.c. of 7 per cent. hydrochloric acid, the solution is then evaporated, and the residue is dissolved in 13 c.c. of water. A 25 per cent. mercuric acetate solution is now added in quantity sufficient to make the total volume 25 c.c. After filtration 12·5 c.c. of the filtrate are treated with 2·5 c.c. of a concentrated phosphotungstic acid solution, the mixture is again filtered, and the filtrate examined in the polariscope. In the case of pseudomucin the hydrolysis with hydrochloric acid should be continued for thirty hours. Ovomucoid was found to contain 24 per cent., and pseudomucin 36 per cent., of glucosamine. W. P. S.

Detection of Combined Glycuronic Acid in Normal Urine. C. Neuberg and O. Schewket. (*Biochem. Zeitsch.*, 1912, **44**, 502-504.)—The naphthoresorcinol test described by Tollens (Analyst, 1908, **33**, 326) is a general reaction for carboxylic acids, and the orcinol test for glycuronic acid also gives a reaction with pentosans. Both these reactions, however, may be used for the detection of combined glycuronic acid if they are applied to the ethereal extract of a urine, and not to the latter directly. The test is carried out as follows: Ten c.c. of the urine are acidified with 2 c.c. of dilute sulphuric acid, 10 c.c. of alcohol are added, and the mixture is shaken out with 20 c.c. of ether. The ethereal extract is washed with water, filtered, and evaporated after the addition of a small quantity of water. The residual aqueous solution is then divided into two portions, to which the tests are applied. The urine to be tested should be as fresh as possible; when urine is kept, the combined glycuronic acid is decomposed, with the formation of free glycuronic acid which is not soluble in ether. W. P. S.

The Indole Reaction. H. Zipfel. (*Zentralbl. Bakt. Parasit.*, 1912, **64**, 65-80; through *Chem. Zentralbl.*, 1912, II., 1497.)—The possibility of the production of indole by bacteria depends on the presence of the tryptophane group (indole-α-aminopropionic acid) in the nutrient medium. The author recommends the use of a medium prepared by dissolving 5 grms. of asparagin, 5 grms. of ammonium lactate, 2 grms. of dipotassium phosphate, 9·2 grms. of magnesium sulphate, and from 0·1 to 0·5 grm. of tryptophane, in 1 litre of water. This solution has the advantage over peptone solution in being free from colour; it is also constant in composition. Any of the ordinary tests may be employed for detecting the formation of indole by bacteria in a tryptophane medium, but Böhme's *p*-dimethylaminobenzaldehyde reaction gives the best quantitative results. W. P. S.

Occurrence of Mercury in the Hair of Persons who have received Subcutaneous Doses of Mercury Compounds. Detection of Minute Quantities of Mercury. C. Strzyzowski. (*Chem. Zeit.*, 1912, **36**, 1237-1239.)—By means of the following method the author has detected traces of mercury in the hair of persons who had previously been subjected to treatment with mercury compounds. The method is capable of detecting the presence of 1 part of mercury in about 90,000,000 parts of substance. From 2 to 10 grms. of the hair are washed successively with ether, alcohol, and hot water, and are then digested with hydrochloric acid, small quantities of potassium permanganate being added from time to time until the substance has dissolved. The solution is filtered, evaporated partially, and then treated with hydrogen sulphide; after the lapse of twenty-four hours, the precipitate, consisting of sulphur and traces of mercury sulphide, is collected on a filter, then dissolved in a small quantity of hydrochloric acid and potassium chlorate, the solution is filtered, and the filtrate is evaporated to about 1·5 c.c. This residual solution is diluted, filtered, and a few small strips of copper-foil are added to the filtrate, which is then boiled for a few minutes; the copper-foil is now removed, dried, and transferred to a tube, the upper end of which is then drawn out to a capillary. After the air has been exhausted from the tube (while the lower part of the tube is heated to about 130° C.) the capillary is sealed, and the tube is heated over a flame in order to volatilise the mercury from the foil into the capillary. The latter is then examined under the microscope, when minute globules of mercury will be observed. These globules may be rinsed with alcohol from the capillary, and treated on a microscope slide with a trace of iodine. A characteristic action of the iodine on the globules may be observed under the microscope. W. P. S.

Toxicity of Mushrooms: Their Hæmolytic Action. J. Parisot and Vernier. (*Compt. rend.*, 1912, **155**, 620-623.)—The symptoms observed in cases of poisoning by mushrooms point to hæmolysis as the cause of death. This has been confirmed, both *in vitro* and *in vivo*, by experiments made with extracts of fungi in sodium chloride solutions containing 9 grms. of salt per litre. Examination of the blood of animals killed by the injection of these extracts showed a cherry-red coloration of the serum (*hæmoglobinæmia*), and the globules were hæmolysed in saline solutions. The *Amanita phalloides*, Fr., was found to possess the most powerful hæmolytic action, but all poisonous species had an intense, though less marked, action. Moreover, many of the edible species also exert a destructive action on the blood, notably *Amanita rubescens*, Pers., *Hydnum repandum*, Lin., *Tricholomia nudum*, Fr., *Laccaria laccata*, Be. and Br., *Craterellus cornucopioides*, Fr., etc. Certain species which do not cause hæmolysis when young and fresh will develop this property as they get older. Generally the hæmolytic action is attenuated by heating, but in certain cases a prolonged period of heating at a high temperature is not sufficient to destroy it entirely. The authors' experiments show that the hæmolytic action is due to a glucoside. The activity of the glucoside is very considerably weakened and retarded by certain substances, such as milk, and particularly cholesterol (yolk of egg). When the hæmolytic action of the fungus extracts had been destroyed by heating, it was found that their toxic action was either very much attenuated or eliminated. When subjected to the ordinary operations of cooking, the mushrooms frequently retain their hæmolytic activity to a certain extent, and it is recommended that such fungi should be cooked for a prolonged time at a high temperature, preferably with the use of oil, in order to effect the complete hydrolysis of the hæmolytic glucoside. J. F. B.

Estimation of Oxalic Acid in Vegetable Substances. A. Gregoire and E. Carpiaux. (*Bull. Soc. Chim. Belg.*, 1912, **26**, 431-434.)—Oxalic acid, in the form of its calcium, potassium, and sodium salts, is found widely distributed in the vegetable kingdom, and to a much less extent in the animal kingdom. At the same time this acid is but rarely estimated in the ordinary course of analysis of vegetable foodstuffs, and the authors therefore describe a method for its estimation, this method having been applied particularly to such substances as sesame cakes and other products, which also contain large quantities of phosphates, calcium salts, and proteins. Five grms. of the finely powdered, fat-free cake are heated on a water-bath for one hour with 20 c.c. of 4 per cent. hydrochloric acid; a quantity of sodium sulphate sufficient to precipitate the calcium salts present is then added, and after cooling the mixture is mixed with about 100 c.c. of 94 per cent. alcohol. The precipitate is collected on a filter, washed with alcohol, a slight excess of ammonia is added to the filtrate, the alcohol is removed by evaporation, and the solution is acidified with hydrochloric acid and filtered. Calcium acetate is added to the filtrate, the calcium oxalate is collected on a filter, washed, dissolved in hydrochloric acid, and the solution evaporated nearly to dryness. This residue is acidified with a few drops of 25 per cent. sulphuric acid, and sufficient anhydrous sodium sulphate is added to form a dry mass, which is then extracted six successive times with ether. The ethereal extracts are rendered ammoniacal, evaporated, the residue is dissolved in water, and the oxalic acid is precipitated with calcium acetate, collected, ignited, and weighed. A sample of sesame cake examined yielded a quantity of oxalic acid, corresponding with 2·94 per cent. of crystallised calcium oxalate ($CaC_2O_4.H_2O$).

W. P. S.

Estimation of the Activity of Commercial Rennet. W. van Dam. (*Landw. Vers.-Stat.*, 1912, **78**, 133-163; through *Chem. Zentralbl.*, 1912, II., 1313-1314.)—The author has observed that in presence of a low hydrogen ion concentration ($2·37 \times 10^{-6} N$) the digestive activity of rennet towards paracasein runs exactly parallel to its coagulating activity. He has based on this an accurate method for establishing the activity of a normal rennet, and he proposes as a standard 1:100,000 rennet powder, a preparation which yields digestion products, under the conditions prescribed, which are equivalent to 26·5 c.c. of $\frac{N}{10}$ acid in Kjeldahl's nitrogen estimation. The digestion experiment is carried out as follows: Into a 100 c.c. flask is weighed as much purified casein as corresponds to 0·8 grm. of anhydrous substance (Kjeldahl factor 6·37). To this are added 20 c.c. *N*-acetic acid, 10 c.c. *N*-sodium hydroxide, and 70 c.c. of boiled water, whereby the above-mentioned concentration of hydrogen ions is established. The flask is slowly rotated in the thermostat at 30° C. After settling, 1 c.c. of a 1 per cent. solution of the rennet powder is added. A control test is also set up containing 1 c.c. of the rennet extract previously heated at 90° to 100° C. for ten minutes. The digestion is continued for twenty-four hours at 30° C.; 75 c.c. are then filtered off for the Kjeldahl estimation, and the number of c.c. of $\frac{N}{10}$ acid neutralised represents the digestion value. By means of the square root law, according to which the quantity of casein digested is proportional to the square root of the enzyme concentration, it is calculated what concentration of the rennet powder must be taken to give a result approximating to 26·5 c.c. of acid. This solution must then be compared with one or more calf-stomach infusions, in order to verify the parallelism of the digestive and coagulating functions. The neutralised infusions of calf-stomach are diluted until their coagulating power is approximately equal to that of the rennet powder solution, and the digestive activity of these infusions is then estimated. If the digestion and coagulation are found to be sufficiently parallel, the solution of rennet powder is again tested for its digestive activity, and, provided the result does not differ by more than 2 c.c. from 26·5 c.c., the strength of the powder may be calculated by the square root law on the basis of 26·5 c.c. for a standard powder of 1 : 100,000 in 1 per cent. solution for 75 c.c. of digested products. J. F. B.

Colorimetric Method for the Estimation of Tryptophane, and the Quantity of Tryptophane in Horny Tissue and Other Proteins. H. Fasal. (*Biochem. Zeitsch.*, 1912, **44**, 392-401.)—The method is based on the violet coloration which is produced when tryptophane, or a substance containing it, is treated with concentrated sulphuric acid and glyoxylic acid. The coloration obtained is compared with that produced by known quantities of pure tryptophane. The author finds that the use of glyoxylic acid in the test is preferable to that of other aldehydes. In testing horn substance, horny epidermis, etc., the material was previously subjected to peptic and pancreatic digestion, and extraction with alcohol and ether. The following quantities of tryptophane were found in various materials: Horny epidermis, 0·30 per cent.; horn (ox), 0·17 per cent.; human nails, trace; hair (white, blonde, and dark), none; casein, 0·65 per cent.; edestin, 0·38 per cent.; lact-albumin, 3·07 per cent. W. P. S.

ORGANIC ANALYSIS.

New Method for Estimation of Alchohol. G. B. Frankforter and F. C. Frary. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 22, 87-127.)—When sufficient potassium fluoride is added to aqueous alcohol, the liquid separates into two layers. If now water is added gradually, with shaking between each addition, a point is reached when the solution again appears homogenous. The end point can be determined very closely if a little solid spirit blue be present, since this makes a very thin film of alcohol easily visible. The analytical method consists in transferring some pure, anhydrous potassium fluoride to a weighed flask, weighing, adding some of the aqueous alcohol to be tested, reweighing, cooling to about 25° C., and adding water a drop at a time until the solution becomes homogenous. A final weighing of the flask is then made, and the alcoholic strength of its contents, and thus of the sample, calculated by reference to Table I. Reference to the table is necessary before commencing an analysis. For example, if a spirit believed to contain from 40 to 50 per cent. of alcohol is to be analysed, the table shows that as much as 12 grms. of potassium fluoride may be necessary to insure separation into two layers if 100 grms. of spirit is taken for the test. If the quantities taken are exactly 12 grms. and 100 grms., and if 20 grms. of water is necessary to render the solution homogenous, then the final solution contains 12 grms. of potassium fluoride in 120 grms. solvent, or 10 grms. per 100 grms. solvent. By reference to the table, it is seen that this corresponds to 44 per cent. alcohol. This is the strength of the alcohol at the end of the experiment after the addition of 20 per cent. of water, and therefore the strength of the original spirit was 52·8 per cent. Potassium fluoride does not salt out methyl alcohol, but the above method gives accurate results with methylated spirit between 15 and 30 per cent. total alcoholic strength. With stronger or weaker methylated spirit the method gives results which may be in error by as much as 1 per cent.

TABLE I.

Grms. per 100 *Grms. Solvent.*

KF.	C_2H_5OH.	KF.	C_2H_5OH.	KF.	C_2H_5OH.
60	2·82	40	6·32	20	23·4
59	2·92	39	6·65	19	25·1

42	5·74	22	20·26	2	78·6
41	6·02	21	21·80		

Potassium fluoride absorbs 62 per cent. of its weight of water against 32 per cent. taken up by lime, and, probably on account of its greater solubility, its dehydrating action is more rapid than that of most drying agents. It cannot, however, be used for the production of alcohol of a strength exceeding 97·5 per cent.

Though potassium fluoride is the most suitable substance for use in the analytical method above described, potassium carbonate may be used. Very small amounts of insoluble matter render the end point uncertain, and it is therefore better to use a filtered, concentrated solution of known strength. The best indicator is solid phenolphthaleïn, as potassium carbonate bleaches spirit blue. Table II. gives a guide as to suitable quantities for analysis and the means of calculating the results:

G. C. J.

Detection of Methyl Alcohol in Ethyl Alcohol and Spirits. A. Bono. (*Chem. Zeit.*, 1912, **36**, 1171.)—Twenty-five c.c. of spirits and 50 c.c. of water (or 10 c.c. of strong alcohol diluted to 75 c.c.) are distilled in a flask with a delivery tube passing to the bottom of a second flask containing 50 c.c. of a cold saturated solution of potassium bichromate with 60 c.c. of sulphuric acid per litre. The vapours issuing from this second flask pass through a condenser into a graduated cylinder. The first 25 c.c. of the distillate, in which formaldehyde can rarely be detected, are rejected, whilst the next 10 c.c. are tested for formaldehyde as follows: Ten drops of a 0·5 per cent. aqueous solution of phenylhydrazine hydrochloride, 1 drop of 0·5 per cent. sodium nitroprusside solution, and 10 drops of 10 per cent. sodium hydroxide solution, are added to 2 c.c. of this fraction, which in the presence of formaldehyde gives a blue coloration changing to green and then to yellowish-red. About 1 per cent. of methyl alcohol may thus be detected. C. A. M.

Analysis of Oil of Citronella. V. Boulez. (*Bull. Soc. Chim.*, 1912, **11**, 915-917.)—From 25 to 50 grms. of the oil are treated with 100 (or 200) grms. of a concentrated solution of sodium bisulphite prepared by saturating the ordinary commercial solution of sp. gr. 1·345 with sodium sulphite. The mixture is shaken until the citronellal has combined with the bisulphite, after which it is allowed to stand for two to three hours, then diluted with 100 (or 200) c.c. of water, and heated with occasional agitation for several hours on the water-bath beneath a reflux condenser. There should then be a sharp separation between the dissolved aldehydic part and the uncombined oily part of the sample. The latter is collected in a tared flask and weighed, and the difference between the result and the original weight of oil gives the amount of citronellal. The geraniol is then estimated in the uncombined portion by acetylation in the usual way. Four samples of citronella oil thus analysed gave the following percentage results:

	I.	II.	III.	IV.
Citronellal	18·00	19·00	58·00	63·00
Geraniol	44·28	45·59	36·16	35·56
Citronellal and geraniol expressed as geraniol ...	62·07	—	—	81·50

C. A. M.

Determination of Aldehydes. B. G. Feinberg. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 187-203.)—An investigation concerning the accuracy with which formaldehyde, benzaldehyde, salicylaldehyde, *p*-hydroxybenzaldehyde, anisaldehyde, and vanillin, may be estimated by methods depending on the use of bisulphite, neutral sulphite, or substituted hydrazines. The most accurate method for the estimation of benzaldehyde depends on the use of *p*-nitrophenylhydrazine. A convenient concentration of benzaldehyde is 0·25 grm. in 75 c.c. of 4 per cent. acetic acid. To this about twice the theoretical amount of the reagent is added, dissolved in 30 c.c. of 30 per cent. acetic acid. After five hours the precipitate is collected on a Gooch crucible, washed with 10 per cent. acetic acid, and dried at 105° to 110° C. Each gram of precipitate should correspond to 0·440 grm. benzaldehyde. Under the conditions described the benzaldehyde will be underestimated by 1·2 ± 0·7 per cent. A similar method gives good results (error ± 0·5 per cent.) with anisaldehyde and vanillin, but these aldehydes can be estimated with almost equal accuracy by means of *p*-bromphenylhydrazine, which is useless as a quantitative precipitant for benzaldehyde. The best results for salicyl aldehyde were obtained with *p*-nitrophenylhydrazine, but the error, though fairly constant, was large, namely $-5 \pm 0·5$ per cent. G. C. J.

Titration of Azo Dyestuffs by Means of Hydrosulphite. E. Grandmougin and E. Havas. (*Chem. Zeit.*, 1912, **36**, 1167-1169.)—A solution of an alkali hydrosulphite reacts with azo dyestuffs in accordance with the equation:

$$R.N:N.R' + 2Na_2S_2O_4 = RNH_2 + R'NH_2 + 4NaHSO_3.$$

The reagent is prepared by dissolving about 3 grms. of solid sodium hydrosulphite in a litre of recently boiled and cooled water, to which 5 c.c. of 30 per cent. sodium hydroxide solution has been added, and allowing the solution to stand for one to two hours. It should be used within four or five hours of its preparation. For the titration of the dyestuff the reagent is introduced into the flask, *A*, and the tube, *B*, of the apparatus shown in the figure, whilst 50 c.c. of a 0·1 per cent. solution of the dyestuff is placed in the lower flask, where it is diluted to 100 or 150 c.c., and treated with 5 c.c. of dilute hydrochloric acid (1 vol. of 36 per cent. acid to 10 vols. of water). The apparatus is then closed, and the air expelled from it by a current of gas, which is subsequently lit at a burner connected with *D*, after which the burette is filled and the dyestuff titrated. The method can not only be used in comparative estimations, but will yield absolute values by standardising the reagent upon a sample of a dyestuff of known purity. The amounts of hydrosulphite used are inversely proportional to the molecular weights of the anhydrous dyestuffs, as is shown by the following examples:

	C.C.	Molecular Weight.
Orange II.	28·0	350
Chrysoin	31·0	316
True Red (*Echtrot*) ...	24·5	400

In a series of estimations of five commercial samples of Orange II. the standard was prepared by twice recrystallising a sample of this dyestuff from a weak solution of sodium chloride, washing the crystals, and drying them at 130° to 140° C. until constant in weight. Taking this now to represent 100 per cent. of the pure dyestuff, the results obtained in comparison with the commercial samples showed percentages ranging from 75·2 to 89·3. So far the method has only been applied to acid mono-azo dyestuffs, which on reduction are sharply transformed into colourless products. Modifications will be necessary to adapt the method to the examination of other azo dyestuffs, such as poly-azo dyestuffs, which only dissolve with difficulty. The accuracy of the method has been controlled by precipitation of the acid dyestuffs with basic dyestuffs and by colorimetric comparisons. C. A. M.

Arsenic Xanthogenate and its Use in Analysis. N. Tarugi and F. Sorbini. (*Boll. Chim. Farm.*, 1912, 51, 361-370; through *Chem. Zentralbl.*, 1912, II., 1398-1399.)—Arsenic xanthogenate, $As(SCSOC_2H_5)_3$, is prepared by mixing a slightly alkaline solution of potassium arsenite with a solution of potassium xanthogenate, allowing the mixture to stand for fifteen minutes, acidifying it with acetic acid, washing the crystalline precipitate with water, and recrystallising it after drying over sulphuric acid. It melts at 94·8° C. (corr.), is completely insoluble in hot and cold water, and does not volatilise with steam. It is sparingly soluble in alcohol, more soluble in ether, benzene, carbon bisulphide, and chloroform, and soluble in hot glycerol, vegetable oils, vaseline, and lanoline. When heated with aniline it is quantitatively decomposed into diphenylthiourea and arsenic trisulphide. Cold mineral acids do not attack it, whilst cold concentrated solutions of caustic alkali dissolve it unchanged. The reaction with aniline may be used in the estimation of minute quantities of arsenic, the separated arsenic xanthogenate being heated on the water-bath with a few drops of aniline, and the residue of arsenic trisulphide heated at 150° C. until constant in weight. Quantitative results are obtained, but in estimating minute traces of arsenic it is preferable to extract the arsenic xanthogenate with chloroform and to evaporate the extract. Conversely the method may be used in the analysis of potassium xanthogenate. For a volumetric estimation 10 c.c. of an alkaline solution of arsenic trioxide of known strength are vigorously shaken with 5 c.c. of the potassium xanthogenate solution and allowed to stand for fifteen minutes, after which the liquid is acidified with acetic acid, diluted with water, vigorously shaken with 20 c.c. of benzene to dissolve the arsenic xanthogenate, and allowed to settle. The aqueous layer is now made up to 100 c.c., 10 c.c. thereof neutralised with sodium bicarbonate, and the excess of arsenic titrated with $\frac{N}{10}$ iodine solution, each c.c. of which is equivalent to 0·024 grm. of potassium xanthogenate.

Carbon bisulphide: This may be detected by means of an arsenite solution containing aniline and alcohol. The solution under examination is added to this reagent, or the air is made to bubble through it for some minutes; the liquid then neutralised with dilute sulphuric acid and diluted with water, and the precipitate freed from arsenic sulphide by recrystallisation. Glistening white crystals of α-diphenylthiourea (melting-point, 151° C.) are obtained:

$$CS_2 + 2C_6H_5NH_2 = H_2S + (C_6H_5NH)_2CS.$$

The reaction is not quantitative. A gravimetric method of estimating carbon bisulphide is to add the solution drop by drop to a solution of arsenic trioxide in potassium hydroxide solution containing alcohol, with continual cooling, or to pass the air to be tested through this reagent. After standing for fifteen minutes, the liquid is acidified with acetic acid, and allowed to stand for twelve hours, and the precipitate separated and weighed. Or carbon bisulphide may be estimated volumetrically with arsenite solution in an analogous manner to that used in estimating potassium xanthogenate. C. A. M.

Composition and Properties of Glycin Picrate and Separation of Glycin from Alanin. P. A. Levene and D. D. van Slyke. (*J. Biol. Chem.*, 1912, **12**, 285; through *Chem. Zentralbl.*, 1912, II., 1196.)—The formula of glycin picrate was found by analysis to be $(C_2H_5O_2N)_2.C_6H_3O_7N_3$ and not $C_2H_5O_2N.C_6H_3O_7N_3$. It melts at 199-200° C., decomposes at 202° C., and is very soluble in hot water, while water at 0° C. dissolves only 1·7 grms. per 100 c.c. For the separation of glycin and alanin the mixture is dissolved in 3 to 4 parts hot water, picric acid added in quantity less than sufficient to neutralise both bases, but more than enough for the glycin alone, and the glycin picrate allowed to crystallise out at 0° C. O. E. M.

Estimation of Glycerol in Fats. R. Willstätter and A. Madinaveitia. (*Ber.*, 1912, **45**, 2825-2828).—The method of Zeisel and Fanto, according to which the fat is saponified with alcoholic potash and the glycerol is afterwards converted into isopropyl iodide by the action of hydriodic acid, is generally considered to be the most accurate method for the estimation of glycerol. The authors now propose an improved method, whereby the fat is treated directly with hydriodic acid. About 0·2 grm. of the glyceride is weighed out into the decomposition flask of the Zeisel-Fanto apparatus and treated with 10 c.c. of hydriodic acid of sp. gr. 1·80. The mixture is heated to 100° to 115° C. (bath temperature) until reaction sets in, as shown by a strong separation of iodine and precipitation of the silver solution in the receiver. The temperature is maintained constant until the silver solution clears again (twenty to forty minutes) and the reaction is practically finished. Then the bath is raised to a temperature of 130° to 140° C., and heating is continued for at least an hour. This is not important in the case of triolein, but is necessary with tristearin. The isopropyl iodide distilled over is weighed as silver iodide. Results are satisfactory, *e.g.*, 9·87 per cent. of glycerol for tristearin, against 10·33 calculated, and 10·32 per cent. for triolein, against 10·41 calculated. If hydriodic acid of sp. gr. 1·70 be employed the results are too low, especially when larger quantities of fat are taken for analysis.

Note on the Acetyl Value of Fats.—As a measure of the hydroxy fatty acids and fat alcohols, Benedikt and Ulzer determine the acetyl value of the portion of saponified fat acid insoluble in water. Lewkowitsch (*J. Soc. Chem. Ind.*, 1897, **16**, 503) proposed instead to estimate the acetyl value of the fat direct without previous saponification. The authors have found that such treatment is not permissible, since acetic anhydride displaces the higher fatty acids in glycerides, with production of acetins. J. F. B.

Quantitative Estimation of Active Hydrogen in Organic Compounds by Magnesium-methyl Iodide. T. Zerewitinoff. (*Ber.*, 1912, **45**, 2384-2389.)—Hibbert (*Chem. Soc. Trans.*, 1912, **101**, 328) has stated that the lower alcohols of the fatty series, when treated with magnesium-methyl iodide in phenetole solution, yield considerably less than the theoretical quantity of methane. Working according to his standardised method for the estimation of hydroxyl groups or "active hydrogen" (ANALYST, 1911, **37**, 117) and using pyridine as the solvent, the author fails to confirm this statement and has obtained theoretical results from methyl, ethyl, propyl, and isobutyl alcohols. He has further extended the investigation of his method to the case of diamines, including representatives of the aliphatic, benzene, benzidene, stilbene, and naphthalene series. The estimations were carried out both in pyridine and anisole solutions. The results were concordant, and showed that substances containing two NH_2 groups react with two atoms of "active hydrogen" at the ordinary temperature, and with three atoms on heating at 85° C., but that the fourth atom does not react at all with magnesium-methyl iodide. Malonamide is an exception, reacting with four atoms on heating, but in the author's view one of these "active hydrogen" atoms is derived from the CH_2 group. The hydrocarbons of the indene and fluorene type in pyridine solution do not react at the ordinary temperature, but on heating at 85° C. for five minutes, a quantity of methane is obtained corresponding to one atom of "active hydrogen." The same applies for the hydrocarbons derived from fluorene by the substitution of a phenyl or naphthyl radical for one hydrogen in the CH_2 group; on the other hand, the carbinols derived from these latter hydrocarbons behave as tautomeric bodies, reacting only partially at the ordinary temperature and with only one "active hydrogen" atom on heating. J. F. B.

New Stability Test for Nitrocellulose Powders. S. A. Weirman. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 4, 157-159.)—The ability of a powder to take up and retain moisture is suggested as a measure of its stability, on the ground that this determines the amount of its hydrolytic decomposition. The sample, of which 10 grms. are sufficient, is weighed, dried for seven days in a sulphuric acid desiccator and weighed again; it is then exposed over water in a desiccator for forty-eight hours, and the gain in weight noted. The total range in weight divided by the surface area of the grain gives the actual "moisture range," values of which for different sizes of grain are comparable. The results are found to be parallel with those of the potassium-iodide starch test. O. E. M.

Exudation of Nitroglycerine from Dynamite. C. P. Beistle. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 4, 7.)—The dynamite is placed in a centrifugal machine, the cups of which describe a circle of 7-inch radius, and rotated for one minute at 600 revolutions per minute. The results obtained agreed with those of the 40° C. oven tests whereas the compression method gives results dependent upon the nature of the absorbent used. O. E. M.

Separation of Nitroglycerine from Nitro-Compounds. A. L. Hyde. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 4, 69-76.)—Complete fractional separation by two immiscible solvents, in one of which the nitroglycerine is more soluble than the nitro-compound, while in the other these conditions are reversed, could not be effected; but an empirical method, in which acetic acid and carbon disulphide were the solvents chosen, gave a definite fraction of the nitro-compound, nearly free from nitroglycerine, in the carbon disulphide. The proportion recovered was dependent on the particular nitro-compound under investigation. O. E. M.

Effect of the Nitrotoluenes on the Determination of Nitroglycerine by Means of the Nitrometer. C. P. Storm. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 4, 117-125.)—The nitric acid liberated from nitroglycerine by sulphuric acid in the nitrometer is taken up quantitatively by admixed mononitrotoluene until this is all converted into dinitrotoluene, if there is sufficient nitroglycerine. Hence, mixtures of these two substances containing less than 35·6 per cent. of nitroglycerine, yield no gas in the nitrometer; with more than this amount the error is 0·55 grm. of nitroglycerine per grm. of mononitrotoluene present. Pure dinitrotoluene and trinitrotoluene are without effect on the determination, but commercial liquid products cause an error proportionate to their content of mononitrotoluene. A liquid dinitrotoluene investigated caused an error of 0·0628 grm. nitroglycerine per grm., and therefore contained 11·36 per cent. of mononitrotoluene. An explosive containing 25 per cent. of nitroglycerine and 10 per cent. of this liquid dinitrotoluene would thus show an error of 0·628 per cent. in its nitroglycerine content. O. E. M.

Modified Form of Stability Test. H. C. P. Weber. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 4, 147-156.)—The sample, if necessary cut into pieces weighing about 0·2 grm., is placed in a test-tube partly immersed in a glycerol or oil bath, and the time required to produce explosion measured with a stop-watch. The temperatures chosen for the bath in this investigation were 200°, 180°, and 160° C.; for each sample at least three tests were made at each temperature, and a curve plotted from the average values and the temperatures. The curves fell into three groups for the samples tested, corresponding to their known classification into good, fair, and bad. Stable powders gave a pronounced bend, and a ratio of explosion periods at 200° and 160° C. of at least 2 : 9, while the ratio fell to 2 : 3 with unstable powders, and the points did not fit a smooth curve so well. Nitrocellulose gave a flatter curve, more nearly corresponding to the theoretical curve constructed on the assumption that the reaction velocity doubles for every 10° C. O. E. M.

Determination of Water in Petroleum and its Products. J. C. Allen and W. A. Jacobs. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 10, 17-23.)—A criticism of ten methods, all of which find use for the determination of water in petroleum or its products. The most exact is that depending on the volume of hydrogen evolved when the sample is treated with finely-cut sodium. The manipulation is identical with that of the well-known carbide method, the results of which are less accurate on account of the solubility of acetylene in oils. Of the other methods, the most accurate is direct distillation of a considerable quantity (200 grms.) of the sample. This method is accurate to within 0·03 per cent. if the distillation is pushed to 150° C., the water removed from the receiver by a micro-pipette and weighed, and the condenser cleaned with a tared plug of absorbent cotton, which has been previously wetted and squeezed as dry as possible. Ice-water should be fed to the condenser to obtain results of the accuracy stated. The other methods described, though useful for some purposes of works control, are only approximately exact, and some of them are only appliable to heavy oils and greases.
G. C. J.

Conditions for the Complete Hydrolysis of Proteins. D. D. van Slyke. (*J. Biol. Chem.*, 1912, 12, 295; through *Chem. Zentralbl.*, 1912, II., 1222.)—Various proteins were heated with 20 per cent. hydrochloric acid at 100° C., and also with 3 N. hydrochloric acid at 150° C., and the ammonia, total nitrogen, amino-nitrogen, and melanin determined in the reaction-product. The amino-nitrogen reaches a maximum, which is the same whether the heating is at 100° or 150° C., when the acid hydrolysis of a protein is complete. The author was unable to confirm the statement of Henriques and Gjaldbaek (*Zeit. physiol. Chem.*, 1910, 67, 8) that egg albumin, when heated with 20 per cent. hydrochloric acid at 100° C., gives only 90 per cent. of the amino-nitrogen obtainable by heating with 3 N. hydrochloric acid at 150° C.
O. E. M.

Rapid Estimation of Pyridine in the Presence of Ammonia in Gas-Water. O. Baessler. (*J. Gasbeleucht.*, 1912, 55, 905-906; through *Chem. Zentralbl.*, 1912, II., 1406.)—In the following modification of Houghton's method the ammonia and pyridine are first estimated together by titration with $\frac{N}{5}$ or $\frac{N}{10}$ sulphuric acid. Another sample of the gas-water is then heated, and the vapours conducted through two slightly-warmed aqueous solutions of sodium hypobromite, whereby the ammonia is oxidised to nitrogen and water, whilst the pyridine passes on and is received in $\frac{N}{10}$ sulphuric acid, the excess of which is titrated with standard alkali. The estimation may also be made by distilling the ammonia and pyridine, and adding to the distillate, after titration, sufficient sodium hydroxide solution to render the liquid slightly alkaline. It is then used for the estimation of the pyridine.

C. A. M.

Direct Determination of Rubber. C. R. Boggs. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 9, 45-58.)—The author describes a modification of Budde's method for the estimation of rubber in vulcanised or unvulcanised samples. The procedure is as follows: The sample is ground until it passes through a 20-mesh sieve; it is thoroughly extracted with acetone and the residue is dried in a reducing atmosphere, care being taken to avoid undue exposure to the air. An amount of the residue corresponding to about 0·1 grm. of pure rubber is placed in a tall shaped beaker of 300 c.c. capacity, together with 20 c.c. of toluene; the beaker is covered and the toluene boiled gently for three hours. Most of the solvent is then evaporated off on the water-bath, 50 c.c. of carbon tetrachloride are added, cooled, and then 50 c.c. of Budde's brominating mixture are introduced (*cf.* ANALYST, 1910, 35. 267). The covered beaker is allowed to remain for twenty-four hours at the ordinary temperature with frequent agitation. Fifty c.c. of absolute alcohol are then stirred in, the precipitate is allowed to settle over night, the solution is decanted through a paper filter free from chlorine, and the residue is washed first with a mixture of 2 parts of carbon tetrachloride and 1 part of absolute alcohol, and then with alcohol alone. The residue is also washed with boiling water by decantation until free from bromides, and is then transferred to the filter. It is washed with a little alcohol and allowed to dry in the air. The residue is then separated from the filter and ground to powder if necessary. The filter-paper is torn up and burned in a porcelain crucible with a little fusion mixture at a low temperature. The powdered residue is then added and mixed with about 15 grms. of the fusion mixture. The contents of the crucible are slowly brought to fusion-point, and gently fused for about ten minutes. The melt is dissolved in water, the solution filtered, acidified with nitric acid, and the bromine is estimated volumetrically with silver nitrate and thiocyanate. The amount of rubber is calculated from the bromine by the formula $\frac{C_{10}H_{16}}{Br_4}=0{\cdot}425$. No correction is applied for the sulphur in the bromide. With purified Para rubber the method gives about 93 per cent. of pure rubber; oxidised rubber is not estimated, so that the method may be applied to determine the tendency to oxidation of samples before and after exposure.

J. F. B.

Relationship between the Amount of Resins and the Viscosity of Rubber Solutions. J. G. Fol. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 9, 71-73.)—In making solutions of Castilloa plantation rubber, the author has observed that a low viscosity generally indicates a high percentage of resins, and *vice versa*. Either the resins decrease the viscosity of the rubber, or the rubber molecules themselves possess a low viscosity, when the material contains a large amount of resinous matter. The viscosities of 0·25, 0·5, and 1·0 per cent. solutions of the rubber in pure benzene are observed in the Ostwald double-bulb viscosimeter, the rate of flow of the solvent itself being taken as unity. The general validity of the above rule is shown by tables, although in certain exceptional cases other factors must come into play. After removal of the resins by boiling acetone, the viscosity of the purified rubber was in some cases higher, and in other cases lower, than that of the original sample. The heating of the rubber, without de-resination, at the same temperature and for the same time as are employed for removing the resins, caused in all cases a considerable decrease in the viscosity of the solutions. J. F. B.

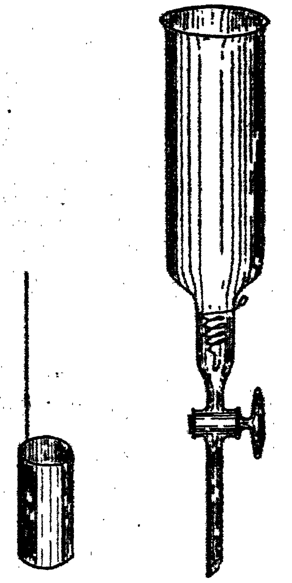
Analysis and Testing of Rubberised Fabrics. M. B. Šetlík and J. Žofka. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 9, 89-93.)—In the examination of a rubberised fabric, the cohesion, adhesion, elasticity, and resistance to rubbing and folding of the coating are first tested empirically. The cloth is then supported on a frame and water is poured on it. The degree of resistance to water is tested for several days both in the case of the original fabric and of the fabric after rubbing between the hands. The action of 5 per cent. ammonia solution and 5 per cent. acetic acid is noted as representing the behaviour of the cloth towards the liquids of the body. The weight per square metre, thickness, and tensile qualities are observed. A portion of the cloth is boiled with chloroform for three hours, and the condition of the coating is then tested by scraping. If it is swollen and comes away in large patches it contains at least 50 per cent. of caoutchouc. The separated coating is extracted with acetone, which removes resins, oils, wax, etc. The residue is saponified with alcoholic potash, which removes rubber substitutes; the remainder is caoutchouc and mineral matters. The presence of a large amount of mineral matter or rubber substitute impedes the swelling with chloroform; coatings rich in resin swell most rapidly under the action of carbon bisulphide. The fabric, freed from its coating, is washed with hot alcohol, dried and weighed, then tested for its tensile properties with the Schopper dynamometer. Fabrics with a 40 per cent. coating are quite satisfactory, even if half the coating is composed of substitutes. Zinc oxide, magnesia, and chalk are not objectionable in reasonable quantities.

J. F. B.

Expanded Meissl-Hiller Table for Invert Sugar. E. W. Rice. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 8, 47-51.)—The table is intended for use in laboratories in connection with the control of factory working where determinations are required of invert sugar in many samples of widely varying composition. As the total amount of all sugars present, as well as the ratio between cane sugar and invert sugar, affects the precipitation of copper, the calculation of results includes factors to cover the conditions in each individual analysis. These calculations are simplified by the use of these tables, which are constructed for the following conditions: Cuprous oxide is precipitated from 50 c.c. of mixed Fehling's solution by 50 c.c. of sugar solution, and the equivalent of invert sugar is calculated according to the Meissl-Hiller method. The columns of the tables contain, first, equivalent weights of copper, cuprous oxide and cupric oxide, which represent the analytical determinations made. Parallel with these are columns showing the corresponding percentages of invert sugar for quantities of 1, 2, 5, 10, and 20 grms. of the sample per 100 c.c. of the solution. These columns are each further subdivided according to the polarisation of the sample. It is essential that all the experimental conditions be maintained rigidly constant. It was found, for instance, that different beakers, apparently identical, gave variations of as much as 0·5 per cent. of the copper precipitated, owing to differing thickness and bottom area; variations between duplicate determinations, due to other causes than the beakers, were found to run about 0·36 per cent. in samples of high purity, and 0·24 per cent. in samples of low purity. J. F. B.

Electrolytic Apparatus for Use in Invert Sugar Determinations.

B. B. Ross. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 8, 75-77.)—The author describes a piece of apparatus (see Fig.) which very materially simplifies the electrolytic determination of the cuprous oxide obtained in the estimation of cupric-reducing sugars, since the electrolysis is effected without removing the oxide from the filter. The filtering funnel illustrated has a stopcock in its stem, and a spiral of platinum wire serving as the anode is fused into the lower portion of the funnel. An asbestos filter-bed is deposited in this portion of the funnel, and the cuprous oxide is precipitated and filtered by the aid of the suction-pump in the usual manner. After the oxide has been washed with hot water, the stopcock is closed and the funnel is filled about three-quarters full of dilute nitric acid, containing about 4 c.c. of acid (1·42 sp. gr.) per 100 c.c. A platinum cylinder, as shown in the illustration, is then immersed in the acid to serve as a cathode, and electrolysis is begun. A current, yielding not more than 1 c.c. of gas per minute, should be used to secure the most satisfactory deposition of the copper. Complete solution and deposition of the cuprous oxide as metallic copper are thus readily attained. J. F. B.



Inversion of Sucrose Solutions by Means of Ammonium Chloride.

F. Strohmer and O. Fallada. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 8, 85-92.)—The nitrogenous constituents which are not easily removed from impure sugar products are known to affect the accuracy of the estimation of sucrose by the

Clerget inversion method, because their optical rotation in acid liquids is different from that in neutral solution. For this reason an inverting agent which has a neutral reaction at the polarisation temperature was desirable. Ammonium chloride reacts at high temperatures as a dissociated mixture of ammonia and hydrochloric acid, and therefore inverts cane sugar. The authors' attempts to use this salt in quantitative sugar analysis have, however, led to no successful result on account of the incompleteness of the inversion under practicable conditions of working. Fifty c.c. of the normal sucrose solution, when heated for one hour at 110° C. with 30 c.c. of a solution containing 5 grms. of ammonium chloride, showed a polarisation of +3·6, as compared with an original polarisation of 49·9. The employment of zinc dust or platinum black as catalytic agents produced no more satisfactory result. Complete inversion was obtained by heating at 110° C. for forty-five minutes, 50 c.c. of a half normal sucrose solution with 30 c.c. of saturated ammonium chloride solution in presence of a trace of acid. On standing in the cold for twenty-four hours this solution gradually attained a maximum lævo-rotation exceeding that of pure invert sugar, accompanied by a coloration indicating the destruction of a certain small amount of dextrose. Further experiments seemed to indicate that the desired end might be attained by neutralising the ordinary acid inverted solution with ammonia or sodium hydroxide. J. F. B.

Detection and Differentiation of Vegetable Tannins. E. Stiasny. (*Collegium*, 1912, 483-499; through *Chem. Zentralbl.*, 1912, II., 1405-1406.)—For the detection of pyrogallol tannins in the presence of catechol tannins, 50 c.c. of the solution (as used for analysis) are boiled for thirty minutes beneath a reflux condenser with 5 c.c. of strong hydrochloric acid and 10 c.c. of 40 per cent. formaldehyde solution, and then cooled and filtered. An addition of 1 c.c. of 1 per cent. ferrous ammonium sulphate solution and 5 grms. of solid sodium acetate is now made, without shaking, to about 10 c.c. of the filtrate, and note taken whether a blue or violet coloration is produced at the bottom of the tube. Bennett's test may also be used, according to which 2 to 3 c.c. of the tannin solution are mixed with 2 to 3 c.c. of 10 per cent. sodium sulphite solution and 1 or 2 drops of 10 per cent. potassium chromate solution. All catechol tannins give a green coloration, whilst of pyrogallol tannins, myrobalans, sumach, and gallotannic acid, give a bluish-red coloration, rapidly changing to brown; and valonia, chestnut, and oak-bark extracts give a deep reddish-violet fairly stable coloration. Schell's test for the detection of mangrove extract in natural and sulphited quebracho extract consists in boiling and rapidly cooling 20 c.c. of the tannin solution, covering it with petroleum spirit and mixing it with 1 c.c. of 20 per cent. cobalt chloride solution and 1 c.c. of strong ammonia solution. Quebracho extracts give a grey-green, mangrove extracts a brown-violet, mimosa a grey-blue, and algarobilla a light brown, coloration in this test. It is not always possible, however, to detect 10 to 20 per cent. of mangrove extract with certainty in this way. In Hoppenstedt's test 25 c.c. of the tannin solution are gradually mixed with 25 c.c. of a 1 per cent. quinine hydrochloride solution and filtered, and 5 c.c. of the clear filtrate of non-tannin constituents are treated successively with 1 c.c. of concentrated acetic acid, 2 c.c. of acetone, and 5 c.c. of ethyl acetate, and shaken. In the presence of mangrove extract the lower layer will be dark yellowish-brown, but colourless in the case of other tannins. In the author's experience certain quebracho extracts and wood pulps may also yield a faint yellow coloration in the lower layer even in the absence of mangrove extract. C. A. M.

Tests to determine the Commercial Value of Wood Preservatives H. F. Weiss. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 13, 279-300.)—From 40 to 90 per cent. of the total cost of treating wood is in general due to the preservative; and as in ordinary practice it is usual to inject about 10 pounds of the oil per cubic foot of wood, although about $\frac{1}{2}$ pound will prevent fungoid growth, it is obvious there is a wide margin for safe reduction. The present paper exhaustively summarises the conclusions arrived at as a result of an experimental investigation of the following properties: (1) The important chemical and physical properties of the preservative; (2) the effect of the preservative on the strength of the wood; (3) the ability of the preservative to penetrate and diffuse through the wood; (4) the permanency of the preservative after its injection, including a study of its volatility and capability of being leached; (5) the combustibility of the treated wood; (6) the toxic efficiency of the preservative in inhibiting the growth of wood-destroying fungi; (7) the corrosive action of the preservative on steel; (8) the effect of the preservative on paint applied to the wood subsequent to treatment.

A description is given of the methods by which each of the above points was investigated, accompanied by illustrations of the special apparatus and plant required for many of them. For the results which follow, a greater accuracy than plus or minus 10 per cent. cannot be claimed, chiefly because of the variables inherent in wood. The results themselves are too numerous for adequate abstraction, but a few of the general conclusions follow. The depth to which oils can be impregnated varies inversely as some function of their viscosity. To secure the best results, the wood and the preservative should be heated to the optimum temperature during the pressure period. With other than water-soluble preservatives the treatment should not be made too rapidly. With coal-tar creosote the fractions of greatest stability are the least toxic. Present practice favours the retention in treated wood of the more volatile fractions by an admixture of the more stable ones. It would appear that in practice there is being forced into wood about two and a half times as much zinc chloride, and fifty times as much coal-tar creosote, as is necessary to prevent decay; more thorough diffusion of less preservative rather than saturation of the outer layers of the wood is thus required. A prolonged seasoning of treated wood considerably raises its ignition temperature. Wood treated with the water-soluble salts mentioned in the tests, although less difficult to ignite, yet proved to be slower burning and more readily extinguishable than untreated wood. All the metallic salts used were much more corrosive in their action on steel than coal-tar creosote. All the oils tested rendered the wood unfit for subsequent painting, copperised oil being the least objectionable. H. F. E. H.

INORGANIC ANALYSIS.

Estimation of Arsenic in Organic Compounds. T. St. Warunis. (*Chem. Zeit.*, 1912, **36**, 1205.)—For the analysis of organic arsenic compounds the combustion of which is difficult, from 0·2 to 0·4 grm. of the substance is stirred, with a platinum wire, into an intimate mixture of 10 grms. of potassium nitrate and 5 grms. of sodium peroxide in a large nickel crucible, covered with a layer of the mixture, and heated gradually to fusion. When quite fluid the melt is stirred, maintained for a short time in a state of fusion, and dissolved in hot water. The solution, which contains all the arsenic as arsenate, is acidulated with hydrochloric acid, filtered if necessary, and neutralised with ammonia. The arsenic is determined as $Mg_2As_2O_7$ by means of magnesia mixture. It may also be estimated volumetrically as uranium arsenate (Brügelmann, *Zeit. anal. Chem.*, 1877, **16**, 20) in the dissolved melt. The acidulated liquid is first rendered alkaline to litmus-paper with sodium hydroxide or ammonia, and then strongly acid with acetic acid, and made up to 100 c.c.; not more than 50 c.c. of this is taken for titration with a uranium solution containing about 20 grms. uranium oxide per litre. Non-volatile compounds which are readily decomposed are fused with potassium nitrate and sodium peroxide in a hard glass tube, 35 cm. long, closed at one end. This is charged, in succession, with a 2-cm. layer of sodium peroxide, the mixture containing the substance, 3 cm. of sodium peroxide, a plug of asbestos, and anhydrous sodium carbonate for the rest of the tube. The sodium carbonate is cautiously heated first, then the sodium peroxide on each side of the substance, and finally the whole tube, the cooled contents of which are dissolved in water and treated as above.

O. E. M.

Determination of Small Quantities of Arsenic by the Gutzeit Test. W. S. Allen and R. M. Palmer. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 9-17.)— Under standard conditions the Gutzeit test gives results as accurate as those obtainable by the Marsh-Berzelius method, which requires much more of the analyst's time. The influence of small amounts of iron is recognised and met by the addition of from 0·05 to 0·1 grm. of iron as ferric salt in every test. The ferric salt is reduced by stannous chloride, and the presence of both iron and tin insures an even and adequate evolution of hydrogen, and longer stains are obtained in this way than when omitting the addition of iron.

The apparatus used by the authors consists of a 60-c.c. bottle, the rubber stopper of which has a single hole. Through this hole passes the tapered end of a tube 7 cm. long and 1·2 cm. in diameter. This tube holds a strip of dry lead acetate paper, and its rubber stopper carries a similar but shorter (4 cm.) tube, which contains glass-wool moistened with a solution of lead acetate. Through the rubber stopper of this upper tube passes a tube 10 cm. long, 4 mm. in internal diameter, and constricted in the middle to support in its upper half the strip of mercuric chloride paper. This is made by dipping filter-paper in 0·5 per cent. mercuric chloride solution, removing excess of solution by use of a rubber roller, and drying rapidly on a cloth in an oven at 100° C. The edges of the paper are trimmed off and rejected, and the rest is cut into strips about 7 cm. long and as nearly as possible 4 mm. wide.

The reagents required are (1) zinc in pieces which pass a screen of three holes to the linear inch, but not one of six holes to the inch. This zinc is washed in hydrochloric acid (1 : 1) and preserved under water. (2) Sulphuric acid (1 : 4), containing 100 grms. of sodium chloride in each litre, the reduction of iron proceeding more readily in presence of hydrochloric acid. (3) Stannous chloride solution, made by dissolving 80 grms. of the crystallised salt in 100 c.c. of water and 5 c.c. of hydrochloric acid. (4) A solution of iron alum.

The solution to be analysed, which must not contain more than traces of sulphide or sulphite, nor nitric acid, chlorine, etc., has iron alum solution added to it in amount corresponding to about 0·05 to 0·1 grm. of ferric oxide. This is followed by 0·5 c.c. of stannous chloride solution, and the mixture is boiled until the iron is all reduced to the ferrous state, when it is cooled and transferred to the Gutzeit apparatus, together with fifteen pieces of zinc and 10 c.c. of the sulphuric acid mixture. After gently shaking its contents, the bottle is placed in a water-bath at a temperature within a few degrees of 75° C., and after thirty minutes the sensitised paper is withdrawn, dipped in melted paraffin, and compared with a series of standards ranging from 0·001 to 0·02 mgrm. Standards preserved in sealed tubes over phosphoric anhydride, and kept in the dark, show no perceptible change in several months. G. C. J.

Titration of Arsenic Acid. A. W. C. Menzies and P. D. Potter. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 367-371.)—When arsenic acid is titrated with sodium hydroxide, using phenolphthaleïn as indicator, a rather uncertain end point is reached when about two-thirds of the hydrogen has been replaced by sodium. Quite sharp end points, corresponding to the formation of disodium arsenate, may be secured as follows. To the solution to be titrated 15 c.c. of a cold saturated solution of barium chloride is added, and the mixture is boiled to expel carbon dioxide. It is then titrated with $\frac{N}{1}$ caustic alkali, with stirring after each addition, until the locally formed precipitate becomes slow in redissolving. The walls of the vessel are now, if necessary, scratched below the surface of the clear solution until the liquid on stirring appears lustrous with fine crystals, after which the titration is completed. Under the above conditions the results are as accurate as the results of a volumetric analysis can be, but the scratching action of a stirring rod to induce the formation of a precipitate of dibarium arsenate is necessary, or the proper end-point may be much overstepped. In fact, with solutions of known titer, it is possible to run in alkali until practically the whole of the arsenic exists as triarsenate before the solution assumes a pink tint. G. C. J.

Volatility of Arsenious Chloride. J. I. D. Hinds. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 227-231.)—Experiments are described which show that the quantity of arsenious chloride lost on boiling its hydrochloric acid solution is a function of the concentration of the arsenic and the acid, and that the rate of loss is much smaller than is supposed by some authors who issue warnings against boiling acid arsenious solutions even in qualitative work. For example, a $\frac{N}{10}$ solution of arsenious chloride, $\frac{N}{1}$ as regards acidity, may be concentrated to half-bulk without loss of more than one-thousandth part of the arsenic present. G. C. J.

Detection of Traces of Arsenic and Antimony. D. R. Staddon. (*Chem. News*, 1912, **106**, 199.)—From 0·5 to 2 grms. of the substance to be examined are dissolved in about 5 c.c. of water. Acids and acid salts are first neutralised. An equal weight of sodium hydrosulphite ("blankit") is added to the solution and the liquid warmed. Rapid reduction to metallic arsenic or antimony, as the case may be, occurs, the precipitate varying from a light to dark brown colour according to the quantity of substance present. The precipitate of arsenic is dissolved by sodium hypochlorite, while that of antimony is insoluble and remains suspended. One part of sodium arsenite in 50,000 parts of water may readily be detected by this method.

A. R. T.

Gravimetric Estimation of Beryllium. B. Bleyer and K. Boshart. (*Zeitsch. anal. Chem.*, 1912, 51, 748-755.)—The precipitation of beryllium as hydroxide is best effected in the cold, using but a small excess of ammonia, and taking care to have ammonium chloride present. Large amounts of the latter introduce no error, but 1 grm. is usually more than sufficient. The precipitate is washed with a hot dilute solution of ammonium nitrate containing a few drops of ammonia, and any precipitate which adheres to the precipitating vessel is removed with a fragment of ash-free paper. The filter-paper and precipitate are transferred to a platinum crucible without previous drying, and when the paper is burnt the crucible is covered and heated in the blowpipe flame for ten minutes. The precipitation should take place in a vessel of porcelain, and not in a glass beaker. Platinum serves as well as, but no better than, porcelain. Precipitation in hot solution, followed by boiling to eliminate excess of ammonia, as is often recommended, may lead to beryllium being underestimated by as much as 20 per cent. Precipitation by means of ammonium sulphide (*cf.* Crookes' "Select Methods," 1894, 150) instead of ammonia gives equally good results, but only if the precipitation be made in the cold and a considerable time allowed to elapse before filtration. Glassmann's method (*Ber.*, 1906, 39, 3368), depending on the use of a mixture of potassium iodide and iodate, gives accurate results, but occupies more time than the ammonia method. G. C. J.

Sensitive Reaction of Free Bromine. G. Denigès. (*Compt. rend.*, 1912, **155**, 721-723).—An aqueous solution of rosaniline bisulphite gives a purple or violet coloration, and eventually a violet precipitate with free bromine. The reagent is prepared by adding 10 c.c. of sodium bisulphite solution (sp. gr. 1·29) to 1 c.c. of a 0·1 per cent. aqueous solution of fuchsin, followed, after about five minutes, by 20 c.c. of hydrochloric acid (sp. gr. 1·18). The compound of rosaniline and bromine is insoluble in water, ether, benzene, and petroleum spirit; sparingly soluble in rosaniline bisulphite solution, but very soluble in methyl, ethyl and amyl alcohols, acetone, acetic acid, and carbon tetrachloride. The solutions of the compound show a characteristic spectrum with two absorption bands, one in the blue and the other in the orange part of the spectrum. The action of bromine in the bisulphite is inhibited by adding hydrogen peroxide. In applying the test, from one drop to several c.c. of the solution under examination are shaken with a mixture of 2 c.c. of the reagent, 2 c.c. of hydrogen peroxide solution, and 1 c.c. of chloroform, and in the presence of as little as as 0·01 mgrm. of bromine a violet tint will be produced. Atmospheric air is tested by being made to bubble through the mixture, or test-papers prepared by saturating filter-paper with the reagent and drying it in the air, may be used. Before use the paper is slightly moistened with water containing 1 to 2 per cent. of hydrochloric acid. The test may be used in the presence of a large excess of chlorides or iodides, and may be made quantitative by colorimetric comparison with standard solutions of bromine. The presence of combined bromine may be detected, *e.g.*, in 2 c.c. of a solution of potassium bromide, corresponding to 0·013 mgrm. of bromine, by adding 0·5 c.c. of a 10 per cent. solution of potassium chromate and 0·5 c.c. of sulphuric acid, shaking the mixture with a fragment of marble to cause a slow evolution of gas, and suspending a moistened and acidulated test-paper 2 to 3 cm. above the surface of the liquid. C. A. M.

Estimation of Free Carbon Dioxide in Water by Titration with Alkalis in the Presence of Phenolphthaleïn. J. Tillmans and O. Heublein. (*Zeitsch. Untersuch. Nahr. Genussm.*, 1912, **24**, 429-449.)—The authors show by their experiments that free carbon dioxide in water can be titrated accurately by dilute alkali solutions, using phenolphthaleïn as indicator. The quantity of carbon dioxide present in the water should not exceed 100 mgrms. per litre, and the temporary hardness must not exceed 10 (German) degrees; otherwise the water must be diluted with neutralised distilled water previous to the titration. The quantity of phenolphthaleïn added is also of importance, and it is recommended that 1 c.c. of a 0·035 per cent. alcoholic solution of the indicator be used for every 200 c.c. of water. The titration must be carried out in a closed flask (*cf.* ANALYST, 1911, **36**, 362).

W. P. S.

Use of Higher Phenols in Testing for Free Lime in Portland Cement. D. C. McFarland and H. F. Hadley. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 5, 83-90.)—Experiments described in detail have shown that the salts formed by calcium with phenol and homologous compounds are only sparingly soluble in any of the ordinary solvents. The speed with which different phenols react with free lime shows great variations. For example, combination takes place immediately in the case of *p*-cresol, whilst *β*-naphthol and phenol do not react so rapidly, and there is only a slight reaction with *α*-naphthol, *o*-ethyl phenol, carvacrol, 1-3-4 xylenol, *o*-cresol, and *p*-nitro-cresol. Of these phenols, only *β*-naphthol and *p*-cresol appeared to react to the same extent as phenol. A rough estimation of the free lime in cement (when small in quantity) may be made by shaking 3 grms. of the sample for an hour with a mixture of 21 c.c. of absolute alcohol, 30 drops of *p*-cresol, and 0·5 c.c. of water, then filtering the liquid, washing the residue with water until colourless, evaporating the filtrate and washings, igniting the residue, and weighing it as calcium oxide. If much free lime is present, however, the results thus obtained are too low, and do not agree well in duplicate estimations. A mixture of 1 c.c. of *p*-cresol, 3 c.c. of absolute alcohol, and 4 drops of water, gives a reagent which reacts much more rapidly than White's phenol reagent (Analyst, 1909, **34**, 71) for the detection of free lime. For example, an abundance of pale red crystals easily observed without polarised light, was obtained in two to three minutes from cements containing 5 per cent. of free lime, and by means of this test it was proved that in old cements free lime may still be present, its particles having been protected by an outside coating formed by the action of the air. For practical purposes this modification of the test is regarded as almost too delicate. C. A. M.

Estimation of Chlorous Acid (Chlorites). G. Lasègue. (*Bull. Soc. Chim.*, 1912, **11**, 884-886.)—The process is based on the insolubility of lead chlorite in alcohol; this salt is slightly soluble in water, but practically insoluble in 80 per cent. alcohol. It slowly oxidises alcohol at the ordinary temperature, but this action is very slight within a period of one hour. The chlorite is dissolved in water, an excess of lead nitrate solution is added, and the mixture is stirred. The mixture then receives the addition of six times its volume of 85 per cent. alcohol, and, after the lapse of one hour, the precipitate is collected on a weighed filter, dried over sulphuric acid under reduced pressure, and weighed. When the chlorite solution contains an excess of alkali, as is often the case when the chlorite has been prepared by passing the gas into an alkali solution, magnesium nitrate is added before the estimation is carried out. The presence of small quantities of chlorides does not interfere with the estimation, and chlorites, chlorides, hypochlorides, and chlorates, may be estimated in a mixture containing the same in the following way: In an aliquot portion of the solution the chlorite is estimated as described. Another portion of the solution is treated with potassium iodide and hydrochloric acid, the iodine liberated being a measure of the chlorite plus hypochlorite. In order to prevent the action of the chlorate on the iodide, the solution must be very dilute, and contain not more than 0·3 grm. of the salt per 500 c.c. In a third portion of the solution the chloride, resulting from the reduction of chlorite and hypochlorite by a standardised alkali arsenite solution, together with the chloride originally present, is titrated with silver nitrate solution. After removing the silver chloride by filtration, the chlorate in the filtrate is reduced by means of sodium nitrite, and the resulting chloride also titrated. The following results were obtained with a mixture of the four salts, the figures *in parentheses* showing the actual quantities present: Chlorine, as chloride, 13·1 (12·5); as hypochlorite, 11·92 (12·5); as chlorate, 37·48 (37·5); as chlorite, 37·34 (37·5). W. P. S.

Quantitative Separation and Estimation of Copper by Means of Hydroxylamine Hydrochloride. A. Bayer. (*Zeitsch. anal. Chem.*, 1912, **51**, 729-735.)—To the solution of copper as sulphate, which may conveniently contain about 0·3 grm. copper in 50 c.c., there is added about 50 c.c. of 25 per cent. solution of Rochelle salt, 25 c.c. of a 15 per cent. solution of sodium hydroxide, and 2 c.c. of a 5 per cent. solution of hydroxylamine hydrochloride. The mixture is boiled for a minute, and the cuprous oxide is filtered off in a tared Soxhlet tube, ignited to cupric oxide and weighed. Neither antimony, zinc, bismuth, lead, iron, arsenic, nor tin interferes, and quantities of ammonia or of nitrates corresponding to 1 grm. of ammonium chloride or sodium nitrate do not influence the results, which are exact. Mercury, if present, is partly precipitated, but introduces no error if the cuprous oxide is ignited to cupric oxide. Silver, gold, platinum, manganese, cobalt, and nickel should be absent. If the three latter metals, but not gold, platinum, or silver, be present, they are easily eliminated by precipitating the copper first as sulphide in acid solution. The precipitate of copper and other sulphides, together with the filter-paper, is oxidised by nitric acid, and the solution taken down to fuming with sulphuric acid, then diluted, and copper precipitated as described. G. C. J.

Electro-analysis of Copper, Antimony, Bismuth, and Tin with Acidified Chloride Electrolytes. E. P. Schoch and D. J. Brown. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 21, 81-91.)—Copper, tin, antimony, and bismuth can be deposited quantitatively and fairly quickly from hydrochloric acid solutions, provided a reducing agent, such as hydroxylamine hydrochloride, is present. An alloy of copper and tin may be analysed as follows: The alloy is dissolved in *aqua regia*, and the solution evaporated to expel free chlorine and oxides of nitrogen. Hydroxylamine hydrochloride (2 grms.) and about 10 c.c. of concentrated hydrochloric acid are then added, and the solution is diluted to 200 c.c. and electrolysed, using the Sand-Fischer apparatus (*Zeitsch. Electrochem.*, 1907, **13**, 469), and limiting the cathode potential to −0·4 volt (against a normal calomel electrode). The copper is deposited in from twenty to forty minutes, and the end-point is recognised by the fact that the current must be reduced to zero to prevent the cathode potential exceeding the limiting value. The beaker is lowered, and the cathode is washed, detached, dipped in alcohol and ether, dried above a flame, and weighed. It is then replaced, 3 grms. of hydroxylamine hydrochloride is added to the electrolyte, and the tin is deposited by means of a constant current of 1·5 amps., the end point, which is reached in twenty to forty minutes, being ascertained by means of hydrogen sulphide. With more than 0·7 grm. tin present in 200 c.c., a lower current density is necessary to ensure good deposits.

In the electrodeposition of antimony, the evolution of hydrogen and attendant stibine must be avoided, the temperature must be above 50° C. or "explosive" antimony may be deposited, and unnecessarily high temperatures must be avoided, as they increase the tendency of antimony solutions to hydrolyse. Good results are obtained at 50° to 75° C. with 20 to 25 c.c. of hydrochloric acid and 2 grms. hydroxylamine hydrochloride in each 200 c.c. of electrolyte, and a cathode potential of −0·4 volt (against a normal calomel electrode); 0·5 grm. may be deposited in ten minutes with an error not exceeding 1 mgrm.

To obtain a good deposit of bismuth it is necessary to limit the cathode potential to −0·25 volt until most of the metal has been deposited, and then to allow it to rise gradually to −0·6 volt during the last few minutes. At 55° to 75° C., with 5 c.c. hydrochloric acid and 2 grms. hydroxylamine hydrochloride present in 200 c.c. of electrolyte, 0·5 grm. of bismuth may be deposited in twelve minutes with an error not exceeding 0·8 mgrm. G. C. J.

Influence of Lead on the Ferrocyanide Titration of Zinc. V. Lenher and C. C. Meloche. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 279-284.)—Contrary to the statements of several authors (*e.g.*, Seaman, *J. Amer. Chem. Soc.*, 1909, **29**, 207), lead does not interfere with the estimation of zinc by ferrocyanide as that operation is usually carried out—namely, in presence of hydrochloric acid and ammonium chloride. The concentration of the latter may be anything between 1 and 20 grms. in 200 c.c., but concentrations as high as 20 per cent. give rise to an indistinct end-point. Indistinct end-points also result from too low or too high concentration of acid, but sharp end-points are obtained over a fairly wide range—namely, from 1·5 to 6 per cent. free hydrochloric acid. Ten c.c. of concentrated hydrochloric acid and 10 grms. of ammonium chloride in 200 c.c. are convenient quantities to have present. The best indicator for general use is a 5 per cent. solution of uranium nitrate. A 1 per cent. solution of ammonium molybdate is more sensitive, but its application is limited.
G. C. J.

Rapid Determination of Magnesia in Limestone by Means of the Hydrogen Electrode. J. H. Hildebrand and H. S. Harned. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 217-225.)—The method depends on the fact that, when caustic alkali is added to a neutral solution containing salts of calcium and magnesium, the concentration of hydroxyl ions increases very slowly until all the magnesium is precipitated as hydroxide, and then increases rapidly to the point at which calcium hydroxide begins to separate. The method therefore consists essentially of the titration of the magnesium, making use of the above-described sharp rise in hydroxyl ion concentration to determine the end-point. In practice it is more convenient to measure the diminishing hydrion concentration which is a reciprocal function of the hydroxyl ion concentration. The necessary apparatus includes an easily constructed form of hydrogen electrode, a calomel electrode, a voltmeter reading from 0·01 to 1 volt, any fairly constant cell with E.M.F. not less than 1 volt, a sliding rheostat or bridge wire of fairly high resistance, and a galvanometer or Lipmann electrometer as zero indicator. The limestone is dissolved in hydrochloric acid, and the solution is freed from carbon dioxide and titrated with normal caustic alkali (free from carbonate) in a beaker into which dip the hydrogen electrode and the syphon from the calomel electrode. By the use of methyl-orange, the neutralisation of the free acid may be quickly effected. From this point onwards electrometric readings are taken and the observed E.M.F. in centi-volts plotted as ordinates against the burette readings as abscissæ. With a small addition of alkali beyond that necessary to change the colour of methyl-orange, the E.M.F. rises rapidly, and a further small addition causes the curve to take a nearly horizontal direction. Larger additions of alkali may now be made between each reading until the curve assumes a steeper gradient, when readings are taken at every 0·2 c.c. When the gradient of the curve begins to diminish instead of increasing, the titration is at an end. The reading of the burette at this moment, less the reading when curve changed its nearly vertical direction to a horizontal one, is the measure of the magnesium present. The method is accurate to within 2 per cent. of the magnesium present. The paper includes a diagram of the whole apparatus, a drawing of the hydrogen electrode, and a typical curve.
G. C. J.

New Volumetric Method for the Estimation of Nitrites, and for the Separation of Nitrous Acid from Nitric Acid. W. M. Fischer and N. Steinbach. (*Zeitsch. anorg. Chem.*, 1912, 78, 134-140.)—The method depends on the readiness with which nitrous acid is converted into its methyl ester (b.-pt. −12° C.). It is sufficient to add a nitrite solution drop by drop to a mixture of dilute sulphuric acid, methyl alcohol, and water, through which a current of air is bubbled, in order to convert the whole of the nitrite into the ester and remove the latter as it is formed. If a known quantity of sulphuric or hydrochloric acid is present in the mixture, the difference between this and the amount remaining at the end of the experiment is a measure of the nitrous acid.

None of the nitrite is oxidised to nitrate during the reaction, and the mixture does not yield a reaction for nitrate at the end of the operation, unless nitrates were present originally in the nitrite solution. The estimation is carried out most conveniently by placing the nitrite solution and 45 c.c. of methyl alcohol in a 300 c.c. flask. The flask is closed with a rubber stopper, through which pass the stem of a tapped funnel, an inlet tube reaching to the bottom of the flask, and a delivery tube, the latter being attached to an exhaust pump. A measured excess of $\frac{N}{10}$ hydrochloric or sulphuric acid and 1 c.c. of methyl alcohol are placed in the funnel, and allowed to drop into the flask, while air is drawn through the apparatus. When all the acid has been introduced, the current of air is passed through the flask for a further five minutes, and the excess of acid is then titrated with $\frac{N}{10}$ sodium hydroxide solution (free from carbonate), using phenolphthaleïn as indicator. If, instead of a nitrite solution, a mixture of nitrite and nitrate is under examination, the nitrate may be estimated subsequently by adding to the neutralised contents of the flask 3 grms. of Devarda's alloy and 20 grms. of potassium hydroxide, and estimating the ammonia formed in the usual way. The method may also be employed for estimating nitrites and carbonates together, as the latter will neutralise an equivalent quantity of the acid in the flask; a separate estimation of the nitrous acid, for instance, by titration with permanganate, will allow the amount of carbonate to be calculated. Results of analyses are given, which show that the method is accurate. W. P. S.

Determination of Oxygen in Iron and Steel by Reduction in an Electric Vacuum Furnace. W. H. Walker and W. A. Patrick. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 21, 139-148.)—Ledebur's method for the determination of oxygen in iron and steel gives low results because hydrogen at a red heat fails to reduce alumina and silica, and the reduction of oxides of manganese is far from complete. The method now described depends on the reduction of all the oxides to carbides by heating them with excess of carbon to a high temperature in an electric furnace, the oxygen being given off quantitatively as carbon monoxide. The furnace illustrated in the paper is a vacuum furnace of the Arsem type (made by the General Electric Company), and requires 14 kw. (200 ampères at 70 volts) to operate it. The charge of metal taken for the test is 20 to 25 grms., and is contained in a graphite crucible and covered with about 5 grms. of powdered graphite. The furnace is exhausted to 0·01 mm. by means of a rotary oil-pump working in series with a Geryk pump, the temperature being raised to 500° to 600° C.

towards the end of the operation. The furnace is allowed to cool, and nitrogen dried by means of sulphuric acid and phosphoric anhydride, is admitted, until the gas pressure is about half an atmosphere. The nitrogen is then exhausted by the pump, heating to 500° to 600° C., when the pressure is reduced to 0·01 mm. The charge is now fused, an operation which requires three or four minutes. A mica window enables the operator to watch the fusion and switch off the current if, as is often the case, there is a tendency to violent ebullition at the moment of complete fusion. After allowing the charge to cool slightly, the circuit is completed once more, and heating continued for twenty minutes. A portion of the gaseous contents of the furnace is now transferred to a glass container by means of a Töpler pump, and is dried and passed over iodine pentoxide, heated to 130° C., the liberated iodine being retained by a solution of potassium iodide and titrated with thiosulphate. The fraction of the gaseous contents of the furnace taken for the final test is determined by the readings of a differential gauge attached to the furnace. When operating as described, the blank to be subtracted from the oxygen found lies between 0·012 and 0·013 grm. This is mainly due to traces of oxygen, which obstinately resist removal during the preliminary exhaustion. One steel examined showed 0·10 per cent. oxygen by the new method and nil by Ledebur's; another 0·23 by the new method and 0·069 by Ledebur's. G. C. J.

Determination of Ozone by Means of Cadmium Potassium Iodide. C. Baskerville and W. J. Crozier. (*J. Amer. Chem. Soc.*, 1912, **34**, 1332-1337.)—Schönbein's method for the estimation of ozone by determining the iodine liberated from metallic iodides is quite generally employed, although open to objections; and the fact that when acid potassium iodide solution is used the reaction is quite unreliable is well known. The authors have confirmed and amplified the work of Baskerville and Hamor, and found that pure cadmium potassium iodide ($CdKI_3.H_2O$) is much more stable than potassium iodide, and is a satisfactory reagent for the estimation of ozone where neutral solutions of potassium iodide cannot be employed.

The cadmium potassium iodide of the above composition must be pure, free from cadmium iodide, potassium iodide, and excess of water. Such a reagent was found to be as delicate as potassium iodide solution of the same strength for hydrogen peroxide and ozone. In the estimations the air to be ozonised was passed from a gasometer through the ozoniser and a bulb (Meyer's) apparatus for holding the solution of the reagent, this apparatus being connected by a ground-glass joint. Similar results were obtained with neutral and acid solutions of $\frac{N}{10}$ strength of the cadmium reagent and neutral potassium iodide, while the results with acid potassium iodide were higher. Satisfactory results were obtained by absorbing the ozone in turpentine oil, liberating the iodine by agitating the oil with the iodide solution, and titrating the iodine with $\frac{N}{10}$ sodium thiosulphate solution. The results with alkaline iodide solutions were unsatisfactory. Cadmium potassium iodide solution, acidified with hydrochloric acid, is more reliable than potassium iodide in neutral solution, but its employment is only necessary when the ozone is absorbed in turpentine oil. A. R. T.

Potash Analysis (Potassium-Sodium Cobaltinitrite Method). E. A. Mitscherlich and H. Fischer. (*Landw. Vers.-Stat.*, 1912, **78**, 75-86; through *Chem. Zentralbl.*, 1912, II., 1312.)—The authors have made further investigations on the composition of the precipitate of potassium sodium cobaltinitrite, and on the potassium factor deduced therefrom (see also *Landw. Vers.-Stat.*, 1910, **76**, 139). The composition of the precipitate changes with the concentration of the reagent. With increasing proportions of the reagent (0·3 grm. of cobalt chloride + 0·5 grm. of sodium nitrite) the quantity of sodium entering the molecule of the product increases at the expense of the potassium. The composition of the salt approaches a limiting value asymptotically after a certain excess of reagent has been added. If this excess amounts to thirty or more times as much sodium as potassium, the variations in composition of the precipitate fall within the limits of error of the estimation. The method, therefore, gives satisfactory results provided a large excess of precipitating reagent be taken; if more than 30 parts of sodium to 1 of potassium be used, it is immaterial how great the excess may be. The reduction factor to be used for calculating from $\frac{N}{10}$ potassium permanganate to potash (K_2O) is 0·000161, not 0·000157 as previously given (*loc. cit.*).

The authors have also shown that their method is applicable for the estimation of potash in fertilisers. With quantities of potash from 0·002 grm. of K_2O upwards, the probable error is, on the average, less than ± 1 per cent. of the quantity to be estimated. J. F. B.

Estimation of Potassium in Potassium Silicate. E. Wilke-Dörfurt. (*Zeitsch. anal. Chem.*, 1912, **51**, 755-760.)—For the estimation of potassium in "phonolith," a low grade potash manure in which the potash exists as silicate, Verweij (*Zeitsch. anal. Chem.*, 1909, **48**, 760) recommended fusion with calcium carbonate and ammonium chloride as in the ordinary Lawrence Smith method for the estimation of alkalis in silicates, followed by the direct precipitation of the potassium in the aqueous extract from the fusion, without previous separation of lime. The convenience of the Lawrence Smith method, which gives the alkalis as chlorides, is admitted, as well as its accuracy, but analytical numbers are now brought forward to show that it is necessary to remove from the solution the very large amounts of calcium chloride which result from the reaction in the crucible, before proceeding to precipitate potassium as platinichloride. If calcium salts are not removed 9 per cent. of potash may be reported when only 7 per cent. is present. Such differences have occurred between the results of different German chemists reporting on one and the same sample of "phonolith." Fresenius and Brinton showed (ANALYST, 1911, **36**, 178) that potassium could be estimated with fair accuracy as platinichloride in presence of an equal weight of calcium, but in the solution resulting from the fusion of phonolith with calcium carbonate and ammonium chloride the ratio of calcium to potassium is much greater than 1 : 1. G. C. J.

Mechanical Analysis of Arid Soils. W. Beam. (*Cairo Sci. J.*, 1912, **5**, 107-119; through *Bull. of the Bureau of Agric. Intell. and of Plant Diseases*, 1912, **3**, 1721.)—Soils of tropical and arid regions differ from those of other districts in their calcium carbonate content, and especially in the amount of calcium sulphate in the subsoil and in the low humus content which in semi-arid regions may reach less than 0·5 per cent. Clay soils—*i.e.*, those which contain about 50 per cent. of clay—yield only about half the clay in the form of a suspension when shaken in a rotating machine (100 motions per minute), unless a 2 per cent. solution of sodium carbonate is employed in place of water. A threefold division is recommended for grading soils of this type: (*a*) particles of more than 2 mm.; (*b*) particles lying between 2 mm. and 0·002 to be separated into particles of 0·2-2 mm., 0·02-0·2 mm., and 0·002-0·02 mm.; (*c*) particles of less than 0·002 mm., the clay. The following procedure is adopted: 100 grms. of air-dried soil are passed through a sieve with 2 mm. round holes. The fine soil is afterwards separated by a 1 mm. sieve and the sandy residue then washed. The fine portion is dried at 110° C., 5 grms. are weighed out, treated with a 2 per cent. solution of sodium carbonate, mixed by means of a cut-down camel-hair brush and transferred to a cylinder, the volume being made up to 10 cm. The whole is allowed to stand for eight to twelve hours, and the supernatant liquor is decanted off at intervals of eight hours, being replaced by 0·5 grm. sodium carbonate, and more water. After three decantations the residuum is again mixed up by means of the brush, and after the removal of the clay, is washed with distilled water in a 200 c.c. vessel, and again left to settle for eight hours. The residue is then dried and weighed, the amount of clay being determined from the difference in weight, the soluble salts and humus being deducted if necessary. H. F. E. H.

Modification of the Method of Mechanical Soil Analysis. C. C. Fletcher and H. Bryan. (*U.S. Dep. Agric. Bureau of Soils Bull.*, 1912, No. 48; through *Bull. of the Bureau of Agric. Intell. and Plant Diseases*, 1912, **3**, 1720.)—Two thousand soils yearly are analysed and added to the collection of 20,000 samples in the Bureau, most of which have been submitted to mechanical analysis. The following are the limits of mechanical grades: Fine gravel, 2-1 mm.; coarse sand, 1-0·5 mm.: medium sand, 0·5-0·25 mm.; fine sand, 0·25-0·1 mm.; very fine sand, 0·1-0·05 mm.; silt, 0·05-0·005 mm.; clay, 0·005-0·0009 mm. The modified method is as follows: The field samples are passed through a 2 mm. sieve, and the fine earth is then dried in aluminium dishes for two hours in an electric oven, cooled in a desiccator, and 5 grm. samples weighed out into 8-ounce bottles. To each bottle is added 2 ounces of water and a few c.c. of ammonia. All are then shaken in a shaking machine for at least seven hours. Each sample is then brought into suspension by the use of a compressed water-jet, and the sands allowed to settle, the time required being controlled by microscopic examination. The liquid portion is decanted into a tube and centrifuged until no silt particles remain in suspension. The clay suspension is poured into a porcelain vessel and the treatment repeated. Thus, finally, the sands are left in the bottles, the silt in the centrifuge, and the clay in the porcelain vessels. The sands are transferred to platinum dishes, dried, and their total weight obtained, after which they are separated by three minutes' shaking in suitably meshed sieves. The silts are then transferred to platinum dishes, dried, and weighed, and the clay water evaporated in enamelled-ware cups of 300 c.c. capacity, the clay being weighed in them without further transference. The clay may also be determined by difference with an accuracy of 1 per cent. Detailed descriptions and drawings of all the apparatus are given. H. F. E. H.

Action of Boiling Sulphuric Acid on Platinum. Le R. W. McCay. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 351-359.)—Boiling sulphuric acid dissolves platinum in considerable amounts. It is shown that the oxygen of the air is not concerned in this action. In prolonged evaporations of sulphuric acid solutions in platinum basins, the action of the acid on the platinum is almost entirely prevented by the presence of a globule of sulphur, and it is suggested that any possible loss of platinum in the parting of silver-platinum alloys with boiling concentrated sulphuric acid could be avoided by a similar expedient. G. C. J.

Note by Abstractor.—That platinum is lost in the ordinary platinum assay has been shown by Steinmann (ANALYST, 1911, **36**, 605).

New Colorimetric Method for Titanium. V. Lenher and W. G. Crawford. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 285-293).—For the estimation of very small quantities of titanium, a method depending on the use of a solution of thymol in sulphuric acid is preferable to the hydrogen peroxide method. The depth of colour produced, which is strictly proportional to the amount of titanium present, is twenty-five times as intense as the colour produced by hydrogen peroxide. The substance to be tested is fused with potassium bisulphate, and the fusion is taken up in concentrated sulphuric acid, cooled, and treated with the reagent. This is prepared by dissolving thymol in a little acetic acid and diluting to a convenient strength with concentrated sulphuric acid. The use of the acetic acid avoids the development of the yellow colour which is produced when thymol is dissolved directly in sulphuric acid. The reagent should not be exposed to direct sunlight. The ratio of thymol to titanium may vary within wide limits, but it is found best to have it not less than 100 : 1. If it is necessary to dilute the test solution or standard, concentrated sulphuric acid should be used for the purpose, as the colour fades appreciably when the concentration of sulphuric acid falls below 80 per cent. Fluorides bleach the colour. G. C. J.

Volumetric Determination of Titanium. P. W. Shimer and E. B. Shimer. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 445-451.)—Reduction of titanic to titanous oxide by means of ordinary zinc is very slow. By the use of a reductor described in this paper, the reduction may be accomplished in fifteen minutes. The reductor consists of a tube 3 feet long and $\frac{5}{8}$ inch internal diameter, drawn out at its lower end, which is plugged with glass-wool. Above the glass-wool the tube is packed with amalgamated zinc of a size that passes through a 10-mesh sieve and over 20-mesh. The drawn-out end of the reductor passes through one hole of the double-bored rubber stopper of a flask, and reaches half-way to the bottom of the flask. To the upper end of the reductor a 4-inch funnel is attached. Before commencing a reduction, the flask is filled with carbon dioxide and connected to the reductor, through which a little hot dilute sulphuric acid has been passed to warm the zinc. The solution to be reduced is now placed in the funnel and drawn through the reductor slowly by applying moderate suction to the tube which pierces the second hole in the rubber stopper of the flask. The rate of flow should be such that the solution drops from the reductor and does not form a continuous stream. The reductor is washed by sucking through it hot water acidulated with sulphuric acid, and the flask is finally disconnected; any air contained in it is expelled by passing carbon dioxide through it, and the solution is titrated with ferric solution, using thiocyanate as indicator.

In presence of a large amount of iron, as in a solution of a steel, it is necessary to put the solution twice through the reductor. In pig-iron, the whole of the titanium is found in the residue insoluble in hydrochloric acid. Vanadium, which interferes with the titration of titanium, is most conveniently separated from the latter by fusion with sodium carbonate and sulphur. The aqueous extract of the melt contains all the vanadium, but no titanium. The undissolved residue is then got into solution by appropriate means, and the titanium determined as described.

G. C. J.

Fusion of Certain Rare Earths with Alkali Carbonates. Separation of Tungsten from Iron, Beryllium, and Aluminium. M. Wunder and A. Schapiro. (*Ann. Chim. anal.*, 1912, **17**, 323-327.)—Fusion of oxides of cerium and lanthanum with sodium or potassium carbonates left insoluble residues in close agreement with theory, provided that solid alkali carbonate was added at the time of boiling the mass with water. In the case of thorium oxide, however, the results were somewhat too low, whilst with didymium and erbium oxides a large proportion remained in solution. For example, on fusing 0·1940 grm. of didymium oxide for an hour with 4 grms. of sodium carbonate, boiling the mass for twenty minutes with 200 c.c. of water, to which 1 grm. of sodium carbonate had been added, and filtering the hot liquid, the insoluble residue weighed 0·1629 grm., whilst a crystalline deposit (0·028 grm.) separated as the filtrate cooled (loss = 14·66 per cent.). The insoluble residue when fused again and treated as before yielded 0·1376 grm. of insoluble residue and 0·0251 grm. of deposit in the filtrate (loss = 15·4 per cent.); whilst after a third fusion the loss was 11 per cent. In corresponding tests with potassium carbonate the respective losses of didymium oxide after the three fusions were 8·12, 10, and 11·97 per cent. Erbium oxide fused for an hour with sodium carbonate, and the mass boiled with water and alkali carbonate, showed a loss of 5·4 per cent.; whilst the losses after two successive fusions with potassium carbonate were 36 and 37·5 per cent. respectively.

Separation of Tungsten.—On fusing tungstic oxide for fifteen minutes with about six times its weight of sodium carbonate or potassium carbonate, the mass was completely soluble in water. For the separation of a mixture of tungstic and iron oxides the mixture (about 0·5 grm.) was fused for an hour with about 5 grms. of sodium carbonate, the mass taken up with water, and the liquid boiled for twenty minutes after the addition of 1 grm. of solid sodium carbonate. The undissolved iron was fused again in the acid, and was finally dissolved in hydrochloric acid and precipitated with ammonia. The tungsten in solution was precipitated by mercurous nitrate dissolved in very dilute nitric acid and neutralised by ammonia.

	Taken. Grm.		Found. Grm.
Tungstic oxide ...	0·2983	first filtrate ...	0·2950
		second filtrate ...	0·0023
Iron oxide ...	0·1106	first fusion ...	0·1132
		second fusion ...	0·1102

Good results were also obtained in a single fusion continued for two hours. Tungsten and beryllium oxide were separated in exactly the same manner and with similar good results. In the case of aluminium oxide the mixture, after fusion with sodium carbonate, was treated with ammonium nitrate in excess to separate the two oxides.

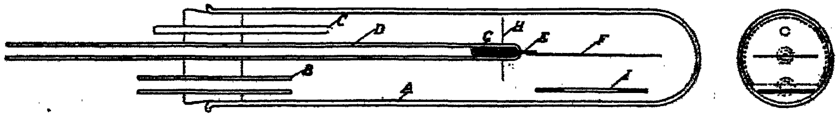
APPARATUS, ETC.

New Calorimeter Bomb, with Special Advantages as to Material of Construction and Method of Operation. S. W. Parr. (*Eighth Int. Cong. App. Chem.*, 1912, vol. 1, 389-393.)—The bomb is constructed from an alloy of nickel, copper, tungsten, and chromium, the composition and general properties of which are described in a paper communicated to another section (sec. 2). The melting-point of the alloy is so high (1300° C.), and the shrinkage at the point of solidification so great, that sound castings are obtained with difficulty, but when obtained, they form an excellent substitute for platinum. Another author (Jesse, vol. i., 233-236) has shown that, in determining the heat of combustion of a sample of coal, not more than 0·2 mgrm. of copper and 0·8 mgrm. of nickel are dissolved by the combined nitric and sulphuric acids present in the products of combustion of coal. The heat of formation of the equivalent quantities of copper and nickel nitrate introduce an error of less than 0·02 per cent. into a calorimetric determination. The other improvement described consists in the use of a rubber gasket in place of the usual lead gasket, and the replacement of the ordinary steel needle valve by a seated valve bearing a rubber gasket. The portion of the gasket which comes in contact with the gases in the bomb is a ring about 0·001 inch in width, and to reach this the hot gases have to pass through a very narrow space, with massive metallic cooling surfaces on each side. There is only indirect proof that the use of rubber gaskets is without effect on the accuracy of the results obtained by means of the bomb. In two series of experiments with sugar and benzoic acid, the greatest deviation from the mean was 7 parts in 10,000; and the ratio of the heat of combustion of benzoic acid to that of sugar was found to be 1·6014, against 1·6003 found by Fischer and Wrede, and 1·6016 the value found by the Bureau of Standards.

G. C. J.

Electrically-Heated Microscope Slide. F. G. Cottrell. (*J. Amer. Chem. Soc.*, 1912, 34, 1328-1332.)—The apparatus has been found useful for the study of liquid crystals and for any observations under the microscope where an adjustment of temperature is desired. The slides are made by cutting, crosswise, ½-inch widths from very thin (0·6 to 0·8 mm.) 1×3 inch microscope slides, the cut edges being rubbed smooth on fine emery cloth or carborundum powder. Both ends of these little slides are then coated with gold or platinum, and the centre part is specially coated with a very thin transparent film of platinum, the platinised ends serving as terminals for the centre of the slide, and the film on the central portion acting as the electrical resistance for heating the slide.

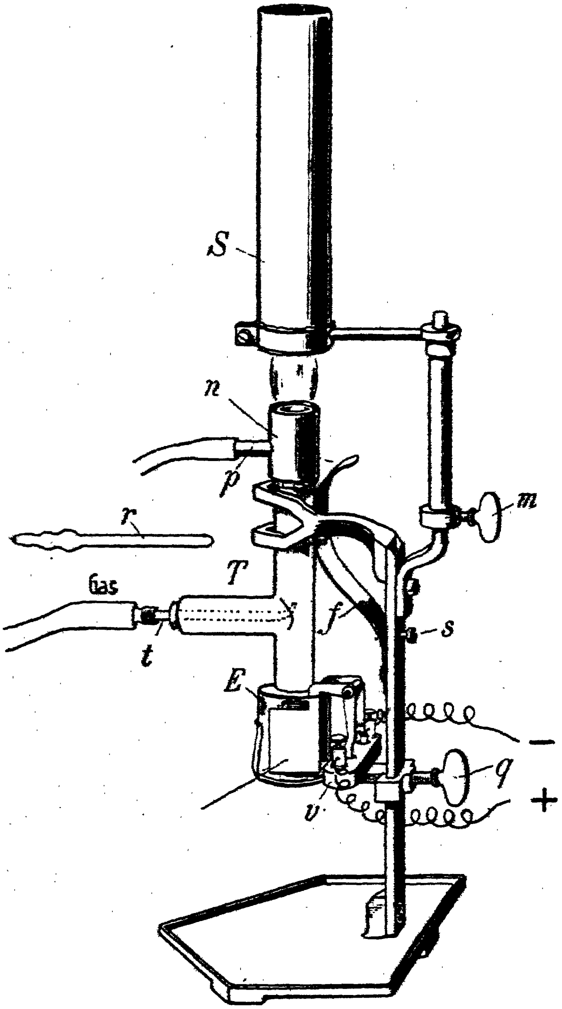
The ends of the slide are painted for about ¼ inch with gold porcelain paint, or dipped in a collodion solution to which a small quantity of gold or platinum chloride has been added, and the adhering film dried in the air. The organic matter is next gradually burned off by means of a Bunsen flame, a brilliant metallic surface being left, which may be thickened if necessary by repeating the process. To obtain the far thinner film required for the centre of the slide, a stout test-tube, *A* (fig.), carrying a rubber stopper, is fitted with a tube, *B*, for connecting to the vacuum pump, an aluminium wire anode, *C*, and a glass tube, *D*, through which is sealed a stout platinum wire, *E*, carrying a welded stiff platinum plate, *F* (cathode). Electrical connection to the last-named is made by running mercury down the glass tube to *G*. The negative wire from the induction coil may be placed in this mercury. A mica plate, *H*, is slipped over the cathode tube to screen the end from deposit and enable the process to be observed as the platinising of the slide *I* proceeds. When the slide has been placed in position, the joints are sealed with melted beeswax containing 10 to 20 per cent. gutta-percha. The vessel is exhausted to 0·01 mm. of mercury, and this point is indicated by the green fluorescence of the glass when the current is applied. As soon as a slight but perceptible darkening of the central portion of the glass slide is observed, it is withdrawn. An ordinary glass slide (3 inches × 1 inch), fitted with binding posts and metal springs, forms a convenient holder for these platinised slides. The rheostat used with these slides consists of a glass cylinder (1 inch × 4 inches high) on a substantial foot. Through a cork stopper pass two glass-stemmed platinum electrodes similar to the cathode in the figure, except that the platinum sheet may be omitted. One of the electrodes should reach to the bottom of the cylinder, the other sliding easily through the cork to allow adjustment of the distance between them. The cylinder is filled with distilled water, acidified with 1 drop of dilute sulphuric acid. For temperatures only slightly above room-temperature, only very faint acidity may be needed. In observing electrolytes, a thin cover-glass may be placed over the platinum surface, but in other cases the material is in actual contact with the slide. The temperature is easily controlled. Probably the temperature could be ascertained by measuring the current flowing through the platinum with a galvanometer, while measuring drop in potential across the film by the compensation method, and from these data



One-fifth natural size.

estimating the resistance of the film, which, in the case of pure platinum, should be directly proportional to the absolute temperature. A. R. T.

Sodium Flame Lamps for Polarisation. E. Beckmann. (*Ber.*, 1912, 45, 2523-2529.)—The objections to the ordinary form of polarisation lamp, in which solid sodium chloride is volatilised in a Bunsen flame, have led the author to design lamps in which the sodium coloration is obtained by the minute globules of liquid projected from the surface of a solution of sodium hydroxide or carbonate which is undergoing electrolysis. Such a lamp is illustrated in the figure. The body of the burner is constructed of porcelain or quartz-glass, and the gas is introduced through a removable side-tube having a small hole, *r*, which serves as a jet. By turning the jet more or less from the vertical direction the amount of air sucked in at the bottom may be regulated. The electrolyte contained in the vessel situated below the burner consists of a 2 to 4 per cent. solution of sodium hydroxide or carbonate, and plate electrodes of nickel are employed. Two accumulators in series or three dry cells provide the current, and the evolution of gas must be so controlled that the liquid appears merely milky, without the formation of large bubbles. If the electrolyte vessel be brought sufficiently close to the bottom of the burner-tube, the whole of the gas evolved is drawn in, and the intensity of the light is equal to that of the ordinary salt burner. The intensity of the flame may be increased by fitting a porcelain or iron shell around the top of the burner, as shown at *n*, forming an annular orifice at the top, and closed at the bottom. A stream of oxygen, not under any appreciable pressure, is conducted through this annular shell. Another form of burner is also



described, in which the electrolytic bath surrounds the top of the burner, and only the outer zone of the flame is coloured by the sodium solution. When a flame of unusual intensity is required, a burner suitably modified to burn hydrogen instead of coal-gas is employed. J. F. B.

Determination of Molecular Weights of Volatile Liquids. C. W. Porter. (*J. Amer. Chem. Soc.*, 1912, **34**, 1290-1293.)—In the Victor Meyer, Gay-Lussac, and Hofmann methods for determining molecular weights, a weighed quantity of the substance is volatilised at a fixed temperature and pressure, and the volume of the vapour is determined by measurement. In other methods the volume and temperature are fixed, and the pressure is determined, or the weight of a known volume of the vapour is estimated, as in Dumas' method. The remaining possibility—namely, the estimation of the molecular weight of a substance by noting the temperature when the volume, pressure, and weight are known and fixed—has been utilised by the author as the basis of his method. A glass bulb of about 300 c.c. capacity is immersed in a glycerol and water-bath contained in a glass jar tubulated near the bottom. A tube of small bore is sealed on each end of the bulb, and one of these passes through a stopper in the tubulure of the jar, and is connected by rubber tubing to a mercury reservoir. The tube at the upper end of the bulb is connected by rubber tubing with a short capillary tube, and this latter is sealed by a solid glass plug and rubber connection. The glycerol bath is electrically heated by means of coils of "nichrome" wire. The volume of the bulb from the plug at the top to a mark on the tube at the lower end is accurately determined. Mercury is poured into the reservoir until the level in the tube is at the mark just mentioned, when the bulb is completely filled with mercury by pressure applied at the top of the mercury reservoir with an air-pump. Before the mercury reaches the top of the tube, a small sealed glass bulb containing a weighed quantity of the liquid to be examined is dropped on to the mercury, so that the long capillary end of the bulb will be directed upwards. The capillary tube fitting on to the top tube of the large glass bulb is then placed in position, held by heavy rubber tube, and wired on. Pressure is then applied till mercury appears at the top of the capillary tube, when the solid glass plug is inserted and the rubber connection wired on. The mercury will have forced the end of the bulb holding the test-liquid into the capillary bore of the attached tube, and, by bending this slightly at the connection, the end of the small bulb may be broken off, when the vapour from the liquid will be free to escape. The bath is next heated and vigorously stirred. When the mercury has been forced down to the mark on the lower tube, the vapour in the large bulb is at atmospheric pressure, and a thermometer in the bath registers the temperature. To obtain exact measurements, the heating is continued till the level in the tube is a little lower than the mark; then the apparatus is allowed to cool slowly and the temperature read off when the level is exactly at this mark. When the rising and falling column reaches this mark at a temperature constant to 0·5° C., the reading is recorded. The volume of the bulb must be corrected for the temperature attained, and allowance made for vapour tension by deduction from the barometric pressure. The results obtained compare favourably with those yielded by the older methods. A. R. T.

Modified Soxhlet Extraction Apparatus with Distillation Arrangement. F. Friedrichs. (*Zeitsch. angew. Chem.*, 1912, 25, 2208.)—The condenser is arranged eccentrically above the extraction vessel, and can be shut off from it by rotation of the hollow ground-in stopper which closes the extraction vessel. This stopper is constricted underneath, so that it delivers the liquid in the axis of the cartridge. When extraction is complete, the stopper is rotated, and the flow of liquid from the condenser diverted, through a stopcock opened for this purpose, to a side flask. The extract is thus obtained freed from solvent. The whole apparatus may be fixed, as it is not necessary to detach the condenser in order to introduce or remove the substance. O. E. M.

REPORTS.

Report to the Local Government Board on the Nature of the Colouring Matter of Flour and its Relation to Processes of Natural and Artificial Bleaching. G. W. Monier-Williams. (*Food Reports*, No. 19, 1912.)—The present work is a continuation of that described by Hamill and the author in a previous report on the bleaching of flour (ANALYST, 1911, **36**, 254). The colouring matter of flour is either carrotene ($C_{40}H_{56}$) or a substance, or mixture of substances, so closely allied to it that the absorption spectra are practically identical. The colour of carrotene can be discharged either by atmospheric oxygen or by nitrogen peroxide, but these two processes are distinct, and result in the formation of different substances. Pure carrotene, on exposure to air, is bleached by absorption of oxygen, no oxides of nitrogen being absorbed from the air. It is only reasonable to suppose that the natural ageing of flour is a similar process, and that in the bleaching of flour by nitrogen peroxide certain substances are produced which are dissimilar to those formed during the natural ageing of flour. Although these substances are present in exceedingly minute amounts, it would appear that artificially bleached flour is not quite the same as flour that has been naturally aged.

The amount of nitrite-reacting substance present in flour tends to increase on storage, although not to any great extent. Even in unbleached flours which had been exposed to the impure air of Widnes, highly contaminated with acid fumes, the maximum amount found was 1·4 parts as sodium nitrite per million. Whether the slight increase in nitrite-reacting substance is due wholly to absorption of oxides of nitrogen or nitrites from the air, or to changes occurring in the flour itself, is not clear. It is noteworthy that unbleached flours showed on the average an increase of nitrite from 0·4 to 1·2 parts sodium nitrite per million, while the bleached samples, which already contained 1·6 parts per million, showed no increase at all except in one instance. The results given by the Griess-Ilosvay test must therefore be interpreted with caution, and from the experiments recorded it appears extremely improbable that unbleached flour stored under ordinary conditions will show more than 1·5 to 2·0 parts per million of sodium nitrite by this test. The report concludes with photographic reproductions of the absorption spectra of the petroleum ether extracts of a bleached and unbleached flour, and of a solution of carrotene in the same solvent. Short addenda are attached—(1) on the effect of prolonged storage upon the nitrite content of highly bleached flour, and (2) on the effect of excessive bleaching upon the baking qualities of flour. H. F. E. H.

Metropolitan Water Board. Sixth Annual Report. A. C. Houston.—This Report contains the results of the chemical and bacteriological examination of the London waters for the twelve months ended March 31, 1912. A considerable amount of the water abstracted from the Rivers Thames and Lea is now stored before filtration, and numerous results are given, of which the following may be cited, illustrating the effect of storage, and also the effect of the subsequent sand filtration of the stored water.

Parts per 100,000.	Thames, before Storage.	Thames, after Storage.	Thames, after Filtration.
Ammoniacal nitrogen	0·0073	0·0024	0·0002
Albuminoid "	0·0155	0·0109	0·0059
Oxidised "	0·26	0·25	0·25
Chlorine	1·76	1·71	1·70
Oxygen absorption, three hours at 80° F.	0·2062	0·1458	0·0892
Turbidity	3·33	0·81	Nil
Colour, mm. brown in 2-foot tube ...	69	39	19
Total hardness	21·67	21·33	21·00
Permanent hardness	5·62	5·40	6·09
Bacteria per c.c.: gelatine	9,155	1,079	10·9
" " agar	356	47	1·7
" " bile-salt agar ...	48	7	—

The author strongly emphasises the value of storage as improving the quality and increasing the safety of the water-supply. The test for the presence of spores of the *B. enteritidis sporogenes* is not now applied to the filtered waters, as they practically always yield negative results. In order to obtain a rapid provisional idea of the quality of the water sent into consumption each day, the five minutes' oxygen absorption test at 80° F. is made, and a result of 0·038 per 100,000 (experimentally arrived at) is taken as the standard which a sample should not exceed.

The author concludes with a review of the position of the London water-supply, in which he states that the river waters are undoubtedly unsatisfactory in quality, and the judicious selection of water is becoming increasingly difficult, as the consumption increases while the volume of the rivers remains constant. The levelling effect of storage, however, renders the possibility of any sudden dangerous pollution a matter of less grave concern than would otherwise be the case. But it is unwise to abstract water from the rivers independently of its quality, and therefore the adoption of certain supplementary processes of purification antecedent to filtration should be considered in the future. J. H. J.

REVIEWS.

THE FREEZING-POINT, BOILING-POINT, AND CONDUCTIVITY METHODS. Second edition. By HARRY C. JONES. Easton, Pa.: The Chemical Publishing Company. 1912. Price 4s.

The name of the author is a sufficient guarantee of the high character of this work, and the fact that this is the second edition shows that its publication has supplied a real want. The author deals with the theory of the freezing-point and boiling-point methods, and with their practical application to the determination of molecular weights, and also explains fully how these methods, as well as the conductivity method, may be applied to the measurement of electrolytic dissociation. Both the theoretical and practical sections are clearly written, and the experimental procedure is described in such a manner that, with the help of the well-chosen illustrations, no one accustomed to the use of ordinary physical apparatus should have any difficulty in making the determinations. Year by year increasing demands are being made on the technical chemist, and operations which were formerly carried out only in the laboratories of colleges and other teaching institutions have now become matters of almost everyday procedure in many technical laboratories. In such laboratories, therefore, this little book may be found very helpful, and chemists generally will find in it, in a concentrated form, information for which they would otherwise have to make somewhat extensive search. A. CHASTON CHAPMAN.

ALLEN'S COMMERCIAL ORGANIC ANALYSIS. By DAVIS and SADLER. Vol. VI. London: J. and A. Churchill. 1912. Price 21s. net.

Corresponding roughly with Vol. III., Part 2, of the last edition, this volume deals with amines, tar bases, the vegetable alkaloids and their preparations, and the plants from which they are derived. So much work has been done on the chemistry of these substances since 1892 that much of the book has had to be entirely rewritten, and the task had been advisedly, if not of necessity, placed in the hands of a number of workers who may be regarded as specialists in their particular subjects.

The general plan of the old volume has been closely adhered to, but the uniformity of style and treatment inherent in a *one man* book has, to a certain extent, been lost. In spite of this, the changes in some of the sections—*e.g.*, that devoted to the general reactions of the alkaloids—are surprisingly small, and paragraph after paragraph appears almost unaltered. While the sections dealing with the toxicology of individual alkaloids have in most cases been rewritten or substantially added to, the treatment is hardly as systematic as could be desired. In some cases, for instance, full information as to medicinal and poisonous doses is given, while, in others, it is entirely omitted. Although the work does not pretend to be a treatise on toxicology, the general processes for the separation, detection, and estimation of the highly toxic alkaloids when present in organic mixtures, might well have been treated at greater length once for all, instead of repeating the description of the preliminary treatment of organic remains at least four times in connection with different alkaloids.

As regards the majority of the alkaloids, recent progress has obviously been made, mainly on the purely scientific side, and the chemical constitution and relations of these bodies has received more attention than the methods for their detection and estimation.

The commoner alkaloids, their salts, the crude drugs from which they are obtained, and the various pharmacopœial preparations containing them are very fully dealt with, and the numerous methods which have been put forward in the British and other pharmacopœias for the assay of drugs, such as opium, are described in ample detail, and some attempt is made to aid the reader in deciding among the competing processes. The sections on tea, coffee, and cocoa have, on the whole, been brought well up to date, and are eminently practical. They contain, however, a somewhat large proportion of obsolete matter, and it comes as a shock to our ideas of the progress of analytical chemistry to find that three-quarters of the analytical tables and of the methods of estimation still in use are, at least, ten years old, and four-fifths date from more than twenty years ago.

In connection with cocoa the numerous methods for the determination of shell receive scant attention, and the paper of Ulrich on this subject, and also Ewer's method for the determination of starch, might well have received mention.

An innovation on the last edition is the introduction of illustrations of the microscopical structure of tea and coffee. In a work of this importance such illustrations may well have a place, but it is not unreasonable to expect that they should be prepared specially for the book, and they should certainly not be confined to two of the best-known substances, neglecting all those with which we are less familiar, and in connection with which some plates would have been really valuable.

The work as a whole suffers somewhat, as is perhaps inevitable, from the system on which it is written, the authors of some of the sections apparently not being aware of what has appeared in others, so that occasionally contradictory statements occur, as, for instance, theobromine is said to sublime at 220° C. in the article on cocoa, and at 290° C. in the chapter on the alkaloid itself.

Apart from these small defects, the volume as a whole presents a most useful and up-to-date résumé of the subjects dealt with, the type is excellent, printers' errors are few, and the text clear and concise. CECIL H. CRIBB.

VINS. Par U. GAYON et J. LABORDE. Paris: Ch. Beranger. 418 pp. + Table of Contents, etc. 1912. Price 7 f. 50.

This volume forms one of a series of "Manuels Pratiques D'Analyses Chimiques," which is intended mainly for the guidance of official (French) analysts and experts, and is issued under the joint editorship of MM. Bordas and Roux. It would be difficult to find two experts who could write with greater experience and knowledge of, and authority on, French wines in general and Gironde wines in particular. One naturally expects from men who combine a rare knowledge of wine chemistry with the art of the wine "connoisseur" something more than a mere statement of analytical methods and results, and in this regard the work under review is no disappointment. From their remarks on the wider objects of wine analysis and on wine from a legal point of view, it is evident that the authors have little sympathy with the narrow analytical standpoint, which is regardless of the genuine difficulties and requirements of a great industry. While it is clear that certain standards are necessary, it is made equally obvious that such standards should be applied without prejudice and partiality, and only as the result of a very wide practical experience. The authors draw attention to an interesting distinction between the legal definition of wine and the commercial definition. Substantially the French legal definition of wine is that it shall be derived exclusively from the fermentation of fresh grapes or of fresh grape-juice. The commercial definition of a satisfactory wine is that it shall be *loyal et marchand*. For a wine to be *loyal et marchand* it must be a natural product, sufficiently well constituted, without hidden defects, and its organoleptic properties must be beyond reproach. Obviously this definition is more satisfactory than the legal one. Every wine that conforms to the commercial definition passes the legal standard, but there may be many legal wines which are by no means satisfactory from the commercial, or, for the matter of that, from the consumer's point of view. In the first part of the work, and under the general heading "Wine from a Legal Point of View," the authors give a résumé of wine legislation in the most important countries, and naturally enough, the information regarding French legislation is very complete. Of particular interest to analysts will be the information regarding the limitations imposed by the French law on the addition of substances normally present in wine and their use in wines deficient in regard to the same, for this is a debatable ground, and the French legislature has, while maintaining its general definition, not excluded the possibility of "ameliorating" by reasonable means a product which would otherwise be commercially worthless. In this connection one may instance the permission to use, within certain limits, tartaric acids in musts which are lacking in acidity. Such musts, if fermented without any addition, almost invariably become the prey of undesirable bacterial activity. In the second chapter the French official methods of analysis are dealt with, and in the third chapter a complete scheme for analysis is set forth. Criticism of analytical methods which have become standardised is liable to be misleading, but so far as such criticism is permissible, the reviewer is of opinion that some of the French methods—for instance those for estimating total acidity, sugar and glycerol respectively—are scarcely as satisfactory as the official German methods. In the succeeding chapter the more ordinary methods of adulteration are described, and methods for determining such adulteration dealt with. Following a chapter dealing with special wines and wine diseases we have an appendix, the first part of which sets out fully in chronological order the laws and decrees constituting French wine legislation. The second half comprises a number of tables giving the results of analyses of French wines from various districts, together with a number of tables of a more special analytical character. The work contains four sheets of microphotographs showing various wine diseases, and seven illustrations in the text.

P. SCHIDROWITZ.

L'ANALYSE DES VINS PAR VOLUMÉTRIE PHYSICO-CHIMIQUE. Par PAUL DUTOIT et MARCEL DUBOUX. Lausanne: F. Rouge and Co. 186 pp. + Table of Contents + 43 illustrations in text. 1912. Price 5 f.

The title of this work scarcely does justice to its contents, for the latter constitute a record of a large number of apparently most carefully conducted experiments on the application of physical methods to the elucidation of analytical problems. Briefly put, Professor Dutoit and his colleague appear to prove most satisfactorily that the conductivity method can be employed for many and diverse quantitative determinations. Much of the work here recorded appears to be unpublished, but as the bulk of it has appeared in journals which are not readily accessible to the analyst in this country, it is probable that the contents of the book as a whole will come as something of a surprise to those who have not been in a position to devote special attention to this subject. The principle employed by the authors is that of combining ordinary volumetric methods with conductivity measurements, or, put very briefly, a solution of the reagent to be employed is run in by means of a burette, and the alteration in conductivity of the solution containing the constituent to be determined is observed. In this manner curves are obtained which show distinctly the saturation points. It is scarcely practicable within the limits of a review to describe or criticise adequately the methods or results obtained by the authors, but it may be sufficient to state that the mass of details set forth by the authors indicate clearly that determinations such as those of chlorides, sulphates, phosphates, lime, total tartaric acid, total acidity, total alkalinity, ash, ammonia, and so on, may be carried out satisfactorily and rapidly. The control figures obtained by gravimetric methods, which are given by the authors, appear to prove beyond doubt that the principle of the method is a reliable one. For those who have to carry out a number of special determinations under routine conditions, the method appears to be an ideal one, and the work can be confidently recommended to every analyst and to those engaged in analytical operations as being not only out of the common, but as one of which the study may result in the saving of much time. P. Schidrowitz.

NEW BOOKS.

Portland Cement: Its Composition, Raw Materials, Manufacture, Testing, and Analysis. By Richard K. Meade. Second edition. Chemical Publishing Company, Easton, Pa., U.S.A. 1911. London: Williams and Norgate. Price $4.50.

Octavo volume, containing 501 pages of subject-matter, with 169 illustrations and numerous tables, followed by an index. The subject-matter is classified as follows: I. Relation between Mortar Materials, and History of the Development of the American Portland Cement Industry. II. Nature and Composition of Portland Cement. III. Raw Materials. IV. Proportioning the Raw Materials. V. Quarrying, Excavating, Drying, and Mixing the Raw Materials. VI. Grinding and Grinding Machinery. VII. Burning: Kilns and Processes. VIII. Fuel, and Preparation of the Same. IX. Cooling and Grinding the Clinker; Storing and Packing the Cement, etc. X. Analysis of Cement. XI. and XII. Analysis of Cement Mixtures and Raw Materials. XIII. Inspection of Cement. XIV. Specific Gravity. XV. Fineness. XVI. Time of Setting. XVII. Tensile Strength. XVIII. Soundness. XIX. Detection of Adulteration in Portland Cement. XX. Investigation of Materials for Manufacturing Portland Cement.

FERTILITY AND FERTILISER HINTS. By J. EDWARD HALLIGAN. Chemical Publishing Company, Easton, Pa., U.S.A. London: Williams and Norgate. Price $1.25.

Octavo volume, containing 143 pages of subject-matter, with 12 illustrations and an index. The subject-matter comprises: I. Chemical Elements needed by Plants, and the Composition of Plants. II. Fertility of the Soil. III. Maintaining Soil Fertility. IV. Farm Manures. V. High-Grade Nitrogenous Materials. VI. Low-Grade Nitrogenous Materials and Functions of Nitrogen. VII. Phosphates. VIII. Superphosphates: Effect of Phosphoric Acid. IX. Potash Fertilisers. X. Miscellaneous Fertiliser Materials. XI. Lime, Gypsum, and Green Manures. XII. Commercial Fertilisers. XIII. Valuation of Fertilisers. XIV. Home Mixtures.

A BRIEF LABORATORY GUIDE FOR QUALITATIVE ANALYSIS. By ARTHUR E. HILL, Ph.D. Chemical Publishing Company, Easton, Pa., U.S.A. 1911. Price $1.

Small octavo volume, containing 76 pages of matter and an index.

SMOKE: A STUDY OF TOWN AIR. By JULIUS B. COHEN, Ph.D., F.R.S., Professor of Organic Chemistry in the University of Leeds; and A. R. RUSTON, B.A., B.Sc. London: Edward Arnold. 1912. Price 5s. net.

Octavo volume, containing 86 pages of subject-matter, with 35 illustrations and an index. The subject-matter is arranged as follows: I. Solid Products of Combustion. II. Gaseous Impurities. III. Town Fog. IV. Dispersal of Soot. V. Influence of Coal Smoke upon Health. VI. Analysis and Manuring Value of Soot. VII. Analyses of Leeds Rainwater. VIII. The Sootfall of London.

LECTURES DELIVERED AT THE CENTENARY CELEBRATION OF THE FIRST COMMERCIAL GAS COMPANY TO SELL GAS AS AN ILLUMINANT. Held at the Franklin Institute, Philadelphia, Pa., April 18 and 19, 1912. Edited and published by the American Gas Institute, New York City.

Octavo volume, containing 174 pages of subject-matter, with 43 illustrations.

THE EXTRA PHARMACOPŒIA OF MARTINDALE AND WESTCOTT. Revised by W. HARRISON MARTINDALE and W. WYNN WESTCOTT. Fifteenth edition. In two volumes. London: H. K. Lewis. 1912. Price, Vol. I., 14s. net; Vol. II., 7s. net.

This work has increased still further in size since the fourteenth edition appeared, and now fills two volumes. Vol. I. contains 1,114 pages of matter, inclusive of the alphabetical index of subjects and posological table. There is also a Schedule of Poisons, and a Therapeutic Index of Diseases and Symptoms, and this is followed by a list of poisons and their antidotes. Vol. II. contains 370 pages of matter, with: I. Analytical Addenda to Materia Medica: Official and Non-Official. II. Synthetic Notes: Physiological Effect in Comparison with Chemical Constitution. III. Physiological Standardisation, etc. IV. Mineral Water Table, with Proportions of Active Ingredients. V. Notes on Antiseptic Power of Chemicals. VI. Analytical Memoranda. VII. Water, Milk, and Butter Analysis. VIII. Carbon Monoxide and Dioxide Tests. IX. Ptomaines. X. Stomach Contents, Examination, etc. XI. Bacteriological Water Examination. XII. Action of Acids on Common Metals and their Oxides: A New Table. XIII. Glossaries of Words and Phrases in Foreign Prescriptions in the Danish, Dutch, French, German, Italian, Portuguese, and Spanish Languages; Tables of Weights and Measures of Approximate Equivalent Doses, and of the Metric Weights and Measures and their Equivalents in the British Pharmacopœia.
